Table of Contents

<i>Table of Contents</i>	<i>i</i>
<i>Series Map</i>	<i>ix</i>
<i>How to Read This Book</i>	<i>xiv</i>
<i>Part I — Scientific Jurisdiction and Synopsis</i>	<i>1</i>
Chapter 1 — Why the Hypothesis Needs a Science	6
1.1 — Why a Separate Science Volume	12
1.2 — Inheritance and Scientific Jurisdiction	18
1.3 — The Research Program in Stages	29
1.4 — The Book’s Evidence Responsibilities	42
1.5 — How to Read as Skeptic and Builder	54
1.6 — Public Artifacts and Scientific Humility	60
Chapter 2 — What Kind of Claim Is the Law of Fairness?	67
2.1 — Claim Families and Category Discipline	72
2.2 — Lawhood, Explanation, and Compression	82
2.3 — Component Claims and Reference Classes	93
2.4 — Severe Tests and Underdetermination	105
2.5 — Confirmation, Rescue, and Model Change	119
2.6 — Narrowing, Retirement, and Defeat	129
Chapter 3 — Ethics and Scientific Authority	139
3.1 — Care Before Evidence	143
3.2 — No Harm-Induction or Balance-Later Designs	151
3.3 — Comfort-First Terminal Research	159
3.4 — Consent, Privacy, and Bystander Protection	172
3.5 — Vulnerability, Assent, and Research Proportionality	185
3.6 — Scientific Authority and Domain Boundaries	198
3.7 — Non-Negotiable Research Red Lines	209
Chapter 4 — Technical Synopsis: Claim, Tests, and Verdicts	219
4.1 — The Scientific Claim in One View	224
4.2 — Status, Notation, and Dimensions	241
4.3 — Measurement and Endpoint Dependency Chain	265
4.4 — Candidate Signatures and Rival Matrix	282
4.5 — The First Protocol in Miniature	301
4.6 — Verdicts, Stop Gates, and Open Problems	317

Part II — PTVC Formal Core.....	333
Chapter 5 — PTVC: Hypothesis, Branches, and Scope	339
5.1 — Truth-Domain Streams, Ownership, and Maximality	345
5.2 — Finite Signed Phenomenal Measure and Exposure.....	359
5.3 — Additive PTVC and Unequal Gross Variation.....	371
5.4 — Bipolar Mixed-Valence Branch and Overlap	381
5.5 — Generalized Terminal Neutrality and Bridge Theorems.....	390
5.6 — Reference Classes, Modal Scope, and Past-Fixity	399
5.7 — Endpoint Domain and Change Control	407
Chapter 6 — Representation and Measurement Interfaces.....	416
6.1 — Latent Objects, Routes, and Estimands.....	421
6.2 — Representation and the Neutral Origin.....	433
6.3 — Sign, Cross-Sign Units, and Scalarity	443
6.4 — Mixed Valence and Identified Sets.....	452
6.5 — Observation Kernel and Protocol Measurement Map	466
6.6 — Missing History and Running-State Uncertainty	475
6.7 — Equivalence, Adjudicability, and No-Neutrality-by-Fiat.....	484
Chapter 7 — Mechanism-Neutral Consequences	499
7.1 — Mechanism-Neutral Consequences of Exact Closure	504
7.2 — Random Endpoints and the Non-Atomic Obstruction.....	514
7.3 — Directional Reachability and Completion Sets	527
7.4 — Endpoint Support and Accessibility	537
7.5 — Bridge, Selector, and Admissible-History Distinctions	546
7.6 — The Reserve-Coupled Route as One Candidate.....	556
7.7 — Discriminating Signatures and Equal-Treatment Rivals	564
7.8 — Formal Failure, Open Theorems, and Route Retirement.....	576
Part III — Measurement and Psychometrics	586
Chapter 8 — Lived Experience and the Evidence Baseline	592
8.1 — Why Lived Experience Is the Target.....	598
8.2 — Representation Before Measurement.....	610
8.3 — Mixed Affect and Multidimensional States	623
8.4 — Scalarization and Identified Sets	636
8.5 — Duration, Memory, and Path Functionals	648
8.6 — Evidence Baseline and Construct Failure	661
8.7 — Fairness Appraisal and Cultural Recurrence	676

Chapter 9 — The Measurement Pipeline.....	693
9.1 — Context of Use and Qualification.....	700
9.2 — Maps, Estimands, and Estimators	712
9.3 — Phenomenal-Value Channels and Auxiliary Witnesses	724
9.4 — Dynamic Measurement and Channel Conflict.....	737
9.5 — Measured-to-Latent Invariance	749
9.6 — Missingness, Provenance, Versions, and Uncertainty.....	758
9.7 — Anti-Score, Privacy, and Non-Deployment Governance.....	768
Chapter 10 — Calibration, Scale, and Uncertainty	778
10.1 — Calibration Within the Stream.....	784
10.2 — Origin, Sign, Unit, and Linking.....	796
10.3 — Longitudinal Invariance and Response Shift.....	807
10.4 — Culture, Language, Development, and Disability.....	818
10.5 — Clinical, Terminal, and Edge-State Calibration.....	830
10.6 — Identified Sets and Uncertainty	841
10.7 — Calibration Audit and Correction	853
<i>Part IV — Consciousness, Stream Routing, and Endpoints.....</i>	<i>864</i>
Chapter 11 — Conscious Unity, Stream Identity, and Routing.....	870
11.1 — Bearer Is Not Body or Biography	876
11.2 — Continuity Evidence and Confidence	887
11.3 — Soft Unity Gates and Threshold Families.....	901
11.4 — Pause, Interruption, and Rebinding.....	915
11.5 — Partition, Fusion, and Multiplicity.....	929
11.6 — Error Costs, Abstention, and Dignity	943
Chapter 12 — Consciousness Theories and Boundary States	955
12.1 — Theory Pluralism and Marker Families	960
12.2 — Sleep, Dreams, and Reversible Low Access	972
12.3 — Anesthesia and Covert Consciousness.....	983
12.4 — Coma and Disorders of Consciousness	994
12.5 — Dementia, Delirium, and Fragmented Access.....	1006
12.6 — Developmental and Nonhuman Cases.....	1015
12.7 — Artificial and Synthetic Candidates.....	1026
12.8 — Boundary-State Evidence and Review	1035
Chapter 13 — Truth-Level and Protocol Endpoints.....	1046
13.1 — Truth-Level Endpoint Domain	1051

13.2 — Protocol Endpoint Objects and Adjudication Predicates	1060
13.3 — Stream Routing, Origin, Maximality, and Junctions.....	1080
13.4 — Accessibility Classes and Terminal Windows	1089
13.5 — Filtrations, No-Look-Ahead, and Endpoint Leakage	1099
13.6 — Return, Resuscitation, and False-Ending Controls	1109
13.7 — Sudden, Diffuse, and Low-Signal Endpoints	1119
13.8 — Comfort-First Care and No-Estimate Outcomes.....	1128
<i>Part V — Study Families and First Tests.....</i>	1136
Chapter 14 — The First Discriminating Protocol	1141
14.1 — The First Decision-Relevant Question.....	1147
14.2 — Population, Enrollment, and Burden.....	1158
14.3 — Measurements, Endpoint, and Data Flow	1169
14.4 — Estimands and Rival Models.....	1181
14.5 — Power, Recovery, and Negative Controls	1191
14.6 — Missingness, Safety, and Adverse Events.....	1203
14.7 — Decision Tree and Public Reporting	1213
14.8 — Protocol Limits and Replication Gate.....	1223
Chapter 15 — Sleep, Dreams, and Affective Reprocessing	1236
15.1 — Sleep as Auxiliary Evidence	1241
15.2 — Dream Experience, Report, and Recall.....	1253
15.3 — Affective Reprocessing Hypotheses	1264
15.4 — Nightmares, Trauma, and Memory Rivals	1277
15.5 — Sleep Stage, Physiology, and Measurement.....	1289
15.6 — Study Families and Data Schema.....	1301
15.7 — Privacy, Public Risk, and Verdict Limits	1314
Chapter 16 — Terminal-Window Tests.....	1322
16.1 — Candidate Route and State Identification	1326
16.2 — Reserve and Horizon Proxies	1341
16.3 — Boundary Exponents and Reserve Dispersion	1355
16.4 — Two-Time Covariance and Martingale Diagnostics	1369
16.5 — Terminal-Window and Intervention Signatures	1381
16.6 — Compression Detectability and Observation Floors	1394
16.7 — Common-Rule Rivals, Falsifiers, and Route Verdict.....	1405
Chapter 17 — Longitudinal and Life-Course Designs.....	1417
17.1 — From Moments to Life-Course Inference.....	1421

17.2 — Active Reports and Experience Sampling	1437
17.3 — Passive Signals, Wearables, and Context.....	1450
17.4 — Marked Observation Processes	1460
17.5 — Clinical Cohorts and Natural Experiments.....	1472
17.6 — Truncation by Death and Competing Events	1484
17.7 — Versioning, Drift, and Transport.....	1496
17.8 — Purpose Limits and Participant Return	1507
<i>Part VI — Candidate Mechanisms and Causal-Locus Tests</i>	<i>1518</i>
Chapter 18 — Completion Geometry.....	1524
18.1 — Completion Geometry and Reachability Sets	1528
18.2 — Completion Kernels and Boundary Values	1542
18.3 — Belief-State and Partial-Observation Realizations.....	1555
18.4 — Path Conditioning and Bridge Constructions.....	1569
18.5 — Absorbing, Hitting, and Bridge Routes.....	1584
18.6 — The Queue Model as an Illustrative Candidate	1598
18.7 — Construction, Identification, and Recovery	1617
18.8 — Route Failure, Retirement, and Frontier Theorems	1637
Chapter 19 — Causal Loci and Interventions.....	1648
19.1 — Candidate Causal Loci and the Representation Gate.....	1653
19.2 — Intervention-Indexed Continuation Laws.....	1665
19.3 — Earliest-Divergence and Action-Invariance Tests	1682
19.4 — Completion-Dependent Action Support	1696
19.5 — Assignment, Commitment, Selection, and Retention	1712
19.6 — Experimental Forks and Mechanism Tournaments	1727
19.7 — Shadow Prices as One Analytic Example.....	1740
Chapter 20 — Interoception and Brain-Body Mechanisms.....	1751
20.1 — Embodied Dynamics as Candidate Mechanisms.....	1757
20.2 — Interoception and Affective Salience	1772
20.3 — Brain–Body Control and Stopping.....	1786
20.4 — Channel Lags and Confounding.....	1798
20.5 — Medication, Disability, Trauma, and Illness	1811
20.6 — Intervention and Perturbation Designs.....	1824
20.7 — Wearables, Artificial Intelligence, and Humility	1837
<i>Part VII — Rival Models, Inference, and Adversarial Tests</i>	<i>1850</i>
Chapter 21 — Adaptation and Homeostasis	1855

21.1 — Adaptation as a Leading Rival Family.....	1860
21.2 — Opponent Processes and Local Counterweights.....	1872
21.3 — Homeostasis, Allostasis, and Mean Reversion.....	1883
21.4 — Ornstein–Uhlenbeck State Dynamics.....	1898
21.5 — The Integrated OU Ledger.....	1908
21.6 — Generative Rival Comparison.....	1918
21.7 — Empirical Separation and Defeat	1930
Chapter 22 — Predictive Processing and Learning Rivals.....	1940
22.1 — Predictive Processing and Error Dynamics.....	1944
22.2 — Active Inference and Expected Control.....	1957
22.3 — Reinforcement Learning and Policy Adaptation.....	1968
22.4 — Safe and Constrained Control Baselines.....	1980
22.5 — Bridge and Doob-Transform Rivals.....	1990
22.6 — Event-Conditioned and Selection Rivals.....	1999
22.7 — Common-Observation Comparison.....	2008
22.8 — When Learning and Control Rivals Win	2018
Chapter 23 — Evolution, Non-Ergodicity, and Outer Limits.....	2027
23.1 — Selection and Experienced Welfare	2031
23.2 — Non-Ergodicity and Within–Between Reversal.....	2042
23.3 — Complexity and Fragile Closure	2053
23.4 — Cross-Species Evidence and Transport.....	2066
23.5 — Developmental and Comparative Boundaries.....	2084
23.6 — Artificial Systems and Synthetic Evidence.....	2093
23.7 — Scope Withdrawal and Outer Limits.....	2102
Chapter 24 — Estimands and Informative Observation.....	2111
24.1 — Unit, Target, Estimand, and Estimator.....	2117
24.2 — Equivalence and No-Estimate Logic	2127
24.3 — Observation Kernels and Measured-to-Latent Bias.....	2136
24.4 — Informative Sampling, Missingness, and Reactivity	2145
24.5 — Delayed Entry, Truncation, and Competing Events.....	2155
24.6 — Sensitivity and Partial Identification	2164
24.7 — Sequential Evidence and Optional Stopping.....	2176
24.8 — Open-Set and Protected-Theory Risk	2186
Chapter 25 — Model Recovery and Adversarial Tests	2195
25.1 — Why Model Recovery Comes First	2199
25.2 — Generative Benchmark Library.....	2212

25.3 — Design Separability and Power	2226
25.4 — Endpoint and Observation Rival Envelope	2240

THE LAW OF FAIRNESS

A new way of seeing every life.

We judge fairness by the visible shape of a life: health and hardship, love and loss, opportunity and misfortune. Yet life is not lived from the outside. It is lived within consciousness, through joy and sorrow, pleasure and pain, peace and fear.

Could life be fair where it is actually lived, even when it appears profoundly unfair from the outside? The Law of Fairness proposes that every felt experience carries weight according to its intensity and duration. Across the completed conscious life, total positive and negative feeling exactly balance.

Picture a scale open for a lifetime. Joy and relief add weight to one side; pain and grief to the other. It may tip heavily for years, but when the conscious life is complete, the two sides balance. Each life carries its own scale. No life balances another.

Lives may differ enormously in length, choices, pleasures, wounds, and circumstances. The scale weighs neither wealth nor virtue, status nor faith. It weighs felt experience alone. Circumstances tell the visible story of a life, but feeling is how that story is lived. The Law asks us not to mistake the visible story for the whole.

WHAT IF THE LAW IS REAL?

A new meaning of utopia.

If the Law of Fairness is real, utopia cannot mean endless pleasure. More comfort, luxury, or consumption does not make a society ideal. If conscious lives end with no lasting surplus of positive feeling, utopia must mean something deeper and steadier than limitless happiness.

“There is no free happiness” does not mean joy is wrong, pain is payment, or suffering is holy. Pleasure alone cannot define a good life, nor appearances a good society. The goal is joy without excess. A fairer world would reduce needless suffering, poverty, disease, cruelty, corruption, and abuse while protecting love, beauty, rest, play, choice, and joy. Moderation restrains excess, work builds worthy goals, and stewardship preserves the world so future generations inherit something worth protecting.

If the Law is real, its deepest equality lies beneath wealth, status, power, culture, and belief. Lives may differ while reaching the same final balance of felt experience. These ten books follow that question from science into life, spirituality, government, cities, law, transition, and peace, exploring how humanity might build a lasting utopia.

THE TEN BOOKS OF FAIRNESS

A complete path from truth to practice.

THE LAW OF FAIRNESS

Explores the core question, defines key terms, and sets the ethical bounds of the series.

THE SCIENCE OF FAIRNESS

Evaluates the Law through evidence, measurement, rival models, protocols, and falsification.

THE UTOPIA OF FAIRNESS

Brings the series into a mature view of what a peaceful world could become.

THE TRANSITION OF FAIRNESS

Asks how a move toward utopia could unfold with care, step by step, under real limits.

THE LIFE OF FAIRNESS

Brings the Law into daily life and asks what it means for how we live.

THE RELIGION OF FAIRNESS

Explores faith, world religions, and the optional path of Fairness.

THE GOVERNMENT OF FAIRNESS

Examines civic structure and the public institutions that give it form in practice.

THE CITY OF FAIRNESS

Builds a civic space for learning, service, and peace with privacy kept safe.

THE CONSTITUTION OF FAIRNESS

Sets out the rights, rules, paths, and checks a lasting utopia would need.

THE PEACE OF FAIRNESS

Builds the base for lasting peace and a fairer future for all humanity.

The series moves from the deepest question about reality to the structures that make a more peaceful world.

THE WORK AHEAD

A shared mission to build a better world.

Read the books, share them, and bring the Law of Fairness into classrooms, research groups, reading circles, and community conversations. Important ideas grow stronger when people examine them together, challenge assumptions, compare perspectives, and turn understanding into shared effort.

Scientists, researchers, clinicians, philosophers, and other experts can help test the Law, refine its measurements, improve its methods, and compare it with strong rivals. Serious criticism is essential. It exposes weaknesses, sharpens the questions, and helps reveal what should endure, what needs revision, and what should be rejected.

Beyond the hypothesis lies a practical challenge: building a world with less corruption and needless suffering, and more room for dignity, freedom, meaning, beauty, and opportunity. If this project speaks to you, bring your knowledge, experience, curiosity, and determination. Progress begins when people from different paths meet, share what they know, and build what survives scrutiny.

Help us make this generation
the one that brought peace to our world.

How to Read This Book

Some questions are important enough to deserve the strongest science we can bring to them. Per-Stream Terminal Valence Closure, or PTVC, asks whether each qualifying conscious stream's complete pre-endpoint history has equal finite positive and negative phenomenal magnitude under the bearer, routing, and endpoint rules defined here. This volume develops that hypothesis through explicit models, observations, and comparisons. The preceding Series Map introduces the series; the chapters that follow develop its scientific questions and tests.

Read the book as a sequence of scientific opportunities and the tests that make them informative. It begins with claim status and ethical authority, then defines the formal object without rewriting it. Later Parts address valence measurement, neutral origin, conscious-stream identity, endpoint construction, missing data, measured-to-latent bridges, candidate routes, study families, and decision rules. Each validated layer supplies a foundation for the next. Instrument validation establishes what can be measured; mechanism comparison identifies which processes explain the observations; and terminal inference assesses the declared closure claim with its remaining uncertainty.

Treat the rival models as central characters. Adaptation, opponent processes, homeostasis, allostasis, predictive processing, computational mood, ordinary mean reversion, conditioned bridges, endpoint selection, memory reconstruction, and observation floors can imitate pieces of the pattern. The Law deserves support only if it survives fair comparison against serious alternatives given the same data, flexibility, and test

budget. A rival victory is useful knowledge, not a failure of the scientific mission.

Read each result by the layer it tests. A study may validate a measure, identify a neutral point, recover a simulated route, narrow a reference class, or favor an explanation without adjudicating complete-stream PTV. Stronger verdicts require independently defined streams and endpoints, credible experiential coverage, honest uncertainty, and a measurement-to-hypothesis bridge.

Use the Table of Contents and Part and chapter introductions to navigate. This technical companion to The Law of Fairness is advanced, especially in its formal and mathematical chapters. Readers seeking an accessible entry may begin with The Law of Fairness, then return for the models, evidence standards, and research program. This volume also stands independently: general readers can follow the conceptual path, while specialists can move directly to their fields and shared methods.

Read as both skeptic and builder. Ask where the hypothesis can break and what theorem, instrument, dataset, simulation, cohort, or humane experiment could decide the issue. Laboratories can contribute immediately by choosing a tractable component and applying methods strong enough to produce a genuinely informative result. Care remains prior to evidence: no harm induction, no delayed treatment, no human-worth score, and no forced meaning. The goal is a research program capable of discovering how far the Law reaches.

Part I — Scientific Jurisdiction and Synopsis

Science begins when a compelling idea accepts a disciplined form of vulnerability. *The Science of Fairness* opens at that threshold. It receives Per-Stream Terminal Valence Closure, or PTVC, as a formally specified candidate boundary hypothesis and asks how a claim about complete conscious streams could become measurable, comparable, corrigible, and genuinely answerable.

The hypothesis is ambitious in a precise way. On its primary finite signed-measure branch, each separately routed maximal qualifying stream is proposed to carry equal finite positive and negative phenomenal magnitudes over its complete strict-pre-endpoint domain. The equality is intrastream and nontransferable, so unequal lives, unequal opportunities, unequal welfare, and unequal gross experience remain fully compatible with the formal target.

That compact statement opens a large scientific landscape. A responsible test specifies the phenomenal representation, neutral origin, sign, scalarity, exposure rule, bearer, ownership and routing, truth-level endpoint, protocol endpoint, observation process, missingness model, measured-to-latent bridge, estimand, estimator, reference class, modality, rival set, and verdict rule. Explicit connections among these layers make their respective roles clear.

The purpose of a separate science volume is therefore constructive. It gives the hypothesis one place where every dependency can be developed at field-expert depth and every improvement can be inherited without forcing the rest of the series to become a technical monograph. *The Law of Fairness*

remains the public formal root; this volume becomes the governed scientific body around it.

The first opportunity is representational. A question about felt experience can be scientifically meaningful only if positive, negative, mixed, and neutral-relative states can be modeled without manufacturing the result through an arbitrary origin or completed-record normalization. Measurement is not clerical support for the theory. It is one of the main discoveries the research program must earn.

The second opportunity is temporal. PTVC concerns a complete strict-pre-endpoint domain, not a final interview or a convenient study stop. Endpoint construction, stream continuity, return, interruption, resuscitation, and terminal-window access therefore become central scientific problems. A valid endpoint bridge can advance the inquiry; an invalid one can stop an inference without erasing the value of the surrounding work.

The third opportunity is comparative. Adaptation, opponent processes, allostasis, homeostasis, predictive processing, learning, selection, memory, observation attenuation, endpoint conditioning, and hidden-state models can imitate parts of the proposed pattern. Strong rivals are not obstacles placed around the contribution. They are the instruments that reveal whether the contribution has distinctive empirical content.

The fourth opportunity is cumulative. Measurement foundations can be improved before complete-stream adjudication becomes possible. Route models can be supported, revised, or retired while the target remains open. Model-recovery studies can show

whether an analysis can distinguish candidate worlds before the analysis is used to interpret empirical data. Each stage can create durable knowledge and open a stronger next test.

Scientific optimism in this volume is earned through that architecture. If PTVC survives these gates, science would gain evidence for a new boundary condition on conscious trajectories, opening work across phenomenology, psychometrics, consciousness, and stochastic dynamics. Early studies need not decide the whole hypothesis. Each must state its object, evidence role, rival pressure, uncertainty, and next decision. Severe testing and reproducible practice make a large conjecture more interesting by turning admiration into work (Mayo, 2018; Munafò et al., 2017; National Academies of Sciences, Engineering, and Medicine, 2019).

This Part establishes that scientific constitution before the book enters its specialized domains. Chapter 1 explains why the hypothesis needs a dedicated science. Chapter 2 classifies the kinds of claim at issue and the ways they may narrow or fail. Chapter 3 defines the ethical and authority boundaries that govern every later protocol. Chapter 4 gives a technical synopsis of the target, dependency chain, signatures, rivals, first protocol, and verdict logic.

The structure also connects the titles across the series. Applications in government, cities, law, peace, private life, religion, or transition can generate operational evidence and valuable research questions. Scientific findings can inform those applications through a documented handoff, with each domain

evaluating them against its own purposes, evidence, rights, and responsibilities.

By the end of this Part, readers should have a compact map of the target, its scientific dependencies, its ethical limits, and the evidence states that can change it. Different specialists can then enter at the dependency they can actually test, without mistaking local progress for whole-hypothesis support.

The rest of the book should carry these standing safeguards by reference and repeat them only when they change a local design, inference, or public claim. That rule matters for readability as well as rigor: repetition that adds no local consequence makes the scientific architecture harder to see.

Chapter 1 — Why the Hypothesis Needs a Science

A hypothesis becomes a scientific opportunity when it can organize better questions than its rivals and accept results that genuinely change its future. PTVC reaches that threshold only through a dedicated research program. The need is not created by the prestige of mathematics, but by the number of distinct scientific obligations packed into the claim.

The public sentence is simple: positive and negative phenomenal magnitudes may close in exact intrastream balance at the true end of each qualifying stream. The scientific sentence is a dependency network. It requires a defensible target, a stable representation, an independently calibrated neutral origin, a qualifying bearer, exhaustive routing, a complete domain, an endpoint object, an observation model, a recovery bridge, serious rivals, and a decision rule.

A dedicated volume connects this network. It brings affective science, terminal care, consciousness research, and statistics into a shared account of their assumptions and interfaces. Readers can see which discipline owns each question and how the resulting work contributes to the scientific target.

The first contribution is governance. Definitions, formulas, protocols, code, instruments, endpoint rules, and public verdicts must remain versioned and linked. A change to a bearer rule is not a cosmetic edit. A change to a neutral origin can change the target itself. Scientific memory makes those consequences visible.

The second contribution is modular failure. An inadequate momentary estimator need not defeat every branch of PTVC, yet it must block the inference that depended on that estimator. A

failed route may retire the route without automatically rejecting the terminal target. A gate-valid counterexample may defeat a declared set-universal branch even when other branches remain open.

This modularity is disciplined by cumulative judgment. Research programs grow when successful components generate novel, risky, and transferable work; they weaken when every difficulty produces only retrospective rescue (Lakatos, 1978). The volume therefore protects local learning without allowing endless deferral of the overall empirical burden.

The third contribution is a staged sequence. Formal verification comes before empirical promotion. Measurement qualification comes before terminal inference. Model recovery comes before real-data model comparison. Safe observational and natural-perturbation work comes before any stronger intervention. Replication and held-out transport come before a broad public verdict.

The fourth contribution is evidence-role clarity. A calibration result may establish the foundation for a later test. A route signature may favor one mechanism family. A pilot may show operational feasibility. A recurring human idea may establish salience and generate comparative hypotheses. None of those achievements needs to be dismissed merely because it is not complete-stream target evidence.

Several foundations are already empirical. Everyday activity choices vary systematically with mood; reward experiments quantitatively link changing feelings to expectations and

outcomes; and biological circuits can integrate error and maintain regulated outputs despite perturbation (Taquet et al., 2016; Rutledge et al., 2014; Aoki et al., 2019). These findings give researchers observed phenomena, candidate mechanisms, and reproducible questions with which to begin.

The scientific opportunity is to discover whether a common relation among signed experiential history, future response, and a separately identified stream boundary explains more than those established mechanisms explain individually or in combination. That possibility is specific enough to investigate.

The fifth contribution is open comparison. A theory that receives more flexible parameters, richer information, or kinder endpoints than its rivals has not earned superiority. Equal-budget comparisons, proper scoring, held-out prediction, sensitivity analysis, and model-recovery benchmarks create a fairer arena for candidate and rival models (Gneiting & Raftery, 2007; Mayo, 2018).

The program also needs transparent prospective specification. Protocol-fixed hypotheses, estimands, endpoint rules, analysis windows, exclusion criteria, and rival families separate confirmatory risk from exploration. A protocol is publicly preregistered only when it is deposited before outcome inspection in a timestamped external registry with a persistent identifier; Registered Reports add a distinct journal-governed commitment (Nosek et al., 2018; Chan et al., 2025).

Current reporting standards make that discipline more concrete. SPIRIT 2025 specifies the minimum content of a trial protocol,

CONSORT 2025 strengthens complete and transparent reporting, and the consolidated ICH E6(R3) guideline links quality by design to proportionate participant protection and reliable results. For PTVC, the practical implication is direct: participant burden, endpoint integrity, missingness, estimand definition, rival comparison, and public reporting are critical-to-quality factors rather than appendices added after the design is fixed (Chan et al., 2025; Hopewell et al., 2025; International Council for Harmonisation, 2026).

Builders benefit from the same discipline. A useful measurement instrument, a strong model-recovery library, an endpoint adjudication method, or a humane data architecture can remain valuable even if PTVC is narrowed or defeated. Outcome-resilient value makes the program more ambitious because it asks every stage to leave science stronger than it found it.

Figures and public summaries must identify whether they show observations, estimates, simulations, or hypotheses. Section 1.6 develops that release standard. Keeping those categories visible in compact artifacts helps prevent visual clarity from being mistaken for evidentiary strength.

Different readers enter through different doors. A general reader needs the question and the dependency map. A field expert needs assumptions, estimands, comparators, and failure routes. A participant needs burden, withdrawal, privacy, and care protections. A public communicator needs language that remains accurate when quoted alone. Designing these entry points explicitly lets readers reach the level of detail they need without changing the scientific status of the underlying claims.

The chapter ends with a demanding but optimistic proposition: answerability is not retreat. It is the form of courage appropriate to a scientific claim. Once the hypothesis has a governed home, its strongest possibilities can be explored without asking rhetoric, adoption, or beauty to carry the weight of evidence. That discipline gives favorable and unfavorable results equal power to improve the research program.

1.1 — Why a Separate Science Volume

The Law of Fairness asks a question that ordinary public language cannot carry safely: whether every separately routed maximal qualifying conscious stream in a declared class satisfies an exact cumulative boundary condition over its complete strict-pre-endpoint domain. Public language can awaken the question, but it cannot govern the representation, bearer and routing rules, endpoints, instruments, models, rivals, or status labels needed to test it. A dedicated science volume exists because the claim is too consequential to remain distributed across inspiration, analogy, and application (Popper, 1959; Lakatos, 1978; Laudan, 1977; Mayo, 2018).

A separate volume can connect scientific references that would otherwise remain scattered across the series. Measurement, consciousness, terminal care, and Artificial Intelligence safeguards each contribute distinct expertise; bringing them together makes their assumptions, interfaces, and evidence roles visible. The reader can then see how those contributions support a coherent research plan and where further work is needed.

The separate volume also prevents a temptation inside ambitious systems: letting coherence impersonate evidence. When ten domains fit together, the fit can feel like discovery. But fit across books is a design achievement, not a finding about nature. The science book exists so the series has one place where the difference is never optional.

1.1.1 — A Formal Claim Needs Scientific Governance

The Law of Fairness receives a formal architecture involving separately routed maximal qualifying streams, finite signed phenomenal measure on the primary branch, exhaustive ownership and routing, a complete strict-pre-endpoint domain, and a truth-level endpoint. Scientific development assigns each term its status, assumptions, observation requirements, tests, and rules for revision.

The first governance problem is version control. A statement of the Law, an estimator of lived experience, a stopping-time rule, a reserve-coupled realization, and a public verdict label are different objects. If one changes, the research program must record which claim version has changed. A favorable result under one bridge cannot be transferred quietly to a different bridge simply because the project prefers continuity.

The second governance problem is assumption visibility. The formal claim may be stated in an idealized latent space, but empirical work requires auxiliary assumptions about representation, scale, sampling, endpoint classification, channel reliability, missingness, and rival processes. A science volume makes those auxiliary assumptions visible so that critics can attack them without being accused of attacking the whole moral aspiration of the series (Popper, 1959; Lakatos, 1978; Laudan, 1977).

Governance also requires contribution typing: definitions specify objects, formal derivations establish consequences of stated assumptions, measurement models link observations to targets,

studies evaluate components or predictions, and results update only the claims they actually reach. Making those transitions explicit keeps each statement connected to its warrant.

The separate science volume is therefore an institutional answer to a linguistic danger. The Law is too large to be left to informal confidence. It needs a place where every important term is made answerable to a method, every method is made answerable to a rival, and every favorable result is made answerable to the status it can actually bear.

A field expert will also look for governance of comparison, not merely governance of definition. If the Law is compared against a simplified rival while the Law receives a richer auxiliary structure, the comparison is biased before the study begins. Scientific governance therefore includes a symmetry rule: a model that is allowed to use context, noise, and hidden state should face rivals that are allowed comparable resources under comparable constraints.

1.1.2 — Applied Coherence Is Not Validation

Applied coherence is not validation. A city, institution, ritual, or interface may be useful because it solves a local problem, and its difficulties may generate research questions, without supplying evidence for PTVC. Translate applied observations into bounded, ethically authorized studies with explicit rivals before they enter the scientific record. Operational success can motivate a test; it cannot decide the target hypothesis (Laudan, 1977; Mayo, 2018).

1.1.3 — A Large Claim Needs Modular Failure

The larger a claim becomes, the more dangerous it is to treat it as one indivisible object. *The Law of Fairness* touches the bearer of experience, the currency of felt valence, the temporal accumulation of experience, the endpoint at which a trajectory closes, the measurement bridge from latent to observed, the candidate dynamics that could realize closure, and the statistical rules that would justify a verdict. Each component can fail in a different way.

Modular testing assigns each study to the component it can actually reach: representation, measurement, endpoint construction, candidate realization, or rival explanation. Failure blocks the descendants that depend on that component without automatically deciding unrelated branches (National Academies of Sciences, Engineering, and Medicine, 2019).

The program therefore uses a dependency lattice rather than a single ladder of belief. That structure prevents one weak instrument from becoming total defeat and one favorable signal from becoming total validation; it lets each success or failure change only the status it has earned.

The separate science volume is needed because no applied book can maintain this lattice without becoming a methods book. Each applied domain has its own burdens. The science book carries the cross-cutting burden of deciding which components are vulnerable, how they are connected, and what consequence follows when one of them fails.

The modular structure also prevents premature despair. If endpoint research proves intractable in one clinical setting, measurement development may still proceed in ordinary longitudinal settings. If a reserve-coupled realization fails, rival comparison may still clarify which ordinary mechanisms explain apparent balancing. A good program learns from partial loss rather than requiring every failure to become total collapse.

Cumulative judgment evaluates how those modules work together. Sustained problems across representation, measurement, endpoints, model comparison, and transport can justify revising or retiring the affected scientific claim. The component record identifies the evidence behind that decision.

1.1.4 — Answerability Before Adoption

Scientific answerability requires explicit predictions, fixed comparisons, and result-contingent decisions before adoption pressure can shape the test. Public interest does not raise evidential status. For confirmatory work, freeze the empirical bridge, name serious rivals, specify adverse-result rules, and preserve the dependency order from representation through measurement, endpoint, model comparison, replication, and transport. Applications may proceed on their own evidence, but they cannot make the scientific claim more nearly proven by momentum (Popper, 1959; Lakatos, 1978; Laudan, 1977).

1.1.5 — Scientific Seriousness Before Support

A hypothesis can be scientifically serious before it is supported when it is coherent enough to state, distinctive enough to generate risky consequences, vulnerable enough to lose, and connected to

methods capable of distinguishing it from rivals. PTVC now has a defined target, candidate consequence families, explicit rivals, and routes to narrowing or defeat. Those features justify treating it as an answerable research program; they do not constitute empirical support. Credibility must come from instruments, comparisons, replications, and results that survive the stated failure conditions (Laudan, 1977; Mayo, 2018).

1.1.6 — The House-Skeptic Function

The house-skeptic function gives criticism equal standing inside the research program. It asks which component is supported, which rival could explain the same pattern, whether endpoint and analysis rules were fixed before outcomes, which missingness process could mimic convergence, and what claim must change if a bridge fails.

To make that role substantive, skeptical and constructive teams should receive comparable access to assumptions, data dictionaries, simulation fixtures, code, protocol history, model budgets, and scoring rules. A rival denied relevant covariates or forced into a weaker observation law is not a fair comparator (Gneiting & Raftery, 2007; Mayo, 2018).

Major objections should enter a challenge log with the component challenged, evidence needed, owner, and interim public status. Chapter 25.7 supplies the detailed red-team and challenge-log procedure; Section 1.6 governs hostile-crop public communication.

1.2 — Inheritance and Scientific Jurisdiction

The Science of Fairness develops the public question introduced in *The Law of Fairness* into a self-contained scientific inquiry. Chapters 4–7 state the hypothesis, define its objects, and derive its principal consequences; later chapters develop measurement, candidate dynamics, tests, and interpretation. Readers can follow the scientific argument within this volume, with external research cited where it informs the analysis (Douglas, 2009).

The book connects the public question to scientific investigation and to the applied titles in the series. A shared formulation lets the books develop distinct responsibilities: this volume specifies the scientific target and methods, while the related titles explore legal, spiritual, civic, clinical, and personal questions in their own domains.

Scientific jurisdiction is bounded authority. This volume owns measurement governance, protocol design, rival comparison, model recovery, replication, narrowing, defeat, correction, and scientific public communication. This scientific remit leaves human worth, spiritual interpretation, legal enactment, government operation, ordinary privacy, and transition authorization within their respective domains.

That division of work is productive. *The Law of Fairness* states the public formal root; *The Science of Fairness* develops and tests the scientific questions; and applied titles evaluate proposals within their respective domains.

1.2.1 — The Formal Hypothesis Is Stated

The first scientific act is specification. This volume states a formal hypothesis about separately routed maximal qualifying conscious streams and exact terminal valence closure over complete strict-pre-endpoint domains. It does not replace the bearer with public identity, the phenomenal target with welfare preference, the endpoint with bodily death, or the latent cumulative object with a dashboard. An operational target must remain recognizably connected to the object it is meant to test.

Specification makes the vocabulary explicit. Qualifying bearer, exhaustive ownership and routing, separately routed maximal stream, phenomenal valence, complete strict-pre-endpoint domain, truth-level endpoint, latent terminal residual, momentary valence estimator, interval contribution estimator, and branch-matched inference are defined here as the objects of scientific inquiry. Science may show that an object is difficult to identify, propose provisional bridges toward it, or conclude that a bridge fails. It may not declare that a simpler neighboring object was the target all along.

The hypothesis also retains its ethical boundaries: PTVc carries no implication of moral desert, victim-blaming, cross-stream transfer, pain as morally owed payment, harm induction, delayed care, human ranking, or machine authority; Chapter 3 governs the corresponding operational protections (Council for International Organizations of Medical Sciences, 2016; World Medical Association, 2024).

The task is to determine what the received objects require from research. What counts as a bearer in a study? Which aspects of felt valence can be observed? How can an endpoint be classified independently of the ledger result? How should each scientific finding be communicated?

The public question motivates the formal target specified here. This volume develops the observations, models, and comparisons through which researchers can evaluate it.

The first jurisdiction rule follows: receive the formal target whole enough to test honestly, then record any scientific narrowing openly. If research shows that a component is unidentified, a reference class is too broad, or an endpoint bridge fails, the change is a scientific status update. It is not a hidden rewrite that preserves the original language while testing something else.

Reception also requires resisting friendly simplification. It would be easier to replace the Law with a familiar claim about adaptation, life satisfaction, welfare, resilience, or moral balance. Those topics have literatures and instruments. But a research program that changes the target to fit available tools has not made the original claim scientific. It has studied a neighboring object.

Approximation is sometimes necessary, but it should never erase the harder target from view. Public readers should be shown both layers: the received formal object and the provisional bridge by which a particular study approaches it. Keeping those layers visible prevents an operational measure from quietly replacing the claim it was designed to investigate.

1.2.2 — The Formulation Becomes a Research Target

A formal model becomes a research target when its definitions are translated into obligations. The ledger is not merely a symbol; it demands a representation theory of lived valence. The bearer and routing rules demand a defensible account of which experiences belong to which maximal qualifying stream. The truth-level endpoint demands prospective construction and adjudication that do not define closure by the ledger value being tested. Some protocol-fixed branches add timing-independence, support-density, hitting, absorption, atom, or continuation premises, and each such premise must remain branch-specific rather than becoming a universal assumption.

The translation turns the formal model into operational questions. For latent $L(t)$ and its measured estimates, the science book specifies the requirements for construction, calibration, versioning, and reporting. For terminal valence closure, it derives measurable consequences under declared observation models and rival data-generating processes.

The model also becomes a target for dimensional discipline. A rate, an integral, a unit, a reserve variable, a horizon, a variance, and an endpoint are not interchangeable pieces of poetic mathematics. Each has assumptions, units, and failure conditions. No equation should travel into public language without its object, dimensions, branch, and status attached (Folland, 1999; Protter, 2005).

A candidate stochastic realization derives a possible process from stated assumptions. Its scientific development identifies those

assumptions, predicts observable consequences, and compares the resulting model with empirical data and alternatives.

Making this formulation a research target also gives critics a fair route in. They can dispute representation, scalarization, bearer qualification, ownership and routing, endpoint construction, branch-specific timing assumptions, reserve coupling, measurement invariance, rival comparison, or verdict logic. That is better than a general dispute over whether the Law feels plausible. A target that can be attacked component by component can also be improved component by component.

The target also demands that proposed failures be meaningful. A failed momentary valence estimator channel is not a decisive refutation of the Law if the channel never estimated the intended construct. But repeated failure of reasonable, prospectively specified bridge families is not irrelevant either. The research target must allow both distinctions, because otherwise the program becomes either too brittle or too protected.

1.2.3 — Scientific Status Is Governed Here

Scientific-status governance is this book's central jurisdiction. The volume defines the procedures, evidence roles, and public language through which PTVC-related claims may be updated, while evidence, independent review, and the wider scientific community determine the verdict. Without that distinction, public language can drift toward whatever status feels most useful at the moment.

Scientific-status governance records how findings update claims. A bounded cohort can support a specified consequence;

measurement work can qualify or revise an estimator; and a comparative result can guide mechanism selection. These decisions make the research record usable.

Negative status belongs here as visibly as support. Nulls, failed instruments, rival victories, narrowing, route retirement, and theory-level loss remain part of the scientific record. A program that publicizes only favorable movement cannot learn reliably from evidence.

Replication is part of status governance. A single site, instrument, clinical setting, culture, or endpoint procedure cannot carry universal language. The science book must require transport before broadening. It must record when a result is local, fragile, incompatible across sites, sensitive to missingness, or dependent on an auxiliary assumption that has not yet traveled.

Scientific-status governance includes correction of public artifacts; Chapter 28 supplies the full propagation, archival, and retirement workflow. A correction must reach the public surface where the overstatement traveled.

Scientific-status authority is narrow and consequential. It does not govern law, faith, city design, ordinary practice, or transition sequence. It determines whether those domains may use scientific language and, when they may, the exact scope that the evidence has earned.

Scientific-status governance also applies to language inside the volume. Words like suggest, support, validate, imply, estimate, demonstrate, and prove are not stylistic variations; they name different relationships between evidence and claim. Treating

those verbs as interchangeable misleads even when a formal warning appears elsewhere.

1.2.4 — Definitions Flow Out; Evidence Flows Back

The series requires a clean direction of flow. Definitions flow outward from *The Law of Fairness* because the root book states the formal claim. Evidence flows back through *The Science of Fairness* because scientific findings must update public status under governed rules. If this direction is reversed, applied success can rewrite definitions, and the project becomes self-validating.

This flow rule protects the formal root from convenience. Suppose measurement works better when the endpoint is defined by a clinical event rather than by truth-level endpoint. The science book may use the clinical event as a proxy under a declared bridge, but it cannot say the endpoint was always that event. Suppose a rival explains terminal concentration better than reserve coupling. The science book may narrow or retire the realization; it cannot quietly alter the formal hypothesis to preserve a favored result.

The flow rule also protects science from canon pressure. A later book may produce an elegant institution, ritual, or transition pathway that depends rhetorically on the Law. That elegance cannot demand that science find support. Evidence must remain able to disappoint the canon. A series that cannot be disappointed by evidence has already left science (Douglas, 2009; Mitchell, 2009; Woodward, 2003).

Flow is not a wall. Applied books can send observations back as research leads. A city may reveal record burden; an ordinary-life

practice may reveal repair dynamics; a religious house may reveal ritual effects; a transition pilot may reveal public-status misunderstanding. But those observations become questions only after they are transformed into research designs with consent, context, rivals, and status limits.

The return flow from science is component-specific. Support for a measurement bridge returns as that bounded update; it does not strengthen every sentence in every title. A failure returns with its scope and consequence, which may require language correction, artifact retirement, source updates, or claim narrowing without creating panic beyond the component affected.

A favorable scientific finding can update the relevant passage in the formal-law book. The handoff identifies the supported component, the evidence behind it, and its established scope, allowing readers across the series to follow the same result.

1.2.5 — Applied Observations Are Research Leads

Applied observations matter because the world often reveals burden before instruments do. A household may expose how care work disappears into routine. A public office may expose how answerability shifts onto citizens. A religious practice may reveal how meaning changes distress. A technological system may reveal how a dashboard pressures users to perform. These are valuable observations, but their value begins as question-generation.

A research lead names a phenomenon that deserves controlled inquiry. It does not state the cause. If a group using a Fairness practice reports more repair, the science must ask whether the

effect comes from attention, community, expectancy, selection, time, language, ritual, reduced isolation, or some Law-specific consequence. Treating the observation as evidence too early would disrespect the complexity that made it interesting.

Harms can also become research leads without becoming research data by default. If a public artifact creates misunderstanding, communication research can examine the pathway. If an experience measure creates anxiety, burden research can examine reactivity. If readers infer terminal destiny, hostile-crop testing can study which fragments carry that inference. The moral problem is immediate; the scientific opportunity begins only after consent, context, rival explanations, and status limits are specified (Fischhoff & Davis, 2014; National Academies of Sciences, Engineering, and Medicine, 2017; National Institute of Standards and Technology, 2020).

Applied observations can reveal rival mechanisms worth formalizing. Relief after ritual may arise through expectancy, attention, social support, or meaning. Terminal calm in a setting with strong death scripts may reflect script-induced appraisal. Apparent variance compression where sensors fail may be observation-gain collapse. Each observation improves the program when it becomes a discriminating question rather than a favored anecdote.

The research lead must pass through a separate door before becoming evidence. That door includes consent, data minimization, context definition, sampling, prospectively specified outcomes, endpoint rules where relevant, rival models, missingness plans, and public-status limits. Operational records

do not become research data merely because they are convenient. Participation in an institution is not research consent.

Applied observations also help the program notice harms that laboratory design may miss. A public dashboard may produce social pressure. A community ritual may intensify guilt for some participants while relieving others. A record system may help officials while exposing families. These are not peripheral anecdotes. They are burden data that can improve future research questions if they are handled under consent and scope discipline.

1.2.6 — Jurisdiction Is Not Mastery

Scientific jurisdiction is bounded. This volume governs scientific claim status; it does not govern human worth, spiritual meaning, legal rights, clinical care, transition timing, or private life. Section 3.6 states the operative domain boundaries. For example, qualifying an affect measure can inform an application while leaving the application's legal and clinical decisions to their own review. A scientific result can therefore sharpen a factual premise without deciding the rule another field should apply. The receiving field remains responsible for integrating that evidence with its own standards, duties, and forms of review.

That limit also applies to participants. Measurement and consent authorize only the declared research uses and inferences; they do not transfer ownership of inner life. Ethics, law, clinical care, disability studies, privacy, and science communication remain responsible for the consequences within their domains. A later request to train a new model on stored reports is a new proposed use, not an extension silently granted by the original

measurement. Secondary use should therefore be treated as a fresh governance decision, with its own stated purpose, access conditions, retention limits, and challenge route. This keeps consent tied to a defined use rather than turning one permission into an open-ended claim on future data.

Cross-disciplinary work therefore uses explicit handoffs: each contribution states what it establishes, the assumptions it carries, and which questions remain for other fields. Scientific precision is strongest when it does not borrow authority from neighboring domains. A useful handoff identifies which conclusion depends on the scientific result, so a later revision can update that conclusion without reopening unrelated judgments. A strong handoff also carries the result's status, uncertainty, and reference class, because those features determine how far the result can travel. The receiving field can then combine it with its own evidence and decision rules without stripping away the conditions that made the scientific statement valid.

1.3 — The Research Program in Stages

A staged research program connects representation, measurement, model recovery, endpoint adjudication, and rival comparison before terminal testing. Work at each stage identifies the conditions and methods needed for the next study (Chambers, 2013; Munafò et al., 2017; Nosek et al., 2018).

This section uses the language of research programs because it fits the problem. A program has a hard formal target, auxiliary assumptions, instruments, models, rivals, and rules for revision. It can become progressive when changes solve independent problems and generate new risky consequences. It can degenerate when changes only protect a favored conclusion after difficulty appears.

The stages introduced here are an orientation, not a substitute for protocols. The program moves from formal coherence to representation, from representation to measurement, from measurement to endpoint and observation, from those prerequisites to rival comparison, and from successful recovery to replication and public status. A later stage never compensates for a failed earlier gate.

The staged architecture gives the project clear decision points. Each stage identifies what has been established, what remains open, and which next investment is scientifically justified.

1.3.1 — Core Claim and Auxiliary Hypotheses

The core claim is the strongest formal target the science receives. On the primary finite signed-measure branch, every separately

routed maximal qualifying stream in the declared truth-domain class has equal finite positive and negative phenomenal magnitude over its complete strict-pre-endpoint domain, equivalently a zero terminal signed residual. The public empirical claim is not identical to that set-universal target. Public inquiry must proceed through validated representation, ownership, endpoint, observation, measured-to-latent bridges, rival comparison, and branch-matched inference. The target gives direction; auxiliary hypotheses make bounded research possible.

Auxiliary hypotheses include representation assumptions. Can lived experience be treated, for a declared purpose, as a signed valence-rate target that accumulates over time? How are mixed affect, numbness, dread, relief, meaning, dignity, memory, anticipation, and bodily distress handled? A failure here would not be a small measurement problem. It would challenge whether the proposed target can be represented in the required form.

Other auxiliaries concern measurement. Candidate momentary and interval estimators may function as estimators only within a specified context of use, with uncertainty, calibration, versioning, missingness, and correction rules. If the estimator changes, the claim version changes. If the estimator cannot preserve sign or scale within the required setting, downstream terminal analysis cannot repair that failure by collecting more data (Chambers, 2013; Lakatos, 1978; Laudan, 1977).

Endpoint assumptions form another auxiliary layer. The truth-level endpoint must be classified through channels not algebraically identical to the ledger estimator. If the endpoint is defined as the moment the ledger reaches zero, neutrality

becomes a tautology. If endpoint channels share hidden tuning with the ledger, residual dependence must be modeled rather than waved away.

Candidate mechanisms include reserve coupling, horizon pressure, queue dynamics, adaptation, predictive control, and homeostasis. Each generates patterns and consequences that can be developed into comparative predictions.

The first stage of seriousness is therefore not data collection. It is an assumption register. The reader should know what would remain if a representation failed, what would remain if a measurement failed, and what would remain if a mechanism failed. Only then can later evidence have a clear target.

The auxiliary structure should be visible enough that a reviewer can ask whether the program is becoming progressive or degenerating. If a measurement bridge is replaced, what new prediction does the replacement create? If a reserve assumption changes, what rival does it now face? If an endpoint rule becomes more complex, does complexity improve independent classification or merely protect the desired terminal pattern?

Some auxiliaries determine whether the next inference is available. A defensible origin, endpoint, and measurement bridge provide the foundation for terminal analysis. The staged architecture directs early work toward those dependencies.

1.3.2 — Progressive Problem Shifts

A research program progresses when a revision does more than protect the core from trouble. It solves an independent problem, clarifies a mechanism, improves measurement, predicts

something not used to build the revision, or exposes the program to a new possible loss. *The Law of Fairness* needs that standard because it will inevitably meet anomalies, instrument failures, ambiguous endpoints, and rival explanations.

A progressive shift might occur if a failed single-channel momentary valence estimator model leads to a better declared observation model that predicts when self-report and physiology diverge, then correctly forecasts those divergences in a new cohort. The revision would not merely rescue neutrality. It would solve a measurement conflict and generate a new testable consequence.

Another progressive shift might arise from endpoint adjudication. Suppose a unity-proxy rule performs poorly in one boundary state but, after expert review, yields a refined confidence-class system that predicts which cases should return no estimate. If that system improves prospective endpoint classification and increases no-estimate honesty, the research program has progressed even before any Law-specific terminal support appears (Laudan, 1977; Munafò et al., 2017).

Progressive shifts can also involve rivals. If an adaptation model explains most local rebound but fails to match reserve-linked drift and innovation behavior under held-out prediction, the Law-specific program gains a sharper target. The gain is not that adaptation was dismissed. The gain is that the contrast taught the program what it must uniquely explain.

An informative revision improves the connection between model and observation. Additional variables, uncertainty models, and

flexibility contribute when they yield clearer predictions, better calibrated estimates, or a more discriminating comparison.

A progressive shift should improve the critic's position as well as the proponent's. After the revision, it should be easier to say what would now count against the program. Better measurement, for example, should create clearer defeat conditions, not only better-looking fits. Better endpoint classification should increase no-estimate honesty as well as terminal precision.

1.3.3 — Degenerating Rescue Moves

A degenerating rescue move is a change made after difficulty appears, not to improve contact with the world, but to preserve a desired conclusion. Such moves are especially tempting here because the Law touches invisible experience. If unfavorable data appear, one can always say the relevant experience was unmeasured, the endpoint was misclassified, the scale was wrong, or the compensation occurred elsewhere. Sometimes these objections may be true. They become degenerating when they remove risk without adding a new test.

The clearest forbidden rescue is endpoint recoding by result. If the measured cumulative estimate does not approach neutrality, the project cannot redefine the truth-level endpoint as whatever time produces a favorable estimate. Endpoint discipline exists precisely to prevent that move. The endpoint must be prospectively specified through unity or mind-continuity channels, and ambiguity must be allowed to produce no estimate rather than a rescued verdict.

Another rescue is origin adjustment after the fact. Because felvalence lacks an instrument-fixed natural zero, empirical work must declare origins, anchors, and equivalence bands before analysis. If the origin is shifted only after a result disappoints the Law, the program has not discovered neutrality. It has moved the ruler (Nosek et al., 2018; National Academies of Sciences, Engineering, and Medicine, 2019).

Measurement expansion can also degenerate. If every failed channel leads to adding more channels until the desired pattern appears, the estimator becomes an oracle for the theory. A legitimate measurement revision must explain why the old model failed, state what the new channel contributes, freeze the update before evaluation, and test whether the revision predicts beyond the dataset that motivated it.

Rival handling can degenerate as well. A rival is not serious if it is made artificially weak, excluded after it wins, or reclassified as part of the Law whenever it succeeds. Adaptation, homeostasis, predictive control, Brownian bridge effects, observation shutdown, clinical confounds, and expectation scripts must be allowed to win under the same constraints imposed on the Law-specific model.

The practical rule is severe but fair: every rescue must pay rent. It must create a new prediction, a new independent measurement, a narrower public claim, or a declared loss. If it merely preserves favorable language, it is not a scientific modification. It is protection from science.

Degenerating moves often begin with true statements. It is true that measures are imperfect. It is true that endpoints are difficult. It is true that unobserved experience matters. It is true that rivals may be incomplete. The danger lies in using true difficulties to make the Law unreachable by any practical test. A serious book must distinguish legitimate uncertainty from theory protection.

The practical safeguard is prospective classification. Before outcome inspection, the protocol states which uncertainty makes the study unusable, which widens an interval, which narrows the claim, and which becomes adverse under valid prerequisites. After the result, those categories do not change merely because the outcome is disappointing. That discipline separates humility from retrospective rescue.

1.3.4 — The First Five Studies

The first five studies should be understood as dependency studies, not as a rush toward terminal proof. Their purpose is to ask whether the empirical bridge is strong enough to justify later tests. A program that begins with dying persons before representation, measurement, and endpoint rules are ready would be ethically and scientifically inverted.

Study one is formal verification and representation audit. It asks whether the received objects are coherent, whether dimensions and process classes are defensible, which assumptions are independent, and which claim versions are identifiable in principle. The deliverable is a target capable of losing, not a verdict about whether PTVC is true.

Study two develops the measurement bridge. It asks whether momentary and interval valence contributions can be estimated with declared channels, sign conventions, calibration, uncertainty, and context of use. Model recovery, channel conflict, missingness, and transport determine whether the bridge estimates the intended construct without becoming a score or a theory-protecting instrument (Chambers, 2013; Lakatos, 1978; Laudan, 1977).

Study three validates consciousness-state and endpoint procedures. It tests whether the bearer and endpoint channels can distinguish waking continuity, sleep, anesthesia, coma, delirium, dissociation, degraded continuity, return, and irreversible loss with graded confidence and protected no-estimate states. The ledger may not define the endpoint whose independence the analysis later invokes.

Study four maps palliative feasibility and burden. It asks whether terminal observation can occur without increasing suffering, distorting care, burdening families, or producing missingness too severe for the intended inference. The deliverable may be a redesigned low-burden protocol, a restricted reference class, or a decision to keep the next stage nonterminal.

Study five is a prospectively specified terminal-dynamics comparison against strong rivals. It tests whether declared preterminal signatures, using the best available measurement and endpoint bridges, out-predict adaptation, homeostasis, endpoint conditioning, observation shutdown, clinical confounds, and expectation scripts. Its first question is whether the consequence

structure is discriminating, not whether exact complete-stream closure has been seen.

These five studies are gates, not publicity milestones. Formal incoherence, failed measurement transport, ambiguous endpoints, unacceptable palliative burden, or rival victory can close the route; terminal recruitment is justified only after earlier uncertainties have been reduced enough that vulnerable participants are not carrying avoidable method-development burden.

1.3.5 — Replication Before Status Upgrade

Report the first study by the component tested, the setting, the instrument and endpoint procedure, and the alternatives compared. Those details identify the result that subsequent studies can reproduce and extend.

Replication upgrades status only when the relevant claim survives independent teams, prospectively fixed analyses, appropriate transport, missingness sensitivity, and adversarial review. Replication should also test the bridge itself: disagreement across instrument versions, endpoint classes, or care settings is evidence about scope, not noise to be averaged away. Chapter 26 specifies the multisite system and Chapter 27 governs the resulting status transitions.

Public status should move more slowly than excitement. A component can gain support, a bridge can improve, a rival can weaken, or a scope can narrow. The phrase validated Law is unavailable until the exact claim version being announced has

passed the prerequisites, rival comparisons, replication, and quantifier bridge required for that announcement.

Replication should also include adversarial sympathy. A replication team should be allowed to disagree about the best rival, the missingness model, or the endpoint confidence threshold. The program should preserve those disagreements rather than smoothing them into a single friendly result. Consensus is valuable only after disagreement has been given room to sharpen the analysis.

Status updates should identify concrete advances: a measurement bridge has matured, a rival has been distinguished in one cohort, a protocol proved humane, or a no-estimate rule worked as intended. Each gain contributes to the research program and deserves a clear account of what was learned.

An inspectable replication packet should therefore exist before the first result is known. At minimum it should preserve the claim version, protocol registration, representation and endpoint specifications, analysis code, synthetic recovery benchmarks, instrument versions, data dictionary, missingness plan, adverse-event logic, decision thresholds, and the exact public wording permitted by each outcome. The packet is not bureaucracy around the experiment. It is the experiment's memory (Chambers, 2013; Munafò et al., 2017; Nosek et al., 2018).

Chapter 26 specifies how frozen and adaptive elements, implementation changes, tacit knowledge, provenance, executable code, and analytical reproducibility are governed across sites. Here the governing rule is enough: replication cannot

upgrade status unless an independent team can reconstruct both the analysis and the claim-relevant implementation without hidden favorable choices (National Academies of Sciences, Engineering, and Medicine, 2019; Nosek et al., 2018; Munafò et al., 2017).

This standard is demanding because broad claims are unusually vulnerable to invisible degrees of freedom. A theory can appear to replicate when each site silently chooses a favorable origin, smoothing rule, endpoint window, exclusion set, or rival budget. Replication becomes evidential only when those freedoms are controlled, recorded, and exposed to a team that has no obligation to preserve the preferred story.

1.3.6 — A Program With Clear Decision Gates

A research program specifies the conditions for pausing a study, retiring a bridge, narrowing a claim, replacing a mechanism, or reaching a theory-level verdict. Those decisions connect the evidence to the next responsible action.

Stopping can occur early. If no defensible representation of the target can be specified, terminal testing should not proceed under a false sense of precision. If measurement channels cannot preserve sign or transfer across required contexts, the public empirical claim must narrow. If endpoint adjudication remains circular, terminal valence closure cannot be tested responsibly. Each stop protects the project from building on a broken dependency.

Stopping can occur at the mechanism level. Reserve-coupled dynamics may fail while other aspects of the inquiry remain alive.

Queue language may prove useful as a model of pressure but not as a Law-specific realization. Shadow-price formulations may help describe horizon pressure while failing as evidence for closure. A serious book lets useful mechanisms retire from stronger claims while preserving the knowledge they helped produce (Nosek et al., 2018; National Academies of Sciences, Engineering, and Medicine, 2019).

Stopping can also occur because rivals win. If adaptation and homeostasis explain the signatures with better prediction, simpler assumptions, and equal or better transport, the Law-specific claim must lose the relevant field. If endpoint-conditioned bridges reproduce the terminal shape without reserve coupling, the program must narrow. If observation shutdown creates false compression, the measurement claim must be corrected before future study.

Public communication is reviewed for clarity, unintended personal interpretations, and participant pressure. When problems recur, the affected materials are paused, revised, and assessed before further release. The correction record identifies what changed and how the revised design addresses the problem.

Stopping also protects contributors from sunk-cost pressure. Researchers, donors, builders, and readers may invest time and identity in the program. The longer they invest, the harder it becomes to admit that a component has failed. A public stop rule gives loyalty a better form: loyalty to the truth conditions that made the project worth beginning.

1.3.7 — Negative Results as Scientific Infrastructure

Negative results are typed outputs, not one null. Distinguish identifiable nulls, invalid instruments, failed model recovery, unadjudicable endpoints, rival wins, burden-limited studies, and nontransport because they block different descendants and imply different next work. Preserve the failed object, the reason, the surviving claims, and the successor obligations in a versioned record; Chapters 27 and 28 contain the detailed status and archive machinery. A negative result is scientifically useful when it changes the next decision or prevents unnecessary participant burden.

1.4 — The Book's Evidence Responsibilities

A monograph that studies fairness has to expose the costs of its own inquiry. Vague status language shifts interpretive work to readers; excessive observation shifts time and discomfort to participants; impractical procedures shift work to clinicians; unclear targets shift model construction to critics; premature conclusions shift repair to later titles. The program should name and govern those costs rather than hide them inside ambition (Council for International Organizations of Medical Sciences, 2016; Emanuel, Wendler, & Grady, 2000; National Academies of Sciences, Engineering, and Medicine, 2019).

That accounting reaches beyond ethics. It includes the inferential cost of flexible hypotheses, the statistical cost of weak comparators, the clinical cost of intrusive observation, the communicative cost of compressed uncertainty, and the archival cost of losing failed versions. Each cost needs an owner, a control, and a recorded consequence.

The first visible map of those burdens appears here. It is not the full Technical Synopsis, which belongs in Chapter 4. It is a dependency lattice that shows how plausibility can rise only when several independently vulnerable components survive. The lattice prevents the reader from mistaking elaborateness for evidence.

The second visible map is a compact table from formal object to status change. It shows how a formal object becomes an empirical target, which study family bears on it, and what public status might change if the study succeeds or fails. The table is not a protocol. It is a contract against overclaim.

Table 1.1. Component-dependency lattice from formal claim to verdict.

Layer	What must be vulnerable	Typical failure	Status consequence
Formal hypothesis	The received target must be coherent and versioned.	Contradictory notation or untracked claim change.	Formal clarification or change-control request.
Representation assumptions	Experience must support a signed temporal target for the declared purpose.	Mixed affect, origin, scalarization, or duration cannot be responsibly specified.	Public empirical claim narrows before measurement.
Observation model	Candidate momentary and interval estimators and related channels must estimate the intended target with uncertainty.	Sign loss, calibration failure, missingness, channel conflict, or version drift.	Instrument retired, bridge narrowed, or no estimate returned.
Endpoint rule	Truth-level stream endpoint must be adjudicated independently of the ledger.	Endpoint defined by the outcome, shared tuning, or low-confidence boundary state.	Terminal analysis blocked or restricted.

Layer	What must be vulnerable	Typical failure	Status consequence
Candidate realization	Reserve, horizon, queue, or control dynamics must generate distinctive consequences.	Closure by construction, nonidentifiability, or rival equivalence.	Mechanism retired or treated as teaching model only.
Study design	Predeclared estimands, sampling, missingness, rivals, and burden limits must hold.	Unusable data, excessive burden, unfrozen bridge, or post hoc outcome selection.	Affected evidence classified as Unusable.
Rival comparison	Serious alternatives must be allowed to win under shared constraints.	Law-specific model wins only against weak or late-added rivals.	No support beyond model-fitting.
Verdict rule	Status update must match component, scope, replication, and transport.	Universal language from local result or silence after failure.	Public correction, narrowing, or defeat label.

Table 1.2. Formal object, empirical target, study family, and possible status change.

Formal object	Empirical target	Study family	Possible status change
Unified conscious stream	Confidence-class bearer and continuity adjudication.	Consciousness-state validation and boundary-state review.	Bearer rule strengthened, narrowed, or suspended.
Latent valence-rate and ledger	Declared candidate momentary and interval estimates with uncertainty and context of use.	Measurement development, calibration, model recovery, and missingness studies.	Estimator qualified, retired, or approved for bounded use.
Truth-level stream endpoint	Endpoint rule independent of ledger estimator.	Endpoint validation, palliative feasibility, and no-estimate classification.	Terminal study permitted, restricted, or blocked.
Reserve and horizon dynamics	Preterminal drift, variance, innovation, and reserve-coupling signatures.	Generative benchmarks and prospective longitudinal tests.	Mechanism supported, narrowed, or defeated against rivals.
Terminal measurable consequences	Equivalence-band outcomes, terminal concentration, and rival comparison.	Humane prospectively specified terminal dynamics study.	Component support, inconclusive status, or local defeat.

Formal object	Empirical target	Study family	Possible status change
Transport and replication	Cross-site and cross-population stability under source-use tags.	Multisite replication, adversarial review, and registered reports.	Bounded upgrade, reference-class ceiling, or no transport.
Public scientific claim	Status label tied to component, scope, uncertainty, and rivals.	Evidence accumulation and correction systems.	Support, narrowing, defeat, or artifact correction.

1.4.1 — Claim Burden

Claim burden is the duty to say what kind of sentence is being spoken. A definition, formal hypothesis, candidate realization, measurement estimate, rival model, preliminary result, and public verdict may all sound authoritative in polished prose. They carry different warrants. The category should be visible in the sentence itself, not recoverable only from a remote disclaimer.

The burden begins with the strong form. The latent target is an exact set-universal boundary condition over separately routed maximal qualifying streams in a declared class, not a directly observed public fact. Public science must proceed through measurable consequences, truth-containing compatibility sets, model comparisons, finite bands, endpoint and observation bridges, and explicit status updates. A chapter that treats those layers as one claim fails before the study begins.

Claim burden also requires scope. A result may concern a measurement bridge in healthy-adult diary data, a terminal signature in one palliative cohort, a sleep-related adjustment pattern, or a model-recovery benchmark under simulated data. The status label must name the component, population, window, instrument, and dependency under discussion (Gneiting & Raftery, 2007; Lakens, 2017).

A claim can become too vague by trying to be safe. Repeating that nothing is proven does not satisfy claim burden. The reader needs to know what has been proposed, what would count as evidence, what would count against it, and which version of the claim is under review. Humility without specificity becomes another form of evasion.

Claim burden is therefore the book's grammar of honesty. Every major sentence must carry its own status or be surrounded by enough context that the status cannot be mistaken. The Law can remain ambitious only if its sentences refuse to pretend they have earned more than they have.

1.4.2 — Identification Burden

Identification burden asks whether the target can be distinguished in principle. It is deeper than reducing noise. A more sensitive instrument cannot identify an object whose origin, unit, scalarization, bearer, endpoint, or reference class remains underdetermined. The central challenge is therefore not merely to build better affect sensors, but to show what those sensors can and cannot identify.

The terminal-zero problem separates direct measurement from empirical exposure. Finite noisy observations can challenge exact closure when a valid residual set excludes zero under independently justified calibration, missing-history, and endpoint assumptions. A deterministic bound and a statistical confidence set license different conclusions, as Section 24.6.4 explains. Neutrality must be identified independently of the result: recentering a record to make its total vanish supplies no evidence for closure.

Endpoint identification is equally binding. If the endpoint is chosen by the ledger, closure becomes a tautology. If it is equated with bodily death without a consciousness bridge, it may miss the truth-level ending of the relevant stream. If endpoint channels and ledger channels share hidden causes, a terminal pattern may reflect the same clinical process entering both estimators rather than PTVC. These dependencies must be declared before endpoint data are interpreted (International Council for Harmonisation, 2019).

Bearer identification also belongs here. A conscious stream is not identical to a legal person, biography, body, or public identity. Sleep, anesthesia, dementia, dissociation, coma, developmental thresholds, nonhuman animals, and future artificial systems all pressure the bearer concept. Chapter 1 does not solve those cases, but it explains why the volume must own a research route for them.

Identification work can produce a No adequate estimate outcome for a particular cohort, endpoint, channel, or state. Reporting that

outcome directs attention to the evidence needed to complete the measurement bridge and gives later studies a clear starting point.

Better sensing can make important contributions to inner-life science when it is joined to clear identification work. Even a highly reliable channel must be connected to a defensible neutral origin, scale, bearer, routing rule, truth-level endpoint, and target-class transport argument. Separating those tasks lets improvements in instruments and improvements in conceptual foundations reinforce one another.

The same point protects participants. If a study cannot identify the target, the ethical response is not to measure more intrusively. Intrusion can increase data while worsening identification by altering the state under study. Sometimes fairness to the person and fairness to the science both require less measurement and more honest abstention.

1.4.3 — Measurement Burden

Measurement burden begins after identification has named a target and still leaves enormous work. Lived experience does not hand itself to science as a single clean signal. Self-report, physiology, behavior, context, sleep, clinical observation, caregiver testimony, passive signals, and records are all partial witnesses. Each witness can be useful; none is sovereign.

Measurement must therefore be treated as disciplined translation, not extraction. The momentary valence estimator is a context-bound momentary estimate under uncertainty, not a device that reads inner life. The interval valence contribution estimate is a context-bound interval estimate under conditions, not a moral

unit. The running measured cumulative estimate is an approximation under a model, not the latent cumulative process itself. Measurement burden requires this layered humility whenever numbers appear.

Calibration is part of the burden. A measure that performs well within one person may not compare cleanly across persons, cultures, ages, disabilities, languages, clinical conditions, or terminal states. Translation does not establish invariance, and identical responses need not carry identical latent meaning. The program therefore distinguishes within-stream calibration, cross-context linking, partial identification, and principled local inference (Borsboom, 2005; International Test Commission, 2018; National Academies of Sciences, Engineering, and Medicine, 2019).

Missingness is not an empty space in a dataset. It can follow distress, fatigue, withdrawal, death, technology failure, family intervention, treatment, or the point at which a protocol no longer fits care. A terminal study that treats those absences as random can manufacture calm by losing precisely the observations most likely to challenge it. The missingness mechanism must therefore be modeled before favorable patterns are interpreted.

Versioning is also measurement burden. If the momentary valence estimator channel set changes, if weights change, if anchor rules change, if a wearable model is updated, if a natural-language model summarizes reports differently, or if a clinical workflow changes observation frequency, the measured object may change. Version labels and bridge tests are required rather than silent continuity.

Interpretation itself also needs governance. When channels disagree, the protocol has to state how self-report, physiology, behavior, clinician observation, and model output are weighted or held apart. Those choices should be versioned and auditable because a clean estimate can otherwise conceal a value judgment about whose evidence counts.

1.4.4 — Participant and Bystander Burden

Participant and bystander burden is part of the data-generating process. Prompts, devices, interviews, family involvement, staff workload, and clinical interference can alter the state observed, who enrolls, who remains, and which data go missing.

Protocols therefore need prospective burden endpoints and stop rules covering fatigue, distress, privacy risk, device discomfort, family pressure, clinical interference, and staff overload. Burden-linked selection and missingness must be analyzed rather than treated as background noise.

Sections 3.3 through 3.5 provide the detailed rules for consent, bystanders, vulnerability, withdrawal, and burden budgets. The evidence responsibility is to identify how measurement changes participation and observation, then account for those effects in the analysis.

1.4.5 — Rival and Negative-Result Burden

Rival burden means giving serious alternatives enough information, flexibility, and expertise to explain the data under common rules. Adaptation, homeostasis, predictive processing, learning, endpoint conditioning, observation loss, treatment, frailty, and selection are competing generators.

Negative results belong to the same record as favorable ones. Failed representation, instrument loss, endpoint failure, rival victory, replication failure, and nontransport each change the relevant component and should remain discoverable.

Section 2.4 defines severe comparison, and Chapters 21 through 25 develop the rival and recovery methods. Strong rivals are allowed to win, and unfavorable results remain part of the scientific memory.

1.4.6 — Correction Burden

Correction burden is the duty to repair the public record where a claim traveled. Claims, instruments, endpoint rules, analyses, and public artifacts must remain traceable enough that readers can distinguish current from superseded authority.

Chapter 28 describes the full correction, propagation, archive, and retirement workflow. When scientific status changes, dependent public language changes with it, while prior versions remain visible as history rather than continuing authority.

1.4.7 — Failure Memory and Successor Design

Failure memory should identify the failed object, the reason it failed, the burdens it created, the descendant claims it invalidates, and the repair a successor version is required to test. A successor does not inherit evidentiary credit from the failed version; it begins with a new empirical commitment. Chapters 27 and 28 provide the full evidence and change-control machinery.

A research program becomes cumulative when its successors are constrained by failures as well as inspired by successes. That

memory is especially important for an ambitious hypothesis, where ambition can erase past disappointment. The evidence responsibility is to move forward only after failure is made legible enough to improve what comes next. The next version should be able to identify the specific uncertainty it reduces and the specific weakness it no longer carries forward. Otherwise repeated revision can create the appearance of progress without making the underlying test more informative.

Superseded drafts, retired diagrams, obsolete instruments, and earlier claims can reenter circulation simply because they remain vivid or easy to find. Preserve their history and retired status, and make current versions easy to distinguish from archival ones wherever researchers or public readers encounter them.

1.5 — How to Read as Skeptic and Builder

This book is written for more than one kind of reader, and the differences matter. A skeptical statistician, a philosopher of science, a builder of civic systems, a clinician, a public reader in grief, and a reader of the wider canon do not need the same invitation. They also do not carry the same risk of misreading (Douglas, 2009; Gelman & Loken, 2014; Mayo, 2018; Nosek et al., 2015).

Each reader role carries a distinct discipline. Skeptics should attack the strongest defensible claim rather than a caricature; builders should not promote conditional usefulness into evidence; scientists should follow the dependency order; philosophers should examine claim class and theory change; public readers should separate importance from proof; and readers of the wider series should let scientific status constrain language without granting this volume authority over every domain.

The goal is a shared discipline. Readers may disagree about the Law, but they should be able to agree about the difference between a formal hypothesis, a measurement bridge, a research lead, a rival victory, and a public status change. That shared discipline is more important at this stage than agreement about outcome.

1.5.1 — For Skeptics

Precise criticism strengthens this book's research program. Critics can identify the component they question, trace its dependencies, and propose observations or comparisons that would clarify it. That contribution belongs throughout the inquiry.

The strongest skeptical attack begins with representation. Can lived experience responsibly be modeled as a signed temporal target at all? If mixed affect, agency, meaning, dread, numbness, relief, anticipation, and memory resist scalarization beyond repair, the program may narrow before any measurement study begins. That is a serious criticism, not a side issue.

A second attack concerns identification. Can a privileged origin be defended? Can an endpoint be classified independently of the ledger? Can terminal concentration be separated from observation shutdown or clinical selection? If these cannot be distinguished in principle, then better sensors will not rescue the relevant public claim (Douglas, 2009; Gelman & Loken, 2014).

A third attack concerns rivals. Adaptation, homeostasis, predictive control, endpoint-conditioned stochastic processes, medication, frailty, disease trajectory, death scripts, and missingness can each produce patterns that may look Law-like. A skeptic should ask whether the Law-specific model predicts more, predicts earlier, predicts in held-out data, and survives model recovery under adversarial simulation.

A fourth attack concerns public risk: a skeptic should test whether the project's language predictably encourages moral-payment readings, unsupported personal-destiny claims, human ranking, or unwarranted claims to public authority. Section 1.6 and Chapter 3 make those communication failures part of release review.

The book asks skeptics for rigor, not gentleness. It also asks them to attack the actual claim version, not a simplified enemy. A

precise skeptic is one of the most important collaborators this volume can have, because the fastest way to make the Law smaller or stronger is to identify exactly where it fails.

Skeptics should also be invited to notice when the book is too weak on its own positive case. Excessive caution can become a way of avoiding a clear claim. A critic may rightly object that a theory has not become testable if it only says what it is not. The best skeptical reading therefore presses both directions: no overclaim, and no evasive underclaim.

1.5.2 — For Builders

Builders may use the fairness-oriented lens to generate bounded questions before PTVC is supported, but usefulness is not validation. An applied system may provide a context for research only through a separate research door with appropriate consent or authorization, minimization, access, retention, and use rules. Operational success remains evidence for the application, not the terminal hypothesis (Mayo, 2018; Nosek et al., 2015).

Build conditionally, label precisely, separate operational records from research data, and avoid dashboards or scores that imply Law-based judgment. When an application reveals burden, confusion, or a useful mechanism, translate that observation into a study with its own design and comparators.

1.5.3 — For Scientists

Scientists should use the book as a dependency stack: representation and origin first; measurement and endpoint qualification next; then model recovery, rival comparison, replication, and transport. Work is useful when it makes one

dependency harder to evade, whether by improving an instrument, strengthening a rival, sharpening an endpoint, publishing a null, or showing where a bridge fails. Findings should be named at the level they reach: phenomenon, measurement relation, mechanism comparison, boundary condition, or target evidence.

1.5.4 — For Philosophers

Philosophers should examine how a large formal claim becomes empirically answerable without quietly changing identity. *The Law of Fairness* raises linked questions about lawhood, explanation, auxiliary assumptions, underdetermination, theory change, measurement, naturalized phenomenology, and the relation between formal structure and empirical status. Its research-program form is central: auxiliaries are unavoidable, but revisions become progressive only when they solve independent problems and generate new risky consequences rather than merely protecting the preferred conclusion.

Underdetermination appears throughout. The same observed terminal pattern may be explained by reserve coupling, adaptation, endpoint conditioning, observation shutdown, clinical scripts, or selection effects. A philosopher should ask not only whether the data fit, but whether the program has generated a distinction that makes one fit more informative than another (Gelman & Loken, 2014; Mayo, 2018).

The origin problem also belongs to philosophy as much as measurement. If valence has no instrument-fixed zero, the meaning of neutrality cannot be imported casually from

arithmetic. The science book must distinguish a latent structural origin from a public operational convention. A philosopher should test whether that distinction is coherent and whether empirical verdicts respect it.

Philosophers should also attend to ethical epistemology. Claims about lived experience can burden the people they describe. A theory may be formally clear and still publicly harmful if its concepts are used to judge, rank, console falsely, or delay care. The project therefore asks philosophy of science to meet moral philosophy at the point where measurement affects persons.

The philosopher's role is not to bless the ambition or dismiss it as metaphysics. It is to ask whether the claim has the right structure for empirical answerability, whether its revisions remain honest, and whether its public language respects the warrant it has earned.

Philosophers may also press the relation between explanation and consolation. A claim can be psychologically meaningful without being explanatory, and explanatory ambition can become ethically dangerous when it touches suffering. Meaning should not be silenced, but it cannot count as evidence. That distinction is philosophical before it is statistical.

Another philosophical pressure concerns natural law language. If the Law is called a law, what kind of necessity is being proposed? Is it an invariant, a boundary condition, a best-system compression, a constraint, a statistical tendency, or a metaphor? This chapter only opens that question. Chapter 2 must carry it with exactness.

1.5.5 — For Public Readers

Public readers may come because fairness, grief, burden, and relief make the question personally important; scientific reading should separate that importance from the status of the evidence. Care follows present need, not PTV; no estimator, ledger, endpoint, or verdict in this book can rank a life, diagnose a person, determine care, or assign spiritual or civic standing. Results may be supportive, adverse, inconclusive, local, or unavailable. The public promise is therefore not certainty but traceable language about what was tested, what changed, and what remains unknown (Council for International Organizations of Medical Sciences, 2016; Emanuel, Wendler, & Grady, 2000; World Medical Association, 2024).

1.5.6 — For Canon Readers

Across the wider series, scientific status should propagate only to passages that actually depend on the changed component. Applied domains retain their own evidence, values, and authority; the science volume contributes a bounded premise, not master jurisdiction. Chapter 28 supplies the cross-book correction machinery. Here the rule is simply dependency-based updating: when a measurement, endpoint, route, or target changes status, revise only the summaries, diagrams, and applications that rely on that object, while preserving the conditions and reference class that made the scientific statement valid.

1.6 — Public Artifacts and Scientific Humility

Public artifacts are the shortest routes by which a careful theory can become careless in the world. A diagram may circulate without the chapter that limits it; a formula may be copied without its assumptions; a cover may imply destiny; a social excerpt may turn a hypothesis into proof; a donor description may make ambition sound like validation. High-reach compression therefore requires its own evidence and hostile-crop review (Fischhoff & Davis, 2014; National Academies of Sciences, Engineering, and Medicine, 2017; Spiegelhalter, 2017; Tufte, 2001).

A scientific visual can be beautiful, memorable, and inviting while showing its subject precisely. Its labels and design should help readers identify the question, the represented quantities, and the relationships being proposed or observed.

The section also establishes correction. Public artifacts are not disposable because they are short. Their shortness is what makes them powerful. If an artifact misstates the science, it must be revised, retired, or publicly corrected where it traveled.

1.6.1 — Visuals Orient; They Do Not Prove

A visual can make a concept visible before the reader knows its technical vocabulary. That is useful. A dependency map can show that representation precedes measurement. A diagram of rival models can show that several explanations compete. A simple ledger illustration can make accumulation intuitive. But the image must never make the reader feel that symmetry, smoothness, or scientific styling has proven the claim.

Visual design should make scientific relationships easy to understand. Graphs identify their variables, endpoint diagrams explain their timing conventions, equations name their objects, and illustrations clarify what the instruments observe. Clear captions connect each image to the argument it serves.

An orientation visual may illustrate a hypothesis, a conditional consequence, or a practical aspiration without becoming a research protocol. The Series Map uses the balance scale to introduce the proposed complete-stream equality and asks what would follow if the Law is real. Read its statements within that declared frame. Figures reporting observations, estimates, or simulations identify those different evidence roles explicitly (Fischhoff & Davis, 2014; Spiegelhalter, 2017; Tufte, 2001).

Visuals must also respect persons. A person in a study should not be represented as a data source emptied of privacy. A terminal image should not romanticize death or imply that dying reveals cosmic justice. A child, disabled person, patient, or grieving family should not become an aesthetic symbol for a scientific hypothesis.

The standard is not dullness. It is truth in miniature. A good visual invites the reader into the burden of inquiry. It makes the problem clearer without making the result easier than it is. It should help a skeptic identify a test, not help a supporter feel that the test has been passed.

For this reason, every visual artifact belongs to scientific governance. It needs a label, a status, a scope, and a release

review. If the visual cannot survive those conditions, it should stay inside internal planning until it can.

A public visual should carry enough provenance to resist detachment: source chapter, model or instrument version, information set, simulation status, accessibility description, and correction route. The purpose is not to crowd the image with production metadata. It is to keep an attractive teaching object from becoming remembered as an observed result when it circulates alone (Fischhoff & Davis, 2014; Spiegelhalter, 2017; Tufte, 2001).

1.6.2 — Formula Status Must Travel

Formulas carry special danger because they look more authoritative than ordinary prose. A formula can define a target, describe a model, derive a consequence, specify an estimator, simulate a rival, or state a verdict rule. These are different statuses. A public formula that does not carry its status invites readers to treat mathematics as evidence.

When the formal ledger is displayed, the reader must know whether it is a received definition, an idealization, an estimator, or a candidate realization. When a reserve-coupled equation appears, the reader must know that it is a model with assumptions, not a measured fact. When an equivalence band appears, the reader must know that it is a public verdict rule under observation error, not direct sight of exact terminal equality.

Formula status also requires assumptions. What is the unit? What is the time variable? Is the process signed? Is reserve measured or latent? How is the endpoint defined? Which observations are

missing? Is the displayed path simulated, filtered, smoothed, or retrospectively aligned? A formula without these conditions can create precision without identification (Box, 1976; Gneiting & Raftery, 2007; Wilson & Collins, 2019).

For public use, attach a plain-language status label to the formula: received definition, candidate realization, estimator, design criterion, or open conjecture. Carry that label across slides, websites, figures, donor materials, classroom handouts, and Artificial Intelligence summaries. The formula need not carry its full derivation, but it must retain the assumptions needed to prevent a definition or simulation from being mistaken for evidence. If detachment would predictably raise the claim's status, redesign the artifact.

1.6.3 — Hostile-Crop Review

Hostile-crop review asks a simple question: if the least charitable reader extracted this sentence, caption, diagram, or formula from its context, would it still be accurate enough not to mislead? This reflects ordinary public communication in a fragmented environment. A claim that is safe only when surrounded by five paragraphs of correction may not be safe as a public artifact.

The test should be applied before release. Crop the headline away from the chapter. Crop the graph away from its caption. Crop the caption away from the graph. Crop the formula away from the assumptions. Crop the public summary away from the full status label. If the artifact now implies proof, destiny, scoring, terminal consolation, or scientific authority that the evidence has not earned, the artifact fails.

The review should test both literal cropping and likely paraphrase. Ask how a supporter, critic, clinician, civil-liberties reader, religious reader, or grieving reader could reasonably restate the artifact. If the shortened meaning becomes proof, score, destiny, permission, or consolation that the evidence has not earned, rewrite the artifact before release. Use specific nouns and verbs so the object studied and the result obtained remain visible even when the surrounding explanation disappears (Spiegelhalter, 2017; Tufte, 2001).

1.6.4 — No Score or Terminal-Destiny Aesthetic

Public visuals must not turn estimates of lived experience into human rankings. Leaderboards, red/green lives, badges, glowing ranks, public burden maps, or other score-like presentations can convert a research estimate into implied trust, worth, holiness, eligibility, clinical priority, or moral standing faster than a disclaimer can undo it.

A balanced scale can illustrate the proposed equality over a completed conscious stream. It must not be presented as an observed verdict on a particular person, proof obtained at biological death, or a guarantee of spiritual justice. The stream endpoint remains distinct from a clinical marker or the last available report. Terminal research retains its narrow clinical and scientific scope (Fischhoff & Davis, 2014; National Academies of Sciences, Engineering, and Medicine, 2017).

The same distinction applies to suffering. A visual may explain the equal-and-opposite net remainder required by exact PTVC; it must not portray that requirement as moral debt, deserved harm,

purification, or a reliable technique for obtaining a chosen reward. The absence of event-by-event pairing does not remove the aggregate requirement. Section 3.7.1 states that distinction.

A safer aesthetic shows inquiry, uncertainty, care, and constraints. It may show instruments with limits, pathways with gates, rival models, consent boundaries, uncertainty bands, and correction loops. It may show the dignity of subjects and the burden of researchers. It should not show a hidden accountant, a cosmic scoreboard, or a final spiritual settlement.

Score aesthetics can also appear in research-facing tools. A model card, participant dashboard, cohort map, or quality-control display may be intended for internal use but later leak into public interpretation. The same no-score discipline should govern internal visual design when the artifact could be misunderstood outside its narrow context.

Images accompanying terminal research should represent care, clinical context, and the participant's expressed choices with dignity. Figures of scientific results should identify the measurements and processes actually depicted.

1.6.5 — Artificial Intelligence Disclosure and Limits

Artificial Intelligence may assist bounded research and public-communication tasks only under documented human responsibility, purpose-limited data use, and independent scientific review. The book must disclose and limit that role because fluent outputs can overstate evidence or omit context. Sensitive participant data require explicit authorization and governance. Treat every AI-generated summary, visual,

translation, or accessibility artifact as a new derivative artifact with source and version provenance, human review, and checks that claim status, assumptions, and correction routes survive. Section 3.6.4 governs authority and Chapter 28 governs correction and retirement.

1.6.6 — Release, Correction, and Retirement

Release review should test status, scope, source, audience, burden, hostile-crop risk, and correctability before public circulation. When evidence or assumptions change, revise or retire the affected artifact where it traveled and preserve a visible correction history. Section 28.6 contains the detailed workflow.

Chapter 2 — What Kind of Claim Is the Law of Fairness?

The word law names an ambition before it names an achievement. In this volume, it refers to a proposed invariant or boundary condition whose scientific status remains that of a candidate hypothesis. The distinction is not semantic housekeeping. It determines what observations can support, what counterexamples can reject, and what public language may responsibly claim.

PTVC sits inside a family of related statements. One statement defines a finite signed phenomenal measure. Another states the additive identity that positive mass minus negative mass equals the signed residual. A further statement proposes exact terminal closure. Optional route models explain how closure might arise. Measurement models explain how hidden objects might become data.

These statements do different work. Mathematical identities follow from definitions. Conditional theorems follow from premises. Empirical hypotheses meet the world. Estimators recover declared quantities under assumptions. Heuristic lenses organize attention. Spiritual or philosophical interpretations supply meaning. A mature science keeps the boundaries visible without stripping any category of its legitimate value.

The strong primary branch is intentionally exact and intrastream. It is not a population average, a tendency toward adaptation, or a claim that circumstances are equal. Under exact PTVC, a genuinely nonzero accumulated balance requires an equal and opposite signed remainder before the true endpoint. This does not identify particular future events, their timing, or a visible-life reward. The branch's representation and domain requirements remain binding.

Modal language matters as well. Existence of one completing continuation, positive-probability completion, fixed-policy probability-one completion, limit-sure reachability, support containment, and closure of every admissible continuation are not interchangeable. Each statement quantifies over a different object and carries a different evidentiary burden.

The chapter uses category discipline to make the positive case sharper. A candidate law can compress diverse findings only if it rules out outcomes that credible rivals permit. If every result can be redescribed as support, the word law adds grandeur but no information. If a compact structure yields risky, branch-matched consequences, the claim gains scientific content before it gains confirmation.

This is the role of severe testing. A good test is not merely capable of producing a low p-value or an attractive curve. It places the claim in a situation where a specified flaw would probably be found and where rival explanations receive enough freedom to reveal themselves (Mayo, 2018; Wasserstein & Lazar, 2016).

Underdetermination is therefore treated as a design problem. A near-zero endpoint distribution may arise from genuine closure, mean reversion, endpoint selection, smoothing, observation floors, attrition, medication, or a fitted bridge. The research task is to construct discriminators that make those explanations disagree before the decisive data are inspected.

Proper scoring and held-out prediction help by rewarding calibrated forecasts rather than stories written after the fact (Gneiting & Raftery, 2007). Equivalence procedures help

distinguish a declared finite band from simple failure to reject a difference (Schuirmann, 1987). Neither method establishes exact latent zero by itself, but each can earn a precise place in the inference ladder.

Confirmation must also remain component-specific. A valid origin calibration supports the representation gate. Successful model recovery supports the analysis architecture. A route signature may favor one candidate mechanism. Replicated complete-stream evidence under a validated bridge would bear on a terminal branch. The word support should never erase the noun that follows it.

Model change is expected in a serious program. New instruments, better endpoint adjudication, and stronger rival models may improve the inquiry. The discipline lies in recording what changed, why it changed, which earlier result motivated it, and whether the revised claim predicted something new before fresh data arrived (Lakatos, 1978).

Rescue is different. Rescue changes the endpoint, reference class, origin, sign, exclusion rule, or success criterion only after seeing that the earlier version failed. A single repair may be justified, but a sequence of result-dependent repairs can exhaust the empirical content of the program even while the prose remains impressive.

Narrowing, mechanism retirement, rival favoring, and theory-level defeat are therefore part of the positive architecture. They give the research program honest destinations other than victory or silence. A narrower true statement can be more valuable than a grand statement protected from contact with evidence.

The chapter also connects the applied series to scientific findings. Each domain can retain useful results, state its own purposes, and evaluate the evidence relevant to its proposals.

By the end of the chapter, readers should be able to identify the kind of claim, the evidence supporting it, the observations that would change it, and the scope in which it applies. Those questions support confident, precise interpretation.

2.1 — Claim Families and Category Discipline

The Law of Fairness reaches across languages that normally remain apart. It has formal language, scientific language, ethical language, public language, religious resonance, and ordinary-life usefulness. That range is one reason the project is intellectually alive. It is also the reason the project can become scientifically unsafe if every language is allowed to strengthen the others without carrying their burdens (Cartwright, 1983; Hempel, 1965; Lakatos, 1978; Lange, 2009).

Table 2.1 distinguishes the main claim categories, the evidence appropriate to each, and the language required when a claim narrows or is withdrawn.

Category discipline is especially important because the Law of Fairness may be meaningful at more than one level. A hypothesis may fail as a universal law and still leave behind a powerful question about hidden burden. A study may support a local tendency without supporting a universal terminal condition. A metaphor may remain beautiful after scientific narrowing. The point is not to force every value into the strongest category. The point is to stop the strongest category from borrowing value that belongs elsewhere.

Specific claim labels make summaries, images, captions, and conversations easier to interpret. A scientific result, a proposed model, a spiritual interpretation, and a practical recommendation each benefit from wording that identifies its role directly.

Table 2.1. Claim categories, support requirements, licenses, and withdrawal language.

Claim family	What it says	What would support it	What it licenses	Withdrawal or narrowing language
Lawlike constraint claim	A proposed invariant or boundary condition on qualifying conscious trajectories.	A replicated, reference-class-specific conjunction of component results, rival defeat, and transport success under frozen bridges.	Strongest scientific ambition, still under hypothesis status until earned.	Withdraw law-language or narrow to a smaller class when the conjunction fails.
Empirical hypothesis	A testable claim that may fail under declared measurement, endpoint, and rival rules.	Prospective results that improve prediction, survive model recovery, and reduce rival plausibility.	Prospectively specified tests, provisional support, component status updates.	Say unsupported, inconclusive, narrowed, or defeated according to the component that failed.

Claim family	What it says	What would support it	What it licenses	Withdrawal or narrowing language
Statistical tendency	A population or reference-class pattern without pathwise universality.	Stable estimates in a named population, endpoint class, instrument version, and transport window.	Local generalization inside stated bounds.	Name the class; do not return to universal language without new transport evidence.
Heuristic and analytic lens	A disciplined way to locate hidden burden, repair, consent, and reviewability.	Practical insight, improved questions, better burden detection, or safer design.	Ethical analysis and design prompts under uncertainty.	Use as a lens for questions and design.
Metaphor and spiritual resonance	An image or meaning structure that illuminates experience without evidentiary force.	Human resonance, pastoral or literary usefulness, symbolic clarity under limits.	Meaning, reflection, ritual, or communication when clearly labeled.	Retain only as image or meaning; remove proof-shaped language.

2.1.1 — Lawlike Constraint Claim

The strongest ambition of the Law of Fairness is a lawlike constraint claim. On the primary finite signed-measure branch, it proposes that every separately routed maximal qualifying conscious stream in a declared class has an exact terminal signed residual of zero over its complete strict-pre-endpoint domain. That is the most demanding version, and for that reason it must be the most exposed.

A lawlike constraint is not a moral command. It proposes a structural restriction with testable consequences; it does not assign purpose, justify suffering, or tell anyone what their experience was for.

Recurring patterns provide starting points for stronger theory. Adaptation after joy and grief, homeostatic regulation, and institutional burden shifting each suggest regularities to explain. A proposed lawlike constraint becomes informative when it adds a specified restriction that can distinguish its predictions from those of simpler accounts (Cartwright, 1983; Hempel, 1965; Lakatos, 1978).

For this volume, lawlike status cannot be announced by title, beauty, or inheritance from the formal-law book. It can only become more defensible through a staged program in which representation, bearer and routing, measurement, endpoint construction, observation, measured-to-latent transport, rival comparison, replication, and reference-class transport survive separately. The exact set-universal form is asymmetric: no finite sample can confirm every stream in the declared class, but one

independently audited, gate-valid counterexample whose truth-containing latent compatibility set excludes zero is adverse to that universal claim and may defeat it or force an explicit narrowing of the class.

Public language should identify the current stage of the claim. Proposed lawlike constraint, candidate invariant, and scientific hypothesis express the Law's ambition while leaving its standing to evidence. If evidence changes the claim, the label and public explanation change with it.

2.1.2 — Empirical Hypothesis

An empirical hypothesis is a claim that asks reality to make a difference. It is not merely consistent with the world; it expects the world to show something under stated conditions. For *The Science of Fairness*, the empirical hypothesis is not that a hidden ledger has been directly observed. It is that certain measurable consequence structures should appear if the latent architecture and the empirical bridges are adequate.

This category connects the formal target to its empirical hypotheses. Those hypotheses concern representation, measurement, endpoint classification, reserve-linked dynamics, terminal or preterminal patterns, and comparative performance against rivals. Each has its own observations, tests, and criteria for updating the research program.

A hypothesis must say what would count as an unfavorable result. It is not enough to say that future science may discover better instruments. A failed observation model can be a local failure. Repeated failure across independently motivated observation

models can become evidence against the public empirical claim. If every failure simply calls for another untested bridge, the hypothesis has stopped paying rent to reality (Lakatos, 1978; Lange, 2009).

An empirical test evaluates a named claim version: its population, endpoint class, instrument, observation model, alternatives, and analysis plan. A revised bridge receives a new version and its own evaluation, with the earlier result retained in the record.

This chapter uses empirical hypothesis language to protect the positive case as well as the negative case. A large hypothesis can be serious before it is supported if it has specific consequences, serious rivals, and defeat conditions. Calling it an empirical hypothesis is not demotion. It is the category that lets ambition become answerable.

2.1.3 — Statistical Tendency

A statistical tendency describes a pattern in a named reference class under stated measurement conditions, including its uncertainty and exceptions. Such findings can establish useful early knowledge and identify the conditions under which a pattern becomes more general.

Tendency status may be the first place where the Law-specific program earns partial public standing. A hospice cohort might show terminal concentration within an equivalence band under one validated instrument. A sleep study might show affective reprocessing patterns that fit a queue or reserve account better than a simple mood-rebound account. A longitudinal design might

show reserve-linked variance behavior in one clinical population. None of those results would establish universality.

The reference class is not an administrative detail. It is part of the claim. Evidence from adults receiving palliative care in one health system is not evidence about children, sudden deaths, nonhuman animals, artificial systems, nonclinical dying, or cultures with different reporting practices unless transport assumptions are defended. Every tendency statement must name who, where, when, how measured, and under what endpoint rule (Popper, 1959).

A tendency may prove real but local, for example, limited to a disease course, reserve trajectory, reporting-capable population, or estimator version. Report that boundary as part of the result. Scope expands only through dedicated transport evidence and may narrow when that evidence fails.

2.1.4 — Heuristic and Analytic Lens

A heuristic is a disciplined way of looking. A fairness-oriented analysis asks where burden is carried, hidden, shifted, reduced, repaired, recorded, consented to, or made reviewable. That question can be valuable even when the strong formal Law remains untested. It can help a researcher notice participant burden, a city designer notice privacy inversion, a government office notice paperwork shifted onto the sick, or a household notice care work that has become invisible.

A fairness-oriented lens earns its value by improving questions or design, not by inheriting evidentiary force from PTVC. It may identify hidden burden, consent problems, practical

improvements, or comparisons worth testing; decisions about care, eligibility, or personal standing still require independent grounds.

Applied domains may use the lens to generate research questions, and science may evaluate whether the resulting questions or designs actually improve detection, safety, or explanation. That is a legitimate form of usefulness without converting the heuristic into evidence for the strong Law.

2.1.5 — Metaphor and Spiritual Resonance

Metaphor gives difficult experience a shape. Words such as ledger, burden, queue, horizon, balance, and closure can make invisible cost more visible. They can help a reader feel the difference between outward condition and inward experience. They can also become dangerous when they start performing scientific or moral work that they have not earned.

Metaphor and spiritual resonance may illuminate experience, but they carry no empirical evidentiary force. A balance or accounting metaphor can express the conditional arithmetic of the hypothesis. It does not thereby establish PTVC, assign moral desert, promise a chosen reward, or impose a spiritual interpretation.

The right posture is not metaphor prohibition. A book without image becomes less human than its subject. The right posture is labeled beauty. A metaphor may invite attention, not settle the claim. It may open a feeling, not close an argument. It may help a reader ask where burden is hidden, not declare that burden has already been redeemed.

2.1.6 — Category Drift as Auditable Error

Category drift is the movement of a claim between statuses without public accounting. It can happen innocently. A writer may speak poetically in one passage, scientifically in another, spiritually in a third, and practically in a fourth. The problem begins when the audience cannot tell which burden the sentence is carrying.

In this project, category drift has a distinctive shape. The Law may sound like a deep law when introduced, a hypothesis when questioned, a metaphor when criticized, a heuristic when applied, and a law again when admired. That cycle gives the claim the benefits of every category while protecting it from the costs of each one. It is not fair to critics, readers, participants, or neighboring books.

Category drift is auditable because it leaves traces. A statement can be checked for what category it invokes, what evidence it cites, what authority it implies, and what correction it would require if the evidence changes. If a public artifact presents a proposed law as empirically established, it requires correction. The title Law of Fairness and a clearly framed statement of what the hypothesis proposes do not by themselves make that error. If a donor page implies validation where the science chapter says research program, the page has shifted burden (Popper, 1959).

The audit must include old materials. Category correction is not only future-facing. Earlier summaries, images, captions, talks, guides, social excerpts, and Artificial Intelligence summaries can continue to carry obsolete status. A serious project must repair its

public memory when the claim changes category. Otherwise the correction lives in the current book while the old authority continues in the world.

Status may change, but the change must be explicit, versioned, justified, and propagated to the public sentence that actually travels. A lawlike claim may narrow to a tendency; a mechanism may retire while a measurement contribution survives; a metaphor may remain after scientific defeat. Use category-specific verbs; hypotheses propose, estimators estimate, tendencies appear, lenses ask, metaphors illuminate; so the claim cannot inflate when admired or retreat into metaphor when challenged.

A useful test of category discipline is which admissible outcomes would require revising or withdrawing the claim. If no possible outcome under its declared test conditions could change its status, the sentence makes no testable empirical claim. The stronger the consequence of a valid adverse result, the more explicitly those conditions should be stated. The discipline is not punitive. It lets strong statements remain strong by attaching them to the exact risk they carry.

2.2 — Lawhood, Explanation, and Compression

The word law has a history too large for any one theory to possess. Some laws describe mathematical relations. Some describe robust empirical regularities. Some name constraints that make many phenomena intelligible at once. Some, after scientific change, lose their deepest status and survive as useful approximations. This section does not attempt to settle the philosophy of laws of nature. It asks the more local question: what would the Law of Fairness have to do before law-language becomes scientifically responsible (Box, 1976; Hempel, 1965; Lipton, 2004; Mitchell, 2009)?

The answer begins with explanation. A proposed lawlike claim must not merely restate what it hopes to explain. It must compress the field. It should make several otherwise separate features intelligible through a smaller set of assumptions, and it should do so while generating consequences that could have failed. If it imports a new bridge for every difficulty, its apparent explanatory scope is purchased by hidden complexity.

The proposed lawlike constraint concerns conscious trajectories, lived valence, endpoint definition, and measurement under uncertainty. Its scientific development brings affective science, consciousness studies, palliative practice, psychometrics, statistics, and rival dynamics into a common set of questions.

Exactness is not privileged because zero is aesthetically pleasing; it earns attention only if, under an independently identified origin, it creates restrictions that approximate regulation does not. The target and its declared bridges must therefore yield consequences

that serious rivals fail to match. If those restrictions never appear, exactness has added grandeur rather than information and the claim should contract. That is lawhood as burden, not lawhood as crown.

2.2.1 — Best-System Ambition

A best-system ambition asks whether a hypothesis belongs in the simplest, strongest, most informative account of a domain. The phrase is useful here because it refuses two shortcuts at once. It refuses the shortcut of mere regularity, since not every pattern deserves lawlike dignity. It also refuses the shortcut of isolated success, since a local fit may be outweighed by complexity, fragility, or poor rival performance.

Best-system appraisal asks whether adding the Law improves the account as a whole. The relevant comparison connects endpoint behavior, preterminal dynamics, measurement, reserve or control mechanisms, and alternative explanations. A successful account gains predictive reach and coherence while keeping its assumptions economical.

This ambition is especially demanding because the object is not a planet, gas, gene frequency, or engineered signal. It is lived experience in a conscious stream. The Law would have to compress patterns across a domain where units, origins, endpoints, and bearers are contested. That difficulty does not make the claim impossible. It makes the standards for law-language higher (Box, 1976; Hempel, 1965; Lipton, 2004).

Best-system ambition also creates a rival obligation. The Law must be compared with homeostasis, allostasis, adaptation,

predictive processing, reinforcement learning, Brownian bridge conditioning, frailty, sedation, selection, and observation artifacts. If those accounts produce the same consequence structure with fewer assumptions or better predictions, the Law loses lawlike standing even if some patterns remain interesting.

The scientific ambition is concrete: explain how reserve-linked dynamics, endpoint behavior, affective reprocessing, and hidden-burden signatures fit together. Shared predictions across those domains would create a focused comparison with alternative explanations.

2.2.2 — Explanatory Compression

Explanatory compression means that a theory reduces the number of independent facts that must be separately accepted. A compressed explanation says: these several patterns hang together because one deeper structure is doing work. The danger is that compression can be faked by hiding assumptions in auxiliary bridges, broad definitions, flexible endpoints, and adjustable measurement choices.

The Law of Fairness aims at compression across a difficult field. It suggests that the total positive and negative phenomenal variation of a qualifying stream may be governed by an exact terminal boundary rather than merely described as disconnected episodes. It asks whether preterminal and terminal patterns, if observed under strong controls, would be better explained as consequences of that candidate boundary than as adaptation, clinical practice, selection, conditioning, or observation effects.

The compression burden is therefore two-sided. The program must explain more than terminal valence closure. It must explain why a measurement stack should have a privileged origin, why an endpoint can be defined independently, why reserve or control dynamics could generate the relevant shapes, and why rivals fail on the conjunction. If each piece requires a separate special story, the program is not compressed. It is an anthology (Lipton, 2004; Mitchell, 2009).

A useful way to count compression is to ask what becomes harder to believe without the Law. If the Law merely renames adaptation, it adds no compression. If it explains why several independent signatures survive prospective specification while simpler models repeatedly miss them, it begins to compress. If it keeps adding exceptions after failures, the compression reverses: the theory becomes bulkier than the facts.

A theory can look simple because the cost of its auxiliaries is hidden from the reader. An untested measurement bridge, a convenient endpoint rule, a narrowed reference class, or an unspecified mechanism may be doing most of the explanatory work. Scientific fairness requires those commitments to be visible so that compression is not purchased by concealed complexity.

Cross-domain convergence becomes informative when one specified structure predicts several domains with a limited set of shared parameters. A candidate state or potential can be estimated in one module, frozen, and used to predict another. The comparison should record the cost of transferring parameters, converting units, and adding context-specific terms. A structure that retains calibrated predictive performance across those

transitions offers a concrete form of explanatory compression: the same commitments explain more of the observations.

2.2.3 — Predictive Novelty

Predictive novelty tests a model on observations it was developed to anticipate. In this volume, terminal patterns, emotional adjustment, and clinical trajectories provide settings in which competing accounts can make specified predictions before the outcomes are inspected.

A prediction is not novel merely because it is printed in a book. For the prospective tests emphasized here, predictive novelty requires evaluation on observations not used to construct or tune the prediction. Discrimination additionally requires the competing models to assign different expectations to those observations. For the Law, candidate consequences might include reserve-linked variance shape, forecast performance under a prospectively specified independent-endpoint branch, model-recovery success, or a signature conjunction that simpler homeostatic and conditioning accounts do not reproduce.

Existing observations can provide comparative evidence when models assign them different probabilities under explicit assumptions. Retrospective comparisons should record how the hypotheses, measurements, and datasets were selected, account for model flexibility, and retain independent tests wherever possible. Prospective prediction offers especially clear separation between model construction and evaluation. Both approaches contribute when their information and selection processes are visible (Salmon, 1984; Woodward, 2003).

Accommodation is not forbidden. A new program often begins by trying to make sense of known anomalies, recurring intuitions, or unexplained patterns. The rule is that accommodation must be labeled and then converted into prospective risk. If the Law explains a known terminal report pattern, the next question is what new data it predicts differently from its rivals.

Prequential performance gives one useful discipline: prediction is assessed as data arrive, not after the full dataset is available for interpretive adjustment. A program that repeatedly improves held-out forecasts under frozen bridges earns more respect than a program that repeatedly fits the past by moving its categories. The Law should seek the former path.

The public language should track this distinction. A result that was predicted prospectively may be called prospective support for the tested component. A result fitted after exploration may be called a generated hypothesis or an accommodated pattern. Both can be part of science. Only one carries the full burden of prediction.

2.2.4 — Mechanistic Depth

The strong Law proposes a structural relation among conscious trajectories. Candidate mechanisms explore how that relation could be realized through reserve-coupled dynamics, queue processes, finite-horizon control, interoception, opponent dynamics, memory reprocessing, or other processes examined in later chapters.

Mechanistic depth comes from specifying how a proposed process works. A Queue model may describe burden ordering;

reserve coupling may generate a mathematical realization; interoceptive control may offer a brain-body route. Each candidate can be developed, compared, and revised on its own evidence.

Mechanistic depth links formal quantities to observables, observables to biological or psychological processes, and those processes to distinct predictions. A mechanism contributes by explaining a process, deriving a restriction, or separating competing accounts (Box, 1976; Hempel, 1965; Lipton, 2004).

The Law's mechanism burden is unusually high because felt experience is not an external object like temperature on a wall. It is lived from within and inferred from without. A mechanistic account must therefore respect first-person evidence, physiological signals, behavioral patterns, clinical realities, and the fact that no single channel owns the person. Depth here means disciplined humility across channels.

Mechanistic depth also limits public overclaim. If a mechanism is candidate, the text must say candidate. If a process is a realization, the text must say realization. If a formula demonstrates possibility rather than observation, the text must say construction, not evidence. The same precision that satisfies experts protects vulnerable readers from hearing destiny.

2.2.5 — Causal and Structural Explanation

Causal and structural explanations answer different questions. A causal explanation asks what process produced an outcome. A structural explanation asks what constraints shape the space of possible outcomes. *The Law of Fairness*, in its strongest ambition,

is closer to a structural boundary condition than to a proximate causal story. But public readers often hear law-language as if it named an agent making events happen.

A structural constraint limits possible trajectories; it does not choose events or supply moral purpose.

Causal explanation still matters. If the proposed boundary condition has empirical consequences, some process must mediate the observable patterns. Reserve, adaptation, sleep, memory, interoception, prediction, and control systems are causal or dynamical candidates. The science can ask which processes generate which patterns without implying that the processes morally justify those patterns (Lipton, 2004; Mitchell, 2009).

A useful local rule is to keep three questions apart. What is the formal target? What process could realize the relevant consequence? What data would distinguish that process from rivals? The first belongs to received formal structure, the second to mechanism chapters, and the third to study and inference chapters. Chapter 2 supplies the category discipline that keeps them from impersonating one another.

Structural explanation also creates a special defeat problem. A mechanism can fail while a structural claim remains open, but a structural claim cannot hide forever behind failed mechanisms. If all independently motivated mechanisms, observation bridges, endpoint rules, and consequence tests fail or become ad hoc, the structure loses empirical content even if metaphysical possibility remains.

The same analytic lens makes this an issue of burden honesty. A theory that claims structural depth while refusing causal or empirical accountability shifts the cost of its grandeur onto others. A theory that distinguishes structure, cause, and measurement lets each carry the burden it actually owns.

2.2.6 — Lawhood Under Rival Pressure

Lawhood under rival pressure means that the favored claim and its alternatives receive comparable information, fitting freedom, diagnostic attention, and opportunity to fail. Rivals must be generative rather than decorative: Brownian bridges, ordinary mean reversion, sedation, disease severity, and other competitors should produce their own expected patterns and face held-out scoring under rules fixed before results (Gneiting & Raftery, 2007; Mayo, 2018).

The positive case becomes meaningful through conjunctions that strong rivals fail. Drift, concentration, or a terminal band alone may be imitated, whereas measurement validity, noncircular endpoint construction, required timing premises, route-state restrictions, model recovery, held-out prediction, and transport expose different failure routes. Lawhood therefore requires victories across study families, each attached to its own reference class and limits (Salmon, 1984; Woodward, 2003).

Rival pressure is a protection against confidence by identity. If adaptation explains a field better, the Law narrows; if endpoint conditioning explains apparent closure, that evidence is withdrawn; if measurement fails, the program abstains. Letting

ordinary explanations win makes the inquiry more publicly trustworthy, not less ambitious.

A useful lawhood audit asks four questions: does the hypothesis compress more structure than it imports, generate prospective restrictions, connect to mechanisms or structural constraints that can fail, and outperform serious rivals? Compression is not simplicity at any cost. A complex model may be warranted, while a simple sentence may merely hide bridges, endpoints, observation rules, and trust assumptions. The audit should therefore count auxiliary assumptions and model flexibility alongside the apparent economy of the headline claim.

Novelty adds temporal discipline. Retrospective explanation can illuminate known phenomena, but progress requires consequences specified before observation. Mechanism and structure add empirical risk: reserve coupling, endpoint dynamics, and interoceptive or control routes are candidate ways for the boundary claim to produce consequences that can be lost. Their evidentiary value increases when the predicted direction, timing, or dependency is fixed clearly enough to distinguish success from later reinterpretation.

Rival performance is the sharpest question. A moving account of hidden burden may still lose to adaptation, homeostasis, predictive regulation, treatment, or observation artifacts. The relevant measure is surplus explanation after those rivals receive full strength, not the emotional force of the theory. A rival victory should therefore identify which additional structure proved unnecessary and which observations gave the competing account its advantage.

Lawhood must also be earned inside the claimed domain. Conservation analogies, thermodynamic or quantum vocabulary, cosmic imagery, capitalized names, and formal symbols may orient readers but supply no necessity or evidence about conscious streams. The proposal stands or falls through its own definitions, discriminators, endpoint discipline, and willingness to forbid outcomes. Borrowed scientific language becomes useful only when it contributes a precise relation or test that remains valid in the phenomenal domain being studied.

A strong future case remains possible. Repeated prospective restrictions, failure of simpler rivals on a predeclared conjunction, and transport without moving the bridges would make law-language increasingly earned. The expert reader should be able to reject the hypothesis and still recognize a fair standard: clarity, assumption visibility, empirical risk, and a genuine capacity to lose. Confidence should rise only to the extent that these successes persist across independent teams, settings, and measurement implementations.

2.3 — Component Claims and Reference Classes

Separating component tests makes a large hypothesis easier to investigate. *The Law of Fairness* connects bearer identity, felt valence, temporal accumulation, endpoint adjudication, candidate dynamics, measurement, and public verdict language. Testing those components individually shows which part of the proposal a result supports or challenges, allowing each finding to guide the appropriate next step (Borsboom, 2005; Hernán & Robins, 2020; Manski, 2003).

Component testing supports cumulative progress. A representation question can remain open while an instrument is revised; an endpoint study can guide measurement development; and a reserve model can sharpen comparison with control-based explanations. Local results show which part of the architecture should be developed next.

Reference classes complete the discipline. Every component result belongs somewhere and not everywhere. A population, endpoint type, disease trajectory, culture, age group, instrument version, and analysis window are not incidental details. They are the scope of the claim. Without them, the project would carry evidence beyond the people, contexts, and methods that produced it.

The following ladder states the dependencies among research tasks. It shows which results enable the next stage and where further development is needed.

Table 2.2. Component-evidence dependency ladder.

Ladder step	Question answered	Possible favorable outcome	Possible failure outcome
Representation	Can lived experience support a signed, temporally additive research target?	A defensible target for restricted scientific use.	No current scalar target; exact-zero claims narrow or abstain.
Measurement	Can candidate momentary and interval estimators or successors estimate the target in context?	Context-limited estimator with uncertainty and version control.	Instrument failure; no Law-specific inference from that channel.
Endpoint	Can the stopping event be classified prospectively and independently?	Endpoint class usable for specified study families.	Terminal inference rejected or delayed.
Realization	Do reserve-coupled or control dynamics describe the data-generating process?	Mechanism or candidate realization survives rivals locally.	Mechanism retires or narrows; other components remain distinct.

Ladder step	Question answered	Possible favorable outcome	Possible failure outcome
Consequence	Does the protocol-fixed signature conjunction appear?	Component support for specified consequence family.	Consequence claim weakens or is defeated in that class.
Reference class	Does the result transport across populations and conditions?	Scope expands cautiously.	Support remains local or disappears.

2.3.1 — Representation Claim

The representation claim asks whether lived experience can be treated, for a scientific purpose, as a signed and temporally additive target. This is not a casual assumption. It asks whether moments of felt burden and relief can be represented in a way that permits accumulation without flattening dignity, meaning, context, or depth into a crude score.

The representation claim is logically prior to measurement. An instrument cannot measure what the theory has not represented coherently. If valence is only ordinal, if neutral origin cannot be defended, if temporal additivity fails, or if experiences differ in kind in ways no scalar can responsibly carry, then the strongest ledger language must narrow before any terminal study begins.

A scientific representation selects the features needed for a defined question. A signed valence-rate representation can be evaluated by how coherently and usefully it describes its intended research context (Borsboom, 2005).

For the Law, the representation claim includes the origin problem. Exact closure depends on a neutral point that is not created by subtracting a sample mean or centering a questionnaire. If the origin is arbitrary, then exact zero is not identified. The project must either defend a privileged origin, test quantities invariant to the chosen gauge, or narrow the claim.

Representation testing determines which mathematical operations a domain supports. Its result can license the next measurement stage, identify a repair, or direct the program toward an alternative representation.

The representation claim is therefore the first place where law-language can lose height. A theory about felt experience cannot borrow the simplicity of its notation. It must show that the notation is worthy of the subject.

2.3.2 — Measurement Claim

The measurement claim asks whether momentary and interval valence estimators or later instruments estimate the intended construct inside a declared context of use. It is not a claim that an instrument reads inner life directly. It is a bridge claim: given a representation, a population, a protocol, a set of channels, and an error model, the estimator tracks enough of the target to support the specified inference.

Instrument qualification is context-specific. Sedation, communication capacity, medication, and language can change the performance of physiological estimators, self-report measures, wearables, and item banks. Testing those contexts

identifies where an instrument supports inference and where it needs adaptation.

The measurement claim must include uncertainty, missingness, drift, calibration, and versioning. A candidate momentary-or-interval estimate is not a human-worth score, civic trust, spiritual rank, religious standing or commitment within a spiritual community, or public eligibility. It is a research estimate under constraints. The word estimate should remain visible wherever public language might turn the measure into access or rank (Borsboom, 2005; Manski, 2003; Nissenbaum, 2010).

A favorable measurement result has a limited grammar. It may say that an instrument estimates a target well enough for a study family under specified conditions. It may not say that the instrument has seen the latent cumulative process or the whole person. If the measurement bridge later changes, earlier claims must be indexed to the old version rather than silently reinterpreted.

Measurement claims are also reference-class claims. A tool validated in English-speaking adult hospice participants cannot be applied without transport to children, different cultures, nonverbal states, neurodivergent populations, sudden deaths, animals, or artificial systems. The burden of extension belongs to the project, not to the people being generalized over.

2.3.3 — Endpoint Claim

The endpoint claim asks whether the truth-level endpoint of a maximal qualifying stream can be prospectively defined without using the ledger outcome later tested. Biological death, legal

death, narrative closure, family memory, or sensor cessation are not substitutes. Defining the endpoint by ledger zero would make closure tautological, so endpoint channels must be prospectively specified and not algebraically identical to the measured cumulative estimate; residual dependence must be modeled. On a separately declared independent-endpoint branch, timing independence from the ledger-generated information set and the branch's support conditions are additional premises.

Endpoint claims vary by class. Slow terminal decline, sudden death, resuscitation, coma, anesthesia, dementia, delirium, sleep, and disorders of consciousness present different evidentiary structures. A result in one endpoint class cannot silently transport to another. Sudden low-signal endings, in particular, cannot be filled in by analogy with palliative windows unless the bridge is defended (van der Vaart, 1998).

Endpoint validation permits terminal or near-terminal data to be interpreted under a defined stopping rule. When the boundary remains unresolved, the analysis reports an indeterminate classification and identifies the evidence needed to resolve it.

Endpoint studies place care, comfort, and consent first. Their procedures combine ethical participation with independently justified classification, and record an indeterminate endpoint when either requirement prevents adequate observation.

The endpoint claim is therefore both scientific and humane. It keeps the theory from defining victory into existence, and it keeps research from treating the last vulnerability of a person as a laboratory convenience.

2.3.4 — Realization Claim

The realization claim asks whether a candidate dynamical model describes the relevant data-generating process. Sections 4.2 and 7.6 develop a reserve-coupled realization that derives closure-related consequences from explicit assumptions. Testing those assumptions and consequences connects the construction to observed dynamics.

A realization claim is not identical to the strong latent claim. The Law might be stated as a boundary condition while a reserve product, queue model, finite-horizon control process, or interoceptive mechanism proposes how patterns could arise. If a candidate realization loses, that result may retire the realization without instantly exhausting the space of possible realizations.

A realization that imposes an endpoint by construction can generate useful predictions about the path leading to it. Empirical evaluation compares those predictions with observations whose selection and measurement are specified independently of the constructed result (Borsboom, 2005; Hernán & Robins, 2020).

The realization claim requires rival processes. Ordinary homeostatic mean reversion, endpoint-conditioned processes, safe-control baselines, and predictive regulation can all generate orderly trajectories. The question is not whether the Law can generate a pattern. The question is whether it generates a conjunction, under frozen assumptions, that rivals do not match as well.

A favorable realization result might support a mechanism family: reserve coupling in slowly declining terminal illness, queue

pressure in certain affective reprocessing, or finite-horizon shadow pricing in choice behavior. Each support statement names the mechanism, the tested reference class, and the evidence that distinguishes it from competing accounts.

The realization claim is where a good theory becomes willing to lose machinery it likes. Reserve-coupled dynamics, completion-potential constructions, conditioned bridges, or any other candidate process must be removable without collapsing dignity or hiding failure. A mechanism that cannot be retired has become doctrine.

2.3.5 — Consequence Claim

The consequence claim asks whether the prospectively specified signature conjunction appears and out-predicts rivals. This is where the Law begins to touch data in a way that can matter. The relevant question is not whether one curve looks suggestive. It is whether a declared family of consequences appears under the declared bridge, with rivals given serious opportunity to win.

A consequence can be preterminal, terminal, sleep-related, life-course, behavioral, physiological, or model-comparison-based. The strongest empirical burden in the current program begins with prospective and comparative consequence structures because exact latent equality is not directly observable. Support is therefore indirect, component-level, and bridge-dependent.

Consequence claims must specify the direction of inference. A terminal concentration result may support a bounded terminal consequence under one endpoint and instrument. A variance-shape result may support a reserve-linked process if measurement

noise, sedation, frailty, and endpoint conditioning are ruled out. A held-out prediction gain may support one model class over another. None alone establishes the exact set-universal target over the declared class (Gneiting & Raftery, 2007; Manski, 2003).

The chapter's worked example is simple. Suppose a prospectively specified palliative study on a declared independent-endpoint branch finds reserve-scaled variance compression, prospective forecast gain under the branch's timing assumptions, and better model recovery for the reserve-coupled candidate than for a homeostatic baseline in one adult cancer cohort. That would be important route and component support. It would not show that every qualifying stream in the declared class closes exactly. It would say that one consequence family survived in one reference class under one protocol-fixed bridge.

Suppose adaptation and medication-adjusted frailty models predict terminal patterns as well as or better than the PTVC candidate. The result then supports parity or preference for those explanations in the tested class and guides the next version of the consequence model.

2.3.6 — Reference-Class Discipline

Reference-class discipline turns a sample description into the boundary of warranted speech. Every empirical status statement should name the population, condition, endpoint class, instrument version, analysis window, and transport assumptions to which it applies. The strongest formal target is broad; every first study is local.

A selected clinical cohort can speak most directly to comparable cohorts, less directly to sudden interruption or other endpoint classes, and almost not at all to nonhuman animals or artificial systems without additional bridges. A study of report-capable adults cannot silently represent nonreporting states, and a culture-specific calibration does not become global because the result is striking. Local truth is not lesser truth; it is truth with honest borders (van der Vaart, 1998).

Transport assumptions must be stated before they are used. A claim that a signature should persist across diagnoses, cultures, communication states, or endpoint classes must name the invariance asserted and the rival reasons it might fail. If the bridge changes after an adverse result, the new bridge defines a new version rather than rescuing the old claim without loss.

The component program forms a dependency lattice. Representation, measurement, bearer and routing, endpoint, realization, consequence, rival discrimination, replication, and transport each have their own validation tasks and connections to the others.

The strong latent claim is the most dependency-heavy node, not a crown that lends authority downward. Failure at one node weakens the claims that depend on it while leaving neighboring nodes open. Conversely, genuine support at a lower node should be reported as support for that node rather than minimized to metaphor merely because the strong target remains unproved.

Reference class runs through every component. Representation may work for some forms of experience and not others;

measurement may be stable in one language, disease class, or communication state and not another; endpoint adjudication may be defensible in slow decline and weak in sudden interruption; route signatures may depend on care context or reserve definition. Transport is therefore part of each claim, not a final decorative test. Two findings can therefore differ without contradiction when their reference classes differ. A genuine conflict begins only when the relevant populations, instruments, endpoint rules, and conditions overlap enough that both claims address the same empirical domain.

Partial identification is a legitimate result. Data may constrain a truth-containing region without isolating one latent value or one explanation. A bounded identified set is progress when its boundaries, assumptions, and unresolved rivals are reported as such rather than converted into hidden certainty. The structure of the identified set can itself guide the next study by showing which assumptions, channels, or bridges carry the remaining uncertainty. Progress can therefore consist in shrinking or partitioning that set with independently justified information before a point estimate becomes defensible.

Component-level reporting supplies the grammar for honest updating. Evidence may strengthen one measurement bridge, weaken an endpoint rule, retire a route, or leave the set-universal target open or narrowed. That is more precise than saying a study supports or refutes the Law without naming the object that changed. This approach allows heterogeneous evidence to accumulate without forcing a single book-level verdict. An improved estimator, endpoint method, or recovery procedure can

remain a durable scientific contribution even when a mechanism fails or the strongest branch remains unresolved.

Transport analysis must name the target population, relevant differences from the enrolled cohort, plausible effect modifiers, and the assumptions needed for reweighting or structural transport. When those assumptions fail, the result remains local or set-valued; sample size inside a narrow class cannot manufacture support outside it (Manski, 2003; Hernán & Robins, 2020). Transport sensitivity should reveal which assumptions are doing the work rather than presenting one reweighted estimate as though extension were automatic. Agreement across independently defensible transport specifications strengthens generalization, while disagreement identifies the boundary that future data must resolve.

Instrument and protocol versions also belong inside the reference class. A classifier validated under one medication pattern, device generation, language, reporting capacity, or care setting may change elsewhere. Failed transport is evidence about the phenomenon, the measurement system, or both, and should narrow public speech rather than be dismissed as nuisance replication (Little & Rubin, 2019; National Academies of Sciences, Engineering, and Medicine, 2019). A version change should therefore be treated as a potential change in reference class until equivalence or transport has been demonstrated. Reporting the exact instrument, software, protocol, and calibration version makes replication interpretable and prevents implementation differences from being mistaken for substantive contradictions.

2.4 — Severe Tests and Underdetermination

An informative scientific test distinguishes a model's predictions from alternatives the method can detect. Terminal and affective observations make that comparison especially useful because several latent processes can generate similar measured patterns. Explicit alternatives and common comparison rules turn those possibilities into tractable questions (Duhem, 1954; Gneiting & Raftery, 2007; Mayo, 2018; Quine, 1951).

Underdetermination is not a skeptical trick. It is a normal feature of scientific inference, intensified here by latent experience, noisy channels, terminal vulnerability, missing data, and endpoint ambiguity. A terminal curve can converge for reasons that have nothing to do with terminal valence closure. A measured cumulative estimate can stabilize because a sensor loses gain. A person's reports can change because medication, social pressure, delirium, adaptation, or family context changed.

The answer is not despair. The answer is severe testing. A severe test makes specific errors likely to show themselves if they are present. It does not merely seek confirmation. It designs the world-facing encounter so that rival explanations, measurement failures, and auxiliary assumptions can break the favored claim.

2.4.1 — Risky Prediction

A risky prediction is one that could plausibly have failed and would have mattered if it did. *The Law of Fairness* should not claim support from patterns it would have expected no matter what happened. If the theory can treat convergence, divergence,

volatility, flatness, silence, and missingness all as favorable without prior rules, it has no empirical risk.

Risk is created by forbidding or disfavoring outcomes. A reserve-coupled signature might predict a particular relationship between reserve decline and ledger variance under a specified bridge. A rival homeostatic model might predict local mean reversion without the same terminal scaling. A Brownian bridge might predict endpoint convergence without independent reserve coupling. The risky prediction is not the pattern alone; it is the pattern as differentially expected across models.

The prediction must be generated before outcome inspection, not narrated afterward. Prospective specification creates a dated record of hypotheses, endpoints, instruments, analysis windows, exclusions, and rival families. It does not sanctify a weak design; it distinguishes a risk taken in advance from an explanation composed after the answer. Public preregistration is claimed only when a timestamped external registry and persistent identifier actually exist (Duhem, 1954; Gneiting & Raftery, 2007; Mayo, 2018; Nosek et al., 2018).

Risky prediction also protects against private hope. A community that wants the Law to be true may notice favorable anecdotes and forget silent failures. A research program that wants the Law to be true may adjust models until the result looks natural. The remedy is to state in advance what the model should not do well under rivals and what would count against it.

A risky prediction can be modest. It need not test the whole Law. It may test one component: a measurement bridge, endpoint

classifier, model-recovery procedure, or reference-class transport assumption. Smaller severe tests often teach more than grand unfocused tests because they know exactly what they can break.

Falsifiability, identifiability, and adjudicability are different achievements. A sentence may be logically falsifiable because a counterexample is conceivable, yet no current study can adjudicate it if the latent target, endpoint, or measured-to-latent bridge is unidentified. Conversely, a highly measurable surrogate may be adjudicable without testing the received target. The program advances only when a design connects a vulnerable claim to an identifiable object and a decision rule that would respond differently in relevant rival worlds (Borsboom, 2005; Mayo, 2018; Woodward, 2003).

The public language after a risky prediction should be restrained and exact. If the prediction succeeds, say which component survived and against which rival set. If it fails, say which component lost. Do not let a successful local prediction become total validation, and do not let a failed prediction vanish into metaphor.

2.4.2 — Underdetermination by Terminal Patterns

Terminal observations bring several explanatory processes together. Clinical care, medication, sedation, frailty, reporting changes, family context, selection, sensor performance, and endpoint conditioning can each influence an observed trajectory. A study becomes informative by distinguishing their predictions.

Concentration near an endpoint is not unique. A Brownian bridge conditioned to end at a value can show approach behavior by

construction. A clinical process that reduces variability near death can mimic variance compression. A dataset that loses the most distressed participants can appear to stabilize. A scale that loses sensitivity at low arousal can produce false neutrality. Each rival must be treated as a potential generator, not as a footnote.

The Law-specific question is therefore conjunctive. Is the endpoint independently defined? Does the result survive observation-model and missingness checks? Is any reserve variable estimated without using the ledger outcome? Does the candidate out-predict endpoint-conditioned, clinical, and measurement rivals on held-out data? Most importantly, can the analysis recover each generator from simulated worlds where the truth is known? A test that returns the same favorable verdict in candidate and rival worlds is not severe, however sophisticated its fit appears (Mayo, 2018; Quine, 1951; Wilson & Collins, 2019).

Terminal studies combine careful inference with comfort-first care. Their design accounts for clinical context, communication, observation quality, and consent so that participation remains proportionate and the resulting comparisons are interpretable.

A terminal pattern can provide valuable comparative evidence when its measurement, endpoint procedure, and alternative explanations are specified. The result identifies the consequence supported within that study and the next conditions to investigate.

The correct public sentence is not: the terminal pattern confirms the Law. The correct sentence is more demanding: this terminal pattern, in this reference class, under this endpoint and

observation model, supports or fails to support this consequence relative to these rivals. That sentence is less dramatic. It is also the beginning of science.

2.4.3 — Model Pluralism

Model pluralism means keeping multiple live explanations in the field long enough for evidence to discriminate among them. It is not indecision. It is the refusal to let one favored vocabulary monopolize interpretation before the data have done their work. For the Law of Fairness, pluralism is mandatory because affective dynamics, consciousness, endpoint states, and measurement each have serious existing theories.

The rival set must include models that are attractive for reasons independent of the Law. Hedonic adaptation explains many returns toward baseline. Opponent processes explain rebound and counterweighting. Predictive processing and active-inference accounts explain regulation through prediction and error. Homeostasis and allostasis explain viability-centered regulation. Reinforcement learning explains policy adaptation under reward and constraint. Clinical models explain terminal decline through disease, treatment, and care context.

A pluralistic field also includes statistical and observation rivals. Smoothing can manufacture approach. Noise floors can manufacture variance contraction. Equivalence procedures can be applied to biased estimators. Missingness can select the visible sample. Flexible latent models can absorb the same pattern under different mechanisms. These rivals deserve equal information, parameter, and tuning budgets because a candidate has not won if

the comparison was calibrated to let it win (Gelman & Loken, 2014; Stanford, 2006; Wilson & Collins, 2019).

Model pluralism protects the positive case by demanding specificity. If the Law wins only against weak rivals, its victory is shallow. If it wins against strong rivals in a known reference class, its status improves. A theory that can say which rival would have explained the result and why that rival failed has earned more trust than a theory that treats alternatives as disbelief.

Pluralism also protects against premature defeat. If one Law-specific mechanism fails, another component may remain live. If one rival wins in one class, another class may remain open. The discipline is not to preserve the Law at any cost, but to identify exactly which model won where and why.

2.4.4 — Auxiliary-Hypothesis Failure

Every empirical test of a large theory depends on auxiliary hypotheses. *The Law of Fairness* depends on assumptions about representation, measurement, endpoint classification, instrument calibration, sampling, rival specification, missingness, and transport. When a test fails, the failure may belong to one of those bridges rather than to the strong latent claim itself.

Auxiliary dependence creates a legitimate diagnostic problem and a familiar escape route. A proponent can always announce that some bridge failed while leaving the core untouched. The responsible response localizes the failed bridge, demonstrates the failure with independent evidence, changes public status immediately, and permits a successor only when the repair creates

a new risky prediction. Without those conditions, auxiliary diagnosis becomes immunity.

For example, suppose a terminal study fails because the endpoint classifier was later shown to conflate irreversible loss of consciousness with reversible sedation. That may be an endpoint-bridge failure, not a defeat of the strong form. But the repaired endpoint bridge must be specified prospectively in the next study. The old result cannot be rebranded as support after the bridge changes (Duhem, 1954; Gneiting & Raftery, 2007; Mayo, 2018).

Suppose instead that multiple endpoint classifiers, measurement systems, and rival comparisons all fail to show Law-specific consequences in a reference class where they should have appeared. At some point, the appeal to auxiliary failure becomes degenerating. The core may remain metaphysically conceivable, but the public scientific claim loses status.

A title-owned fairness analysis again reveals the fairness problem. If the core keeps prestige while each failed bridge is discarded without public cost, the theory has shifted burden onto instruments, participants, critics, and future studies. Auxiliary hypotheses may protect inquiry only when their own failures are recorded and paid for in claim status.

2.4.5 — Local Versus Theory-Level Defeat

Local defeat occurs when a component, mechanism, instrument, endpoint class, reference class, or prediction fails. Theory-level defeat occurs when the failures reach the dependencies required by the strong claim and cannot be repaired without destroying

empirical content. Confusing these two levels makes science either too brittle or too evasive.

A local defeat may retire a momentary valence estimator version, a reserve proxy, a terminal classifier, a conditioned-path candidate route, a completion-potential model, or a reference-class transport assumption. Such defeats are valuable. They teach the program what not to say. They prevent weak bridges from carrying stronger public language. They also allow surviving components to remain under discipline.

A weak study does not defeat the strong claim. One gate-valid counterexample can contradict a declared set-universal branch under its stated inferential guarantee. Separately, repeated failure of independently motivated bridges and discriminating predictions can justify retiring the empirical program without establishing that the latent target is false. A theory that preserves its headline only through outcome-dependent changes to origins, endpoints, instruments, or reference classes loses the scientific standing claimed for that version (Mayo, 2018; Quine, 1951).

The exact set-universal form is asymmetric. No finite sample confirms every qualifying stream in a declared class. A counterexample matters only when the stream qualifies under the prospectively fixed bearer and routing rules, the truth-containing residual object is nonempty and excludes zero, and the representation, endpoint, observation, missingness, and measured-to-latent bridges are adequate for that conclusion. When those conditions hold, one stream is adverse to the protocol-fixed universal branch; a population average cannot rescue it.

The chapter's second worked example lives here. Suppose adaptation models repeatedly out-predict Law-specific models in slowly declining adult terminal cohorts, while the measurement and endpoint bridges are adequate. The Law need not vanish from every domain, but it must narrow in that class, retire the defeated consequence claim, and stop using those cohorts as support. If future work proposes a new bridge, it begins as a new version.

Distinguishing local from theory-level defeat protects both ambition and honest inference. It keeps a difficult idea open to productive investigation while ensuring that adequate contrary evidence has its stated consequence.

2.4.6 — Severe-Test Reporting

A severe test is incomplete unless the report states what had a genuine chance to go wrong and demonstrates that the analysis could have detected it. The report names the component tested, empowered rivals, frozen bridges, negative controls, model-recovery thresholds, failure routes, and decision rule for status change. Without a recovery result, apparent discrimination in real data may only reflect an analysis that favors one model by construction.

Report each study through its scientific object. A palliative study examines a defined endpoint class and consequence family; a sleep study investigates reprocessing and associated dynamics; a measurement study qualifies an estimator. This specificity lets each contribution receive appropriate recognition.

The report should distinguish prediction, retrodiction, accommodation, and exploration. A predicted effect under a

frozen plan has one status. An exploratory pattern has another. A model tuned after data has another. All can be useful. They cannot be given the same public language (Stanford, 2006; Wilson & Collins, 2019).

Severe-test reporting includes failed and unusable results. An unavailable estimate can identify unfinished measurement work; informative missingness can identify the conditions needed for inference; and a rival victory can show that PTVC-specific structure is unnecessary in the tested class. Each outcome has an explicit next action.

Public reporting should make meaningful scientific progress easy to recognize. Name the component supported, the observations that changed its status, and the next question those findings open. Precise reporting gives each result its full value.

The final reporting rule is hostile-crop safe: an isolated result sentence still names the component, reference class, and status ceiling. If three distant paragraphs are needed to prevent a local sentence from implying proof, the local sentence carries too much borrowed authority and must be rewritten.

Example: terminal concentration near a neutral band has little Law-specific force if endpoint-conditioned simulations, sedation, or informative dropout reproduce it. The result becomes more discriminating only when independently estimated reserve relations, stable measurement gain, noncircular endpoint classification, and held-out superiority to strong rivals survive together; and even then it is component support in that reference class, not universal validation.

A second worked example goes the other direction. Suppose the Law-specific model predicts a reserve-linked signature, but a clinical frailty model with medication, delirium, and care-context variables out-predicts it across held-out sites. Suppose model recovery shows the analysis could have detected the Law-specific pattern if it were present. In that case, the rival wins for that class. The correct response is narrowing or defeat of the consequence claim there, not a search for a poetic interpretation.

These examples show why underdetermination is not a reason to stop. It is a reason to build sharper discriminators. If several latent stories can explain one pattern, the program should seek patterns that divide them: timing, reserve coupling, noncircular endpoint construction, branch-specific endpoint premises, negative controls, transport behavior, and forecast performance. The work becomes more technical because the claim is large.

Severe testing also changes the moral tone of the book. The project is not asking dying people, sleeping people, grieving people, or ordinary readers to serve as illustrations for a beautiful idea. It is asking whether a precisely stated claim survives designs that count the burden of being studied. A severe test that violates care is not severe in the sense this book requires, because it has shifted the burden of clarity onto vulnerable subjects.

Underdetermination remains even after good tests. The goal is not to eliminate every alternative forever. The goal is to reduce live alternatives in a declared model space and report the remainder. A scientific verdict is always relative to what was compared, what was measured, and what could have been detected.

Severe testing must be designed before emotional investment hardens around a preferred result. If the first genuinely dangerous test arrives only after the community has built identity, public artifacts, and institutional plans around support, the social cost of losing becomes part of the data environment. A humane research program therefore makes loss speakable early. The chapter's philosophical point has a practical purpose: reduce the burden carried by future scientists who may need to report disappointing results.

2.4.7 — Auxiliary Hypotheses and the Duhem Problem

No empirical test confronts an isolated proposition. A terminal-pattern study simultaneously relies on a representation of valence, a neutral origin, a stream-routing rule, an endpoint construction, an observation process, an estimator, a missingness model, a rival set, and a decision rule. When the prediction fails, the data do not announce which member of that network was responsible. This is the practical force of the Duhem problem for the Law of Fairness.

The answer is not to pretend the network can be eliminated. The answer is to type it. Each auxiliary should have an owner, a source of independent motivation, a validation route, a version, and a known effect on the inference. Representation failure should not be redescribed as endpoint failure. Endpoint circularity should not be repaired by widening an equivalence band. A model-recovery failure should stop real-data interpretation rather than become a footnote after a striking curve appears.

A dependency graph makes this discipline visible. Upstream gates include whether the target quantity is coherent and whether the

instrument can identify it in the relevant population. Midstream gates include routing, time, endpoint, and observation. Downstream gates include estimators, candidate signatures, rivals, multiplicity, transport, and verdicts. Success at a downstream node cannot compensate for failure above it, because the downstream calculation would no longer be about the intended object (Duhem, 1954; Gneiting & Raftery, 2007; Mayo, 2018).

Auxiliary hypotheses can often be tested with data independent of the principal prediction. Neutral-origin procedures can be evaluated in longitudinal cohorts; missingness models in synthetic and semi-synthetic data; endpoint rules against independent clinical adjudication; and model recovery before cohort analysis. Together, these studies qualify the components used in terminal inference.

Synthetic challenge data are especially useful because the generating truth is known. Researchers can ask whether the pipeline recovers a PTVC-consistent route when that route generated the data, an Ornstein-Uhlenbeck process when mean reversion generated them, a conditioned bridge when endpoint conditioning generated them, and an observation artifact when dropout generated the shape. If the pipeline cannot tell these worlds apart in simulation, it cannot claim to distinguish them in human data.

Negative controls provide another route through underdetermination. A candidate signature should disappear, reverse, or remain invariant under declared perturbations for reasons specific to the model. If the same result appears under a

control window that should contain no endpoint information, if it survives randomized endpoint labels, or if it strengthens when measurement quality worsens, the signature is probably not carrying the intended meaning. Controls turn abstract rival pressure into inspectable consequences. A useful control therefore challenges a specific pathway by which the apparent signal could be produced without the candidate mechanism. Convergence across controls with different failure modes provides stronger discrimination than repeating variations of the same check.

Underdetermination changes what a favorable result means: within a declared representation, endpoint, observation model, estimator, and rival set, one prediction structure survived better than the alternatives tested. The program gains credibility by reducing viable explanations while keeping the assumptions and unresolved alternatives visible.

Endpoint analysis brings several ordinary processes into the same frame: changing reserve, care, family presence, medication, speech, and observation quality. Comparing their predictions helps identify which process explains a terminal pattern. The most informative designs seek observations on which these processes predict different timing, direction, or magnitude rather than merely asking which can fit the same final curve. This turns clinical complexity into comparative leverage while preserving the limits imposed by care and measurement.

2.5 — Confirmation, Rescue, and Model Change

A research program is not a statue. It should learn. Instruments improve, endpoint rules sharpen, rivals become stronger, and mechanisms are revised. The scientific problem is not revision itself. The problem is rescue that changes the tested claim while keeping the old public authority. This section distinguishes improvement from evasion (Gelman et al., 2013; Kuhn, 2012; Lakatos, 1978; Laudan, 1977).

The Law of Fairness needs a rule for updating because its strongest form cannot be confirmed by a single study, and its component claims will develop unevenly. A result may strengthen one bridge, weaken another, retire a mechanism, open a new reference class, or force abstention. Those possible status movements must be specified before data arrive.

Confirmation should be understood as a change in status under a defined model space, not as a mystical glow around the whole series. Bayesian updating, likelihood comparison, prequential performance, model recovery, and severe-test logic can all help. None can remove the need to ask what the tested claim actually was.

The framework's burden question frames rescue as a burden issue. If a theory changes its endpoint after failure without acknowledging claim change, the researcher keeps hope while the public carries confusion. If it changes the origin after a negative result, the critic carries the cost of chasing a moving target. Fair updating records the movement.

2.5.1 — Bayesian Updating as One Tool

Bayesian updating offers one way to express how evidence changes degrees of belief. A result has confirmatory force when it is more expected under one model than under alternatives, given prior assumptions. This can be useful for *The Science of Fairness* because component claims are uncertain, rival models are many, and evidence will accumulate gradually rather than arrive as a single decisive spectacle.

Bayesian language must be used with humility. Priors are not neutral simply because they are numerical. Model spaces are not complete simply because they are formal. A posterior can look decisive because serious alternatives were not included, because prior mass was assigned too generously, or because the observation model was treated as known when it was not. Numerical updating cannot rescue a poorly defined claim.

For the Law, Bayesian confirmation is most useful at the component level. A measurement validation result may update belief in one estimator. A model-comparison result may update belief in a reserve-coupled realization relative to a homeostatic rival. A transport study may update belief about a reference class. None of those posterior shifts should be described as proof of the exact set-universal target (Gelman et al., 2013; Kuhn, 2012; Lakatos, 1978).

Bayesian analysis also helps expose prior-sensitivity. If support for a component depends on highly favorable priors, the report should say so. If a rival model receives little prior mass because

it was inconvenient rather than implausible, the analysis is not fair. The rival set is part of the burden the claim must carry.

Updating cannot ignore versioning. Evidence updates a specific claim version. If the bridge changes after the result, the posterior for the old version does not automatically transfer. A new endpoint, instrument, or origin convention requires its own model and status history. Otherwise Bayesian language becomes a polished form of category drift.

2.5.2 — Likelihood and Predictive Comparison

Likelihood and predictive comparison ask a direct question: which model expected the observed data better under declared assumptions, and which model predicts new or held-out data better? For a program facing many rivals, this question is more useful than asking whether a pattern feels compatible with the Law. Comparative prediction asks more of a model than compatibility alone.

Held-out prediction matters because it reduces the freedom to sculpt a story after seeing the result. A Law-specific model may fit a training dataset because its bridges and parameters were tuned there. The stronger question is whether it predicts a new dataset, new site, new endpoint class, or new time window better than homeostatic, adaptive, bridge, clinical, and observation-process rivals.

Calibration is as important as raw accuracy. A model that gives high-confidence wrong predictions is not merely inaccurate; it is dangerous. In a public-risk project, overconfident models can create proof drift, media overclaim, or research escalation.

Predictive comparison should therefore examine uncertainty, calibration, abstention behavior, and failure modes (Lakatos, 1978; Laudan, 1977).

Prequential performance is a useful discipline for longitudinal studies. The model makes predictions as the stream unfolds, and each new observation tests the forecast without access to the future. This matters for the Law because endpoint-aligned analysis can otherwise create the illusion that the model saw the end coming when it was only aligned after the fact.

Predictive comparison can also defeat mechanisms without defeating the entire question. If a predictive-processing rival repeatedly forecasts measured trajectories better than a Queue model, the Queue model should narrow or retire. If a clinical frailty model explains variance compression better than reserve coupling, reserve coupling loses in that class. The Law-specific program learns by letting other models own the data they explain.

The public language after predictive comparison should be exact. Say that one model out-predicted another under a specified bridge. Do not say that the Law has been confirmed because a model with Law-like variables performed well. The bridge between model performance and law-language must remain visible.

2.5.3 — Independent Motivation for New Bridges

A bridge connects the latent claim to an empirical test. It may be a measurement instrument, endpoint classifier, origin convention, reserve proxy, scalarization method, rival model, or transport rule. Bridges can change as science improves. The rule is that a new

bridge must be independently motivated before or beyond the failed result, not invented solely because the old bridge lost.

Independent motivation can take several forms. A measurement bridge may be supported by validation studies outside the Law-specific test. An endpoint bridge may be grounded in consciousness science and clinical classification before terminal valence closure is analyzed. A reserve proxy may be justified by biological theory and external data. A rival set may be expanded because a field has advanced, not because the favored model needs an easier comparison.

A bridge that appears only after an unfavorable result may still generate a future hypothesis. It may not erase the status of the failed test. The failed version remains failed or inconclusive under its own bridge. The new bridge begins with a new version label and a new risk burden. This preserves the original test record while making the revised bridge available for a new prospective test (Nosek et al., 2018; Vehtari, Gelman, & Gabry, 2017).

The distinction between progressive and ad hoc revision begins here. A progressive bridge explains the failure, predicts something new, and exposes itself to further risk. An ad hoc bridge absorbs the failure while adding no new exposure. The first improves the research program. The second turns the program toward immunity.

A bridge revision must leave an audit trail: what changed, what failure motivated it, which earlier claim loses authority, and what new prospective prediction exposes the revision to risk. Without

that record, participants, critics, and readers inherit the cost of an unnamed moving target.

2.5.4 — No Moving Endpoints or Origins

Endpoints and origins are especially dangerous bridges because they can turn failure into success by definition. If the endpoint moves after the trajectory is seen, the test may be selecting the place where the result looks best. If the neutral origin moves after the distribution is known, equivalence can be manufactured. The chapter therefore treats endpoint and origin movement as a major form of claim change.

The endpoint is not a decorative timestamp. It defines which trajectory is being tested. A study of truth-level endpoint cannot become a study of biological death because the signal is easier to obtain. A low-signal ending cannot be treated as neutral because the instrument fell silent. A resuscitated or reversible state cannot be forced into terminal closure because the theory wanted a clean end.

Exact neutrality requires a justified neutral point. Cohort means, personal baselines, and questionnaire midpoints provide useful reference points for relative analyses. Terminal valence inference additionally specifies how its chosen origin represents phenomenal neutrality and how uncertainty in that origin affects the result (Gelman et al., 2013; Kuhn, 2012; Lakatos, 1978).

A study may refine endpoint and origin rules prospectively. It may learn from failure and build better rules for the next version. What it may not do is reinterpret an unfavorable result by moving the clock or zero point and then claim that the same hypothesis

survived. The bridge has changed, so the claim version has changed.

When an origin or endpoint remains unresolved, an indeterminate result identifies the evidence needed for the next study. Resolving that question provides a firmer basis for the ensuing comparison.

Public communication should be blunt here. No moving endpoints. No moving origins. No neutrality by recentering. No closure by choosing the place where the curve looks closed. These are not hostile rules; they are the conditions under which a positive result could deserve belief.

2.5.5 — Progressive Versus Ad Hoc Revision

A progressive revision explains a failure, changes a declared object or bridge, and creates a new prospectively testable risk. An ad hoc revision changes the endpoint, origin, reference class, or auxiliary structure only after an unfavorable result in a way that preserves the preferred conclusion without adding independent exposure to failure. Mixed cases should be labeled as new candidate versions pending severe test rather than treated as continuous support (Lakatos, 1978; Laudan, 1977).

2.5.6 — Versioned Theory Change

Versioned theory change records the object that changed, the evidence that forced the change, the earlier claim or public artifact that loses authority, and the new risky prediction that the revision must face. Formal-definition changes, empirical-bridge changes, and applied-domain corrections remain distinct. Chapter 28 provides the full register, migration, and cross-book propagation procedure.

Bayesian and likelihood tools can live inside this bridge record. They can show how much a result changes relative support among models. But the record should also include non-numerical obligations: source of priors, omitted rivals, context of use, endpoint confidence, participant burden, and public wording changes. Updating is not only a calculation. It is a governance act.

The question becomes almost procedural: who carries the cost when the bridge changes? In an answerable research program, the theory pays by losing status or version continuity where appropriate. The public, the critic, and the participant do not pay by having to chase an unnamed moving target.

Bayesian language can clarify updating, but it cannot cleanse a badly formed model space. If the only live models in the comparison set are weak versions of rivals and a protected version of the Law, a posterior shift toward the Law is bookkeeping over an unfair contest. The fair comparison includes strong rivals, plausible observation artifacts, and the option that none of the proposed models deserves confidence. Otherwise the math has inherited the hidden bias of the menu.

2.5.7 — Predictive Scoring and the Cost of Flexibility

Model change becomes easier to judge when prediction is separated from accommodation. A model assessed on the observations used to invent its features may fit beautifully while saying little about what comes next. Held-out data, prospective forecasts, and prequential evaluation impose the needed order: the model speaks before the outcome, and the outcome can answer back.

Proper scoring rules reward calibrated probabilistic predictions rather than confident retrospective stories, but the score and prediction task must be fixed for their intended use. Log scores, interval scores, calibration measures, and decision losses answer different questions. Cross-validation also depends on correct grouping, time order, clustering, preprocessing, and leakage control; random splits within one person do not establish transport to new persons, and smoothing before a temporal split can leak the future (Gneiting & Raftery, 2007; Vehtari, Gelman, & Gabry, 2017).

Flexibility must be counted. Searching across origins, endpoint windows, reserve proxies, exclusions, transformations, latent states, rival sets, or scoring rules can create apparent stability when no analysis was prospectively privileged. Multiverse or specification-curve work can reveal sensitivity, but it cannot retroactively convert exploration into confirmation. The report must preserve the analytic history and the uncertainty around model differences.

Complexity is warranted when it earns recovery, discrimination, or transport. A larger hidden-state model may absorb local irregularities yet fail to predict held-out transitions, survive sealed-world recovery, or retain meaning across cohorts and channels. Unrecoverable complexity is another source of underdetermination, not depth. Simulation can check whether the added states are recoverable from the measurements the study will actually collect. Additional structure should therefore be retained only when the data can distinguish its components well enough for the resulting interpretation to be meaningful.

Otherwise, apparent mechanistic detail may simply redistribute uncertainty into parameters that cannot be separately identified.

Flexibility should therefore be budgeted rather than denied. A materially changed model requires fresh holdout or replication evidence, and the cost of rescue is paid through renewed exposure to failure rather than a rhetorical claim that the revised model remains the same test (Chambers, 2013; Gelman & Loken, 2014; Nosek et al., 2018). The revision plan should reserve data or replication capacity for testing the specific improvement that motivated the change. That reserve prevents all available evidence from being consumed during model development, leaving no independent information with which to evaluate the revision. A flexible program remains scientifically disciplined when every substantial change creates a corresponding obligation for fresh evidence.

2.6 — Narrowing, Retirement, and Defeat

The Law of Fairness research program distinguishes local support, partial support, instrument failure, endpoint failure, mechanism defeat, rival victory, reference-class narrowing, inconclusive evidence, and strong-form defeat. Defined before evaluation, these outcomes connect each result to an appropriate response (Lakatos, 1978; Laudan, 1977; National Academies of Sciences, Engineering, and Medicine, 2019; Popper, 1959).

This section gives the chapter its exit map. The exits are not escapes from evidence. They are the honest paths by which a claim changes status after evidence. A smaller true claim is better than a larger protected one. A retired mechanism is better than a mechanism kept alive as ornament. A defeated strong form is better than a strong form that survives by ceasing to say anything.

Narrowing or defeat changes the status of the scientific claim, not the independent duties of care, privacy, and dignity governed in Chapter 3; the burden lens may remain useful only as a non-evidentiary analytic tool.

The following outcome map is a discipline for future chapters. Each status has different public language. No chapter should call a component result validation, no summary should call an inconclusive study defeat, and no public artifact should hide a rival victory inside a phrase such as mixed evidence.

Table 2.3. Outcome status, public wording, and prohibited reinterpretation.

Outcome	What happened	Public wording	What must not happen
Reference-class narrowing	A pattern survives only in defined populations or conditions.	Supported in that class; transport open.	Do not universalize.
Component narrowing	A representation, measurement, endpoint, or consequence survives without the full Law.	Component support.	Do not upgrade to strong form.
Mechanism retirement	A candidate realization or mechanism loses to rivals.	Mechanism retired or narrowed.	Do not keep using it as if supported.
Retirement to heuristic or metaphor	Scientific claim loses, but lens or image remains useful.	Useful lens or metaphor only.	Do not call resonance evidence.
Strong-form defeat	Adequate tests or counterexamples defeat the universal claim.	Strong form withdrawn or defeated.	Do not rescue by category drift.
Dignity after loss	Ethics and care remain unchanged.	Care and dignity do not depend on verdict.	Do not make people carry the theory's disappointment.

2.6.1 — Narrowing to a Reference Class

Reference-class qualification identifies a result supported in a particular population, condition, endpoint type, or instrument context. This local knowledge supplies a clear basis for replication and transport studies.

A reference-class claim should name its limits in the sentence itself. Supported in verbally report-capable adults receiving palliative care under instrument version two. Supported in slow terminal decline but not sudden death. Supported in one culture-language calibration but untested elsewhere. The wording may feel less elegant than universal language, but it prevents evidence from becoming imperial.

Reference-class narrowing can be progressive. A local finding can generate sharper transport studies. It can reveal moderators, failure conditions, and rival boundaries. It can teach the program where the Law-specific pattern is plausible and where other processes dominate. A smaller map is still a map (Lakatos, 1978; Laudan, 1977; National Academies of Sciences, Engineering, and Medicine, 2019).

The danger is rhetorical rebound. After a careful local statement, public summaries may return to the phrase the Law is supported. That rebound must be prevented. The science volume should make local status quotable so summaries can remain safe without long explanatory scaffolding.

A result may exclude nonverbal, disabled, sedated, pediatric, or nonhuman cases from the tested reference class; it cannot turn

exclusion from an estimand into a conclusion about consciousness, standing, dignity, or eligibility for care.

The acceptance rule is exact: until transport is defended, the claim stays in its class. If transport succeeds, the class expands. If transport fails, the boundary becomes part of the result.

2.6.2 — Narrowing to a Component

Component findings can advance the project and neighboring fields together. A measurement stack may improve affective science, an endpoint classifier may sharpen consciousness research, and a model-recovery method may strengthen rival comparison. A terminal consequence that survives a local test supplies a defined result for replication and extension.

Component support should be celebrated precisely because it is not exaggerated. A program that can say we learned this smaller thing has become scientifically productive. The component may benefit research, care, measurement, or theory even if the strong Law never reaches validation. That is not failure of the book's ambition. It is the ordinary dignity of science.

The component language must be precise. Representation support means the target may be scientifically usable in a context. Measurement support means an estimator behaves adequately for a task. Endpoint support means a stopping event can be classified under a rule. Realization support means a candidate mechanism describes a pattern. Consequence support means a signature appeared. Each is different (National Academies of Sciences, Engineering, and Medicine, 2019; Popper, 1959).

A component can also outlive the Law. If the strong form fails, a measurement-related insight may still be valuable. An endpoint discipline may still improve palliative or consciousness research. Rival-model infrastructure may still strengthen affective science. The project should be prepared to preserve those contributions without calling them Law support.

A component result is reported by its object: chart, tool, classifier, estimator, endpoint, or local consequence. That precise label tells readers what the study achieved.

2.6.3 — Mechanism Retirement

Mechanism retirement occurs when a candidate process loses to rivals or fails its own predictions. A Queue model, reserve-coupled realization, shadow-price account, interoceptive pathway, or sleep-reprocessing mechanism may turn out to be wrong, too local, or less predictive than an alternative. The program must be able to remove such machinery cleanly.

Mechanism retirement can preserve scientific value. Scientific mechanisms are tools for learning how a claim could be realized. If a tool fails, the program has learned something about the space of possibility. A mechanism that fails its declared test should retain only the narrower role the evidence supports.

Mechanism retirement requires public propagation. If a mechanism has appeared in diagrams, public summaries, or neighboring books, those materials must be corrected. A retired Queue model cannot keep functioning as the hidden engine of applied advice. A retired reserve model cannot keep decorating

proof-shaped images. The mechanism's status must travel (Stanford, 2006).

Retirement may be local. A mechanism might fail in terminal studies but remain useful in sleep or ordinary affective reprocessing. It might work in slowly declining reserve but fail in sudden endpoint classes. The retirement statement should name scope rather than deleting nuance. The goal is accuracy, not punishment.

When predictive processing, homeostasis, adaptation, or clinical models perform better under the declared comparison rules, the record credits their explanatory contribution. That finding helps the field select and develop the next model.

2.6.4 — Retirement to Heuristic or Metaphor

If a scientific claim is retired but a heuristic or metaphor retains independent value, the public label should say so explicitly: the scientific claim was not supported in the relevant form, while the remaining lens is non-evidentiary. Any retained application remains bounded and noncoercive.

2.6.5 — Defeat of the Strong Form

Defeat of the exact set-universal target is the most serious negative outcome. On a declared branch and reference class, one independently audited, gate-valid stream is adverse when its nonempty truth-containing latent compatibility set excludes zero under the protocol-fixed inferential guarantee. Local instrument failure, endpoint ambiguity, observation failure, or loss of an optional mechanism may instead block inference, narrow a class, or retire the affected route; route failure becomes target adversity

only when a protocol-fixed entailment warrants that step. A credible counterexample cannot be absorbed by quiet scope drift: any narrowing must be explicit, versioned, and accompanied by withdrawal of the broader language. Program-level defeat can also arise when independently motivated bridges repeatedly fail and replacements cease to generate novel risky predictions (Laudan, 1977; National Academies of Sciences, Engineering, and Medicine, 2019).

Defeat also includes empirical-content exhaustion. If every independent bridge fails and each replacement merely explains the previous failure without predicting something new, the program loses scientific character. It may continue as philosophy, spirituality, or metaphor, but not as a live empirical research program with the same authority.

Report theory-level defeat clearly and calmly: identify the affected claim, the evidence behind the verdict, the findings that remain useful, and the materials and public statements that require correction.

2.6.6 — Dignity After Scientific Loss

Scientific loss changes a claim, not the standing of persons or the duties in Chapter 3. Public language should state exactly what survived: for example, a qualified measurement component can remain usable even if a mechanism is retired and terminal evidence remains inconclusive.

When the strong empirical program is defeated or retired, dependent tables, summaries, diagrams, and applied claims

should be corrected or withdrawn through the Chapter 28 process. Scientific status changes; care and dignity do not.

2.6.7 — Defeat as Knowledge Transfer

Defeat should change more than the label attached to a preferred hypothesis. It should transfer what was learned into the fields that made the loss intelligible. If conditioned paths explain an apparent closure signature, the result belongs to stochastic-process research; if allostatic regulation wins, it belongs to affective science; if observation shutdown produces the pattern, it belongs to missing-data methodology and clinical study design.

The transfer begins by separating what failed from what remains valid. A measurement instrument, humane burden protocol, endpoint-adjudication procedure, negative control, or model-recovery suite may remain useful even when the terminal target or a candidate route fails. Scientific loss can reduce one theory while enlarging the surrounding body of knowledge.

A rival victory must remain a rival victory. The preferred program may learn from the winning account, but it cannot absorb that explanation and preserve its former status. A successor theory needs a new identity, dependency map, and statement of what the earlier evidence no longer supports (Lakatos, 1978).

Defeat also creates correction duties. Diagrams, summaries, websites, teaching materials, and cross-volume references that imply a stronger status must be corrected or withdrawn. The record should state what failed, what remains useful, and how the burdens contributed by participants, clinicians, families, and staff will prevent repeated work or repeated harm.

Credit, citation, funding, and training should follow the result. Later work should cite the defeated model for the problem it clarified and the rival for the explanation that prevailed. If the decisive advances came from missingness models, palliative methods, endpoint adjudication, or conditioned-process theory, the next research investment should strengthen those capacities rather than preserve the identity of the losing mechanism. Resource allocation should therefore follow demonstrated explanatory and methodological value rather than institutional attachment to a favored theory. This helps ensure that defeat redirects scientific capacity toward the tools and questions that proved most informative.

A successor should begin with the loss. It should list abandoned claims, remaining validated tools, which rival explains best, unresolved uncertainties, and evidence required for a genuinely new hypothesis. Beginning from the defeat prevents continuity of name from disguising discontinuity of content. The successor should also identify which earlier results remain interpretable under the new framework and which require reanalysis. That separation prevents inherited evidence from quietly supporting a claim it was never designed to test.

Defeat may reveal a poorly framed problem. A terminal-closure program might find that the tractable object is the interaction among affective dynamics, endpoint selection, observation loss, and memory. Reframing is legitimate when declared as a new question and when unresolved discrepancies among instruments, cultures, clinical states, and endpoint classes remain visible. A useful reframing should make those discrepancies more testable

rather than merely absorb them into a broader theory. The new question earns attention by creating clearer empirical distinctions than the one it replaces.

Reusable scientific objects should stay attached to the claim they failed to support. Benchmark simulations, measurement-failure signatures, burden thresholds, endpoint criteria, and negative controls become more valuable when their provenance records which attractive path no longer deserves the same investment (Munafò et al., 2017; National Academies of Sciences, Engineering, and Medicine, 2019). Preserving that provenance also helps later researchers understand why a tool was created and which failure modes it was designed to expose. Reuse is strongest when the object travels with both its demonstrated utility and the limits revealed by the original test.

A successor may retain an instrument while rejecting the terminal law, preserve the intrastream unit while changing the endpoint claim, or keep the ethical infrastructure while replacing every realization. That inheritance is progress only when continuity and abandonment are explicit. A program earns trust by letting reality end a story without taking the science, care, or contributors down with it (Lakatos, 1978; Laudan, 1977). Scientific continuity should therefore reside in validated methods, transparent records, and durable safeguards rather than in preserving the identity of a theory. This allows useful knowledge to survive even when the explanation that originally motivated it does not.

Chapter 3 — Ethics and Scientific Authority

A science of lived experience is judged not only by what it can detect, but by what it refuses to make people carry. Ethical design is therefore part of epistemic design. A study that distorts care, pressures participation, erases privacy, or changes the very state it claims to observe can be both morally wrong and scientifically uninterpretable.

The governing order is simple: care comes before evidence. Clinical treatment, comfort, rescue, pain relief, family presence, lawful protection, and ordinary professional duties are never delayed to preserve a measurement window. The scientific record must be designed around that priority rather than asking participants to fit the record.

This principle governs study design and participant protection throughout the program. No experiment may induce suffering to create compensatory dynamics, manipulate a person toward an endpoint, delay care to observe an unaltered trajectory, or invite self-testing. A conditional balancing requirement is not moral payment or permission to cause harm, and no person owes the project a demonstration of the hypothesis.

Ethical research instead seeks naturally occurring variation, low-burden measurement, existing data, simulation, model recovery, noninvasive observation, and clinically indicated changes whose primary purpose remains care. The most valuable protocol may be the one that discovers how little additional burden is needed to answer a sharper question.

Terminal research receives the strongest comfort-first rule. The truth-level endpoint cannot be manufactured by a study, and the

protocol endpoint cannot govern bedside decisions. Sedation, analgesia, oxygen, repositioning, privacy, family access, and withdrawal of research procedures remain under clinical and participant authority (World Medical Association, 2024).

Consent must be ongoing rather than symbolic. A signature begins a relationship; it does not transfer ownership of a person's inner life. Capacity, comprehension, voluntariness, language access, fatigue, distress, medication effects, and changed circumstances may alter what continuing participation means.

Bystanders and families require independent protection. A participant's consent does not automatically authorize the capture of a spouse, child, caregiver, clinician, visitor, or household environment. Record routing must distinguish direct participant data from collateral information and offer removal, shielding, or noncollection routes.

Vulnerability is not a permanent label attached to a population. It can arise from illness, dependency, grief, detention, poverty, cognitive change, institutional hierarchy, language barriers, digital exclusion, or the pressure created by a trusted professional. Proportionate safeguards must respond to the mechanism of vulnerability rather than use the label as a substitute for design.

Independent review is necessary but not sufficient. Ethics committees, data and safety monitors, clinicians, participant advocates, privacy specialists, and community partners each see different failure modes. Their authority should be real enough to pause, modify, or end a procedure, not merely to endorse a

protocol at the beginning (Emanuel, Wendler, & Grady, 2000; International Council for Harmonisation, 2026).

Scientific authority is deliberately narrow. Researchers may report evidence about a declared component under stated conditions. They may not convert a latent estimate into a human-worth score, care priority, insurance decision, employment criterion, spiritual status, civic rank, or personal forecast. No archive, model, institution, or artificial system owns the participant's inner truth.

Return of results also requires discipline. Participants may deserve understandable aggregate findings, corrections, and clinically relevant information when a validated pathway exists. They should not receive speculative terminal-ledger interpretations, hidden classifications, or burdensome alerts that the science cannot support (National Academies of Sciences, Engineering, and Medicine, 2018).

These safeguards are not warning wallpaper. The chapter states the shared floor once, then ties each later protection to a concrete mechanism: a sensor that interrupts sleep, an endpoint that conflicts with care, a family member caught in a recording, a model that invites ranking, or a public artifact that reveals more than the protocol allowed.

The result is a more hopeful research program. When participants retain authority, clinicians retain professional judgment, and abstention remains publishable, the inquiry can pursue difficult questions without asking anyone to become expendable. Humane limits improve the chance that the evidence will deserve trust.

3.1 — Care Before Evidence

Care before evidence is the first operational law of this research program. The presence of a hypothesis never suspends the ordinary duties owed to a suffering person, and the research question cannot reinterpret a person's need for help as a temporary state whose later balance may excuse present neglect (Council for International Organizations of Medical Sciences, 2016; Emanuel, Wendler, & Grady, 2000; World Medical Association, 2024).

This section sets the floor beneath every later protocol. The floor is not mystical and not merely therapeutic. It is a rule about priority: clinical safety, shelter, crisis support, pain relief, communication access, and ordinary human presence come before data collection, endpoint clarity, or public explanation.

A theory about total lived burden is especially dangerous if it makes present burden seem provisional. *The Science of Fairness* must refuse that danger at the beginning. The moment a person needs care, the research question becomes smaller than the need before us.

This rule also preserves scientific integrity. A participant who is denied care, pressured to perform meaning, or asked to endure discomfort for signal clarity no longer belongs to an ethically interpretable study. The procedure has changed the phenomenon. The failure is not only moral; it is epistemic.

The familiar research-ethics language of respect, beneficence, and justice becomes sharper here. Respect means the person is not translated into the theory without permission. Beneficence means

relief and risk minimization outrank elegant inference. Justice means the costs of research do not fall most heavily on those least able to refuse.

Later chapters will discuss endpoint rules, candidate momentary and interval estimates, terminal signals, and rival models. This section says what all of them inherit: no result is worth less care, and no uncertainty about the Law weakens the duty to respond to suffering now.

3.1.1 — Present Suffering Is Present

Every protocol should contain a visible present-need trigger: acute pain, panic, breathlessness, confusion, fear, unsafe housing, hunger, exposure, abandonment, or any condition that makes data collection secondary. Staff respond to the need first, pause or stop research as required, and record the care event only to the extent consent and clinical governance permit. A possible terminal balance never reduces the urgency of present suffering; ignoring present need would be both ethically wrong and scientifically confounding (Council for International Organizations of Medical Sciences, 2016; Emanuel, Wendler, & Grady, 2000; World Medical Association, 2024).

3.1.2 — Clinical and Social Care Remain Prior

The priority of care is not limited to physicians or hospitals. Terminal research may occur in hospice, nursing homes, home care, shelters, family settings, or ordinary communities, where transportation, translation, food, housing, disability access, caregiver respite, safety planning, and crisis support can determine who can participate and what becomes observable.

These supports are ordinary protections, not research rewards or leverage; if study staff become the only route to them, both voluntariness and the data-generating context have changed.

Clinical care does not become secondary because a person enters a study. Physicians, nurses, chaplains, social workers, therapists, aides, family caregivers, and crisis workers do not become servants of the research schedule. Their obligations remain directed toward the person, not toward the elegance of the data.

The distinction matters because the Law of Fairness touches settings where research and care can easily blur. A terminal study may occur inside hospice. A measurement study may recruit from a clinic. A life-course study may observe people during hardship. In each case, participants must know that care is not contingent on participation and that refusal will not cost them help (International Council for Harmonisation, 2026).

The therapeutic misconception is not only a consent-form problem. It can be built into tone, setting, dependence, and hope. If a participant mistakes research participation for individualized clinical care or believes that refusing will reduce the care otherwise available, the consent process has not done its work. The protocol must separate research contact from clinical entitlement visibly enough that refusal remains real.

A care-prior design should include a care-independence statement, a refusal-protection route, and a staff escalation path. If the study uncovers unmet need, it routes the person to support without making that support a study benefit that pressures others

to enroll. Care discovered by research should still belong to the person, not to the recruitment strategy.

Clinical and social care remain prior because the study is not the highest institution in the room. The person's safety, comfort, voice, and material need come first. Research may observe and learn under that rule, but it may not reorganize care around itself.

3.1.3 — No Scientific Desert

Scientific desert also has a quiet institutional form. Reviewers may never say that a participant deserved pain, but a report can imply it by describing severe burden as an instructive case, a morally necessary endpoint, or an unusually useful trajectory. The safer language names exposure, condition, injury, loss, stressor, symptom, and context without converting them into earned states. In data dictionaries, adverse circumstances should be coded as conditions to protect and understand, not as morally meaningful ledger entries. This distinction matters because later statistical models may inherit the coding scheme. Coding exposure and context separately from personal attributes helps later analyses preserve that distinction.

Scientific findings must never be translated into desert. A pattern in data cannot show that someone deserved a burden, earned a loss, invited a disease, merited grief, or received pain as correction. The word fairness in this project does not authorize blame.

This distinction must be made early because visible suffering often invites moral causality. People ask why a child suffers, why a gentle person dies, why luck is uneven, and why grief falls

where it falls. The scientific volume cannot answer those questions by making victims responsible for pain or by treating suffering as evidence about desert (National Commission, 1979).

Even a future result favorable to the Law would not identify the moral meaning of any event. Section 3.7.1 states the conditional net-remainder arithmetic; here the ethical point is narrower: no illness, injury, deprivation, loss, or other event becomes deserved, earned, or justified.

Recruitment materials, consent scripts, public diagrams, and study reports should distinguish conditional balance requirements from a known personal balance or a moral account to settle. Participants are not recruited to prove that their burdens are justified. Study descriptions identify the measured trajectories, uncertainty, and limits of the proposed inference.

No scientific desert also protects staff and families. Researchers must not impose an explanation of a loved one's suffering, describe it as morally deserved, or use it to discourage care. Questions about PTVC can be answered through its conditional arithmetic and stated uncertainties without declaring anyone's actual balance or assigning a purpose to their pain.

The framework can reveal hidden burden without assigning blame for it. Its better use here is to ask who is carrying cost, who can refuse, who can be helped, and who is being asked to bear the burden of evidence. It does not rank the person who suffers.

3.1.4 — No Forced Meaning

No forced meaning applies to researchers as well as to family, clergy, media, and public readers. A bereaved parent, a patient

approaching death, a nurse after a difficult shift, or a survivor describing trauma may use language that is sacred, skeptical, angry, grateful, confused, or silent. The study may classify speech acts for analytic purposes, but it may not tell the person what the experience means. The most humane codebook includes a category for refusal of interpretation. The most honest public report can say that a pattern was observed without saying that a human being's pain completed a lesson. Scientific humility is not the absence of interpretation; it is the refusal to seize another person's inner authority.

Forced meaning asks a person who is already suffering to satisfy someone else's need for coherence. In a project about fairness, that transfer is especially dangerous because the theory can tempt observers to make narrative peace before the person has chosen any meaning at all. Comfort, refusal, silence, and plural interpretation remain legitimate (World Medical Association, 2024; Council for International Organizations of Medical Sciences, 2016).

Scientific language can force meaning when it presents a pattern as personal explanation. A terminal chart, a calm expression, a dream report, a silence, or a family anecdote must not be treated as the participant's final message. Evidence about a model is not authority over a life story.

This rule does not forbid participants from speaking. If someone chooses to describe meaning, regret, peace, anger, doubt, faith, resentment, or refusal, the research can record that statement under consent and context. The point is that the meaning belongs to the person, and the right to revise or withhold it remains.

Consent materials should therefore separate study explanation from existential interpretation. They can say what data may be collected, why the study exists, what risks are present, and what may be learned. They should not tell participants that their involvement gives their suffering a role in proving the Law.

No forced meaning keeps the science clean. It prevents researcher expectancy, family desire, spiritual pressure, and public storytelling from becoming hidden variables. The study can ask whether a pattern exists; it cannot decide what anyone's pain meant.

3.1.5 — Care Survives Every Verdict

Consent materials should state before enrollment that symptom relief, emotional support, communication access, withdrawal, and ordinary care continue under every analytic branch. Participants, staff, and families must never feel that comfort contaminates the study or that leaving threatens help. This separation protects dignity, voluntariness, and validity by removing pressure to perform a terminal story for the theory.

Care does not depend on scientific status. It remains when the strong form fails, a component survives, the study is inconclusive, or measurement collapses. Human beings receive care because their burdens matter before any theory succeeds, not because a model describes them correctly (Council for International Organizations of Medical Sciences, 2016; Emanuel, Wendler, & Grady, 2000).

The same independence applies after favorable or adverse results. No finding creates a class of lives more worthy of care, and no

cumulative estimate determines triage, clinical priority, or social support. Those decisions follow their own ethical and legal standards.

Care-independent planning should specify clinical support, crisis response, interpreter and transportation access, privacy, and ordinary communication with the care team without conditioning them on analyzable data or study completion. This reduces selection pressure and keeps research from becoming the price of help (World Medical Association, 2024).

When a claim narrows or fails, public and clinical records should carry a concise care-continuity consequence: treatment, support, privacy, and dignity remain in force because the hypothesis never licensed them. Negative results concern the claim, not the person's entitlement to relief.

Later science can therefore build and lose models under a prior commitment: the person in front of us is not waiting for the universe to certify their need. That independence is one of the clearest tests of whether care truly outranks claim status (Wendler & Grady, 2008).

3.2 — No Harm-Induction or Balance-Later Designs

A theory becomes most dangerous when it imagines that the decisive experiment is the one ethics forbids. For the Law of Fairness, the tempting forbidden experiment would be to create burden, withhold relief, manipulate the life-course, or watch deprivation unfold in order to see whether later experience balances. This section says no before the temptation acquires technical dignity (Council for International Organizations of Medical Sciences, 2016; Emanuel, Wendler, & Grady, 2000; National Commission, 1979; U.S. Department of Health and Human Services, 2018).

The refusal is not a retreat from science. It is a definition of admissible science. A research program can be rigorous without becoming cruel. It can study naturally occurring variation, clinical trajectories, observational data, optional low-burden devices, and ethically reviewed interventions designed for independent benefit. It cannot manufacture suffering for Law-specific inference.

The forbidden designs remain scientifically informative in one limited sense. They clarify what the project is not allowed to test directly and therefore force a better methodological route. When a clean but violent design is unavailable, the program must rely on prospective observation, natural experiments, careful rival modeling, simulation, model recovery, negative controls, and explicit uncertainty.

This distinction protects against a second danger: post hoc moralization of harm. A harmful event that occurs in the world

may become an object of study under consent and protection, but it does not become a good event because it provides data. The study did not earn the harm; it arrived after it.

Balance-later designs are rejected because they turn the theory into an excuse for present indifference. They ask one period of suffering to be justified by an imagined future offset. The science volume must use the opposite discipline: present burden counts now, and future data collection cannot erase how it was produced.

In research terms, harm induction also contaminates inference. Fear, deprivation, humiliation, untreated symptoms, and coercive stress alter physiology, reporting, adherence, attrition, and social behavior. The procedure would change the trajectory it claims to test while violating the person it claims to study.

3.2.1 — No Deliberate Suffering

No study may create or intensify pain, deprivation, trauma, fear, humiliation, social isolation, material insecurity, sleep disruption, clinical discomfort, or emotional distress for Law-specific evidence. Existing suffering may be observed under consent and protection, and independently justified beneficial interventions may be studied, but deliberately worsening a condition to create a balancing contrast is outside the program (Council for International Organizations of Medical Sciences, 2016; Emanuel, Wendler, & Grady, 2000; National Commission, 1979).

3.2.2 — No Withholding or Delay

Withholding can hide inside scheduling: a device fitting before medication, an interview before rest, a questionnaire before transport, or a recording window before family contact. No

protocol may delay treatment, rescue, comfort, analgesia, social assistance, safety planning, translation, clinical response, or material help for cleaner data. Whenever research and care compete, care comes first; the study records the intervention and models the resulting signal under humane care rather than preserving an untreated state (National Commission, 1979; U.S. Department of Health and Human Services, 2018).

Operationalize this rule with an escalation clock that names the distress trigger, responder, stopped procedure, and reporting route. A needed care event ends or changes data collection immediately. The resulting missingness or treatment effect is modeled as part of the observation process; any actual protocol deviation is still reported.

This rule also protects against inequity: participants with less power, language access, advocacy, or independence must not be the ones least able to interrupt a research schedule. In terminal or crisis settings, care and safety remain prior to measurement.

3.2.3 — No Unethical Path Manipulation

Life-course manipulation is the fantasy test that must remain forbidden. A researcher might imagine that extreme enrichment, deprivation, isolation, care intensity, or imposed repair would make the Law easier to evaluate. Such designs would corrupt the project at its root because they use lives as trajectories to be engineered rather than persons to be protected. Ethical science can study naturally occurring differences, policy changes, clinical pathways, and historical variation under careful confounding analysis. It cannot assign a person to suffer in order to see whether

later relief appears. A study may learn from the world's existing unfairness. It may not manufacture unfairness and then call the result evidence.

The Law's strong form concerns whole conscious trajectories, which makes life-course manipulation especially tempting and especially forbidden. No research program may engineer enriched and deprived lives, manipulate opportunity menus, alter family support, distribute hardship, or shape a person's path in order to see whether later experience balances.

This prohibition includes designs that would be unacceptable even if consent were claimed. A person cannot be asked to accept a deprived trajectory so a hypothesis can be tested. A family cannot be randomized into avoidable burden. A community cannot become the comparison arm for a civilization-scale claim (World Medical Association, 2024).

Ethically justified interventions may be studied when they have an independent care, social, clinical, educational, or supportive purpose. Their felt effects may be analyzed under an appropriate protocol, but the intervention is justified by its independent benefit, not by the Law; engineering suffering or withholding help to produce a balancing contrast remains prohibited.

Path manipulation also corrupts reference classes. A trajectory engineered for research would not reflect natural life-course dynamics, ordinary care, or voluntary adaptation. It would reflect behavior under artificial moral and institutional pressure, so its results would be hard to interpret even if ethics were ignored.

The program must therefore use ethically available variation: natural experiments, clinical pathways, longitudinal observation, consented diaries, low-burden measures, and independent support interventions. A world already full of unfairly distributed burden gives science enough to study without creating more.

3.2.4 — No Self-Experimentation Through Danger

Self-experimentation can look morally cleaner because the subject and investigator are the same person, but the risk is not solved by consent when the design is dramatic, illegal, self-harm-adjacent, or socially contagious. A public figure who endangers themselves to test the Law would create pressure on admirers, critics, and vulnerable readers to treat danger as devotion. The project must refuse that theater. Private journals, voluntary reflection, low-burden experience sampling, and ordinary health records can be useful when governed properly. Risk-taking as proof-seeking is different. It confuses courage with validity, and it invites a mythology in which pain becomes a research offering.

A public theory can tempt admirers or critics to perform dramatic self-tests. Someone may try to create extreme pleasure, extreme pain, risk, deprivation, intoxication, sleep loss, social humiliation, or dangerous endurance to see whether experience later compensates. This chapter rejects that pathway absolutely.

Self-experimentation does not become safe because it is voluntary. A person can be pressured by belief, pride, despair, public attention, group loyalty, or the desire to produce evidence. The project must not praise, publish, amplify, or interpret dangerous self-tests as research (Council for International

Organizations of Medical Sciences, 2016; Emanuel, Wendler, & Grady, 2000; National Commission, 1979).

This matters for public communication. A careless phrase about testing the Law in one's own life could invite ledger management or experiential extremes. The safer language is narrow: private reflection may be meaningful, but it is not evidence, and no one should seek pain, risk, deprivation, or crisis for the theory.

No-crisis recruitment belongs here. A person in grief, terminal fear, suicidal crisis, panic, spiritual emergency, financial desperation, or public humiliation is not an opportunity for dramatic data. They need help, privacy, and support. Research invitation, if any, must wait until refusal can be real and care is secure.

Approved studies provide independent oversight, justified measurement and endpoint definitions, protocol control, adverse-event response, and rival comparison. The project excludes dangerous self-testing and pursues its empirical questions through those approved studies.

The public rule is simple: do not hurt yourself or take risks to test the Law of Fairness. The science volume will not treat such acts as evidence, nor will the wider project honor them as courage.

3.2.5 — Forbidden Designs Stay Informative

The value of a forbidden design is analytic. It identifies a causal contrast that cannot be pursued directly and forces the program to specify the estimand, confounds, and humane alternatives needed to study it indirectly. The ethical boundary therefore sharpens the method rather than weakening the question.

For example, directly inducing suffering might appear to identify a later counterweight. Since that design is prohibited, the program must instead use observational contrasts, natural symptom fluctuation, care interventions with independent benefit, negative controls, and careful rival modeling. Those humane alternatives should be judged by the identification they actually support, with any remaining limits stated explicitly (National Commission, 1979; U.S. Department of Health and Human Services, 2018).

Similarly, withholding comfort might seem to preserve a natural terminal path. Since withholding is prohibited, the program must model treatment within the terminal process. Sedation, analgesia, family presence, clinical escalation, spiritual support, and withdrawal choices become modeled variables, not nuisances.

The same is true for path manipulation. Because the project cannot engineer lives, it must face selection, non-ergodicity, culture, disability, socioeconomic context, and missingness honestly. This keeps the program grounded in the conditions it can responsibly observe.

A forbidden-design register should travel with prospective specification. It tells reviewers and red teams which apparently decisive tests are excluded and why. It also prevents later public critics from claiming that the program avoided such tests because it feared the result. The answer is more principled: some knowledge is not worth obtaining that way.

Excluded designs can clarify methodological questions and motivate acceptable alternatives. The same exclusion applies to pilot studies, self-experiments, documentaries, and donor-funded

challenges. A noninvasive surrogate can answer a narrower contrast when its relationship to the excluded intervention is explicitly modeled.

A prohibited experiment can still define an identification boundary. If deliberate harm would be required to separate two mechanisms under otherwise identical conditions, the program should say that the causal contrast is unavailable rather than substituting a weaker observation and keeping the same verdict language. Natural changes, clinical variation, and carefully modeled observational data may narrow the possibilities, but the assumptions that connect them to the unavailable intervention must remain explicit (Manski, 2003; Hernán & Robins, 2020). The resulting bound can identify which additional naturally occurring variation would be informative.

Simulation can then ask what a safe design can learn before recruitment. Synthetic worlds can vary the hidden mechanism, observation loss, treatment changes, endpoint process, and burden-triggered stopping under the prohibition on induced suffering. If all ethically admissible designs fail to distinguish the candidate from its rivals, that result is not a reason to relax the ethical boundary. It is evidence that the proposed question is not presently adjudicable at the desired level (Box, 1976; National Academies of Sciences, Engineering, and Medicine, 2019). Comparing simulated confusion across observation schedules can then prioritize feasible designs before any participant is contacted.

3.3 — Comfort-First Terminal Research

Terminal research can contribute valuable knowledge about care, measurement, endpoint uncertainty, and observation when it is governed by comfort first. Palliative care remains the primary clinical purpose of the setting. The strongest scientific design treats symptom relief, family support, and clinical judgment as part of the process being studied, while keeping observation proportionate and participation voluntary (Council for International Organizations of Medical Sciences, 2016; Sanders et al., 2024; World Health Organization, 2020; World Medical Association, 2024).

Comfort-first terminal research keeps the person approaching death at the center of care. Their pain, breath, agitation, silence, preferences, family relationships, spiritual life, and refusal take priority over the study's need for completeness.

Sedation, delirium, organ failure, fatigue, medication, symptom control, family presence, cultural context, communication capacity, and device availability all shape terminal observations. Including them in the study's design and analysis connects the measurement model to the actual clinical setting.

Comfort-first design distinguishes among research activities. Quiet observation may have one burden. A wearable sensor may have another. A diary prompt, interview, bedside device, family questionnaire, or clinician workflow task may carry still another. Each must be justified separately and stopped separately.

The relevant burden is not only the participant's burden. Families may be grieving, guilty, fearful, exhausted, or protective. Staff

may be overloaded, morally distressed, or pressed by protocols against clinical judgment. A site may lack time, privacy, interpretation services, or technical support. These are design variables, not background noise.

A terminal protocol follows the participant's care and preferences. A request for quiet ends observation; device discomfort prompts removal; family overload pauses contact; and excessive staff burden triggers redesign. An endpoint that cannot be classified through those conditions receives a No adequate estimate result.

Table 3.1. Terminal-study burden and stop matrix.

Research activity	Participant burden	Family or staff burden	Scientific risk	Stop or redesign rule
Quiet chart review under governance	Privacy exposure through clinical context	Record-preparation and review workload	Incomplete context and selected documentation	Use only with purpose limitation and no individual inference beyond the record
Optional bedside sensor	Discomfort, sleep disruption, skin irritation, feeling watched	Placement, troubleshooting, removal requests, family anxiety	Sensor gain collapse, device removal, adherence bias	Remove immediately on discomfort, distress, clinical interference, or staff overload

Research activity	Participant burden	Family or staff burden	Scientific risk	Stop or redesign rule
Brief participant interview	Fatigue, emotional strain, privacy loss	Scheduling and support burden	Response shift, demand characteristics, selective reportability	Shorten, postpone, or stop when fatigue, distress, or preference requires
Family or caregiver report	Grief burden, guilt, interpretive pressure	Family time and emotional labor	Proxy error, meaning projection, family script bias	Use only as contextual proxy with consent and never as final inner life authority
Clinician classification	None directly if integrated into care notes	Additional charting, moral distress, workflow strain	Observer expectancy, treatment linked confounding	Limit to clinically natural documentation or compensate staff time and monitor burden

3.3.1 — The Dying Person Owes No Result

A person approaching death owes the study no result. Silence, withdrawal, sleep, distress, loss of signal, changed capacity, a request for family only, or any care priority may end observation and produce a protected no-estimate branch. Neither family interpretation nor model output may be substituted for a missing participant channel, and a missing terminal record must not be

personalized as fear, imbalance, or failure (Council for International Organizations of Medical Sciences, 2016; World Medical Association, 2024).

3.3.2 — Palliative Care Outranks Measurement

A palliative-care priority is not merely the absence of interference. It means the protocol is designed around clinical response, not clinical response around the protocol. Device placement should yield to positioning, hygiene, pain control, oxygen, family presence, spiritual care, privacy, and rest. Questionnaires should yield to fatigue. Recording schedules should yield to symptom crises. The study may record that care changed the observation process, but it may not ask care to wait while data remain clean. The burden of measurement must be carried by the research design, never by the dying person's body or the staff's uncounted labor.

Palliative care is not a confound to be minimized for theory. It is the governing clinical duty in terminal research. Analgesia, sedation when clinically indicated, symptom relief, psychosocial support, spiritual care, family presence, and comfort measures follow patient need and clinical judgment, not protocol convenience.

The consequence is methodological as well as ethical. A protocol cannot ask clinicians to hold medication constant for signal clarity when symptoms require change. It cannot ask staff to delay a comfort intervention so a measure can be collected first. It cannot ask families to postpone presence or ritual to preserve a data

window (World Health Organization, 2020; World Medical Association, 2024).

Instead, the research design records care as part of the observed trajectory. Medication changes, sedation depth, delirium episodes, oxygen support, repositioning, family visits, clinician interventions, and device removals become time-stamped context where consent permits. They are not failures of nature. They are real terminal conditions.

The design must also accept that palliative care can make certain inferences impossible. If a person is deeply sedated for comfort, the study may lose direct self-report. If delirium fluctuates, the study may lose stable interpretation. If a device is removed because it irritates the participant, the time series ends. No-estimate is a legitimate result.

Palliative priority should appear in site training. Research staff must know whom to call, when to leave, how to respond to distress, and how to explain that the study has no authority over care. Clinicians must know they are free to act for comfort without asking permission from the research team.

Example: during a scheduled prompt, a participant develops acute breathlessness. The nurse stops the prompt, removes any interfering device, provides clinically indicated treatment, and asks research staff to leave. The interruption is recorded as care-priority, not participant deviation; the missing interval is not imputed as calm, distress, or neutrality (World Medical Association, 2024; International Council for Harmonisation,

2026). Event details are retained only to the extent permitted by consent and clinical policy.

If the participant later asks to resume, the study reconfirms consent, checks that burden remains proportionate, and records changed medication and observation conditions as a new segment. If participation does not resume, the analysis follows its predeclared partial-information or no-estimate branch rather than substituting family testimony for the lost channel.

The site then asks whether the event exposed a design defect: repeated device interference, poorly timed prompts, or unmanageable staff load triggers redesign or paused enrollment. Care-first becomes scientifically credible when it changes both the procedure and the analysis exactly as the protocol says it will (Sanders et al., 2024; World Health Organization, 2020).

3.3.3 — Sedation and Delirium Are Clinical Realities

Sedation and delirium are not nuisances to be subtracted after the fact. Both are part of the terminal clinical context; proportionate sedation may be part of humane care, while delirium is a clinical condition requiring assessment and appropriate management. A study that excludes them too easily may select for a false picture of dying; a study that includes them without modeling them may mistake treatment, physiology, or reportability for a ledger signal. The right posture is classification with humility. Sedation depth, indication, medication timing, delirium assessment, communication capacity, pain crisis, oxygenation, infection, metabolic instability, and family interpretation all belong in the

observation model. A low-signal endpoint does not become meaningful because the theory needs a signal.

Sedative exposure, sedative effect, delirium, and reduced reportability are not interchangeable variables. Dose, timing, indication, prior tolerance, organ function, symptom crisis, paradoxical agitation, fluctuating attention, and motor suppression can alter channels in different directions. A protocol therefore models treatment and state transitions separately, records uncertainty in each classification, and abstains when the available channels cannot distinguish diminished expression from diminished experience (International Council for Harmonisation, 2026; World Medical Association, 2024).

A weak protocol treats sedation as a nuisance variable and delirium as noise. A stronger protocol specifies both as clinically meaningful intercurrent states, records their timing and indication, and declares which inferences remain admissible. Deep sedation may leave some physiological observations while defeating claims about conscious valence. Delirium may carry distress while defeating stable questionnaire interpretation. The result is not forced into a clean trajectory; the permitted inference changes, narrows, or becomes unavailable (International Council for Harmonisation, 2019; International Council for Harmonisation, 2026).

A terminal observation model distinguishes changes in clinical sedation, neurological state, device availability, reportability, and sensor performance. Estimating these processes helps interpret why a measured signal changes near the endpoint.

Delirium requires special humility. Agitation, hallucination, fear, confusion, withdrawal, or muteness can be overinterpreted by observers seeking meaning. The protocol should protect families from being asked to decode every expression and protect clinicians from research pressure to assign theoretical significance to clinical signs.

Sedation and delirium also affect missingness. Participants in low-signal states may drop out of self-report, fail device adherence, or become noncommunicative. If the study excludes those periods silently, it may select only the most reportable endings. If it includes them without qualification, it may interpret absence as calm. Both errors are preventable only if the observation model is honest.

The safest rule is status labeling. Every terminal segment should be labeled by consciousness confidence, reportability, treatment context, sensor availability, and inference permission. Some segments support only care description. Some support measurement feasibility. Some support component analysis. None supports more than the labels allow.

3.3.4 — Family and Staff Burden

Family and staff burden should appear in the protocol budget before recruitment begins. A bedside study may ask relatives to tolerate equipment, answer questions, interpret preferences, manage visitors, protect privacy, and carry the emotional weight of being watched while losing someone. It may ask nurses, aides, chaplains, interpreters, physicians, and social workers to add research tasks to already saturated work. If those burdens are

unmeasured, they reappear as missingness, protocol deviations, recruitment failure, moral distress, and staff turnover. Counting them is not administrative overhead. It is scientific responsibility directed toward the production of knowledge itself.

These pathways should enter operations records as measurable process variables. Prompt delay, skipped classifications, device removal, staffing ratios, overnight response time, protocol pauses, and reasons for missed contact can reveal when site workload changes the observation process. The aim is not to score staff performance; it is to distinguish latent change from workflow-induced visibility change (Little & Rubin, 2019; Rubin, 1976).

Families may feel that participation honors the person, helps future patients, pleases clinicians, proves something sacred, or avoids regret. Those motives can coexist with genuine consent, but they can also become pressure. Recruitment and continuing consent should make clear that stopping is not betrayal and nonparticipation is not failure (Council for International Organizations of Medical Sciences, 2016; Wendler & Grady, 2008; World Medical Association, 2024).

Clinical and research staff time has to be counted explicitly. Nurses, aides, physicians, chaplains, social workers, and coordinators already work under pressure. Devices, forms, reminders, family explanations, incident reports, and endpoint classifications can alter care even when each task seems small. A protocol that depends on invisible labor has not established feasibility.

The site should therefore maintain a burden budget for staff and family contact. It should track time added per shift, missed tasks, after-hours calls, emotional strain, technical failures, and complaints. When burden exceeds a preset limit, the protocol pauses or shrinks rather than asking people to absorb it.

Family and staff burden also affect external validity. A protocol feasible at a highly resourced academic hospice may fail in a small facility, a rural home-care setting, a crowded ward, or a community with different language needs. The result should not travel farther than the burden conditions allow.

A comfort-first terminal study honors family and staff by treating their burden as real knowledge. Not every cost belongs to the participant alone. Terminal research must identify who carries hidden work and answer for the work it creates.

3.3.5 — Stop, Withdraw, and Remain Silent

The right to silence is especially important because this project studies felt experience. A participant may stop speaking because of fatigue, fear, medication, privacy, dignity, spiritual practice, distrust, or simple preference. The study cannot presume that silence is data in the direction it wants. A no-inference state should be available whenever the communicative channel fails for reasons the protocol cannot ethically resolve. Withdrawal should be fast, nonpunitive, and possible through the participant, an authorized surrogate within limits, or a clinical stop order when participation burdens care. The research record may preserve the reason for stopping; it may not turn the stop into a hidden endpoint story.

A terminal protocol must make stopping easy. The right to withdraw cannot be buried in a consent form, spoken once, and then surrounded by gratitude, urgency, devices, staff effort, and family hope. Withdrawal must remain available, visible, and free from interpretation.

Stopping can occur for discomfort, fatigue, privacy, family request, staff workload, clinical change, loss of capacity, distress, device irritation, spiritual preference, data-security concern, or no stated reason. The protocol does not require a morally adequate explanation. The participant or authorized route may simply say no (Council for International Organizations of Medical Sciences, 2016; International Council for Harmonisation, 2026; World Medical Association, 2024).

Remaining silent is also a protected choice. A participant may decline interviews, decline meaning questions, decline final messages, decline dream sharing, decline family interpretation, or decline public quotation. Silence should not be coded as denial, imbalance, fear, or evidence. It is often the most dignified form of agency left.

Withdrawal raises data questions. The consent process should state what happens to already collected data, what can be deleted, what cannot be withdrawn because it has been aggregated or legally retained, and whether derived analyses can remain. Those distinctions must be understandable before the terminal period, not negotiated during crisis.

A stop rule must also be independent of investigator disappointment. If a participant withdraws near a valuable

endpoint, the study loses the endpoint. If a site pauses because staff burden is too high, the study loses the site temporarily. If a family declines further contact, the study loses context. These losses are not failures of cooperation; they are ethical facts. The analysis plan should anticipate these losses so that investigators do not face incentives to reinterpret withdrawal or burden after seeing its effect on statistical power. Ethical stopping is most credible when its scientific consequences are accepted in advance.

A research program earns trust when it can preserve silence and still publish honestly. It should be able to say: the endpoint was not observed; the inference was not made; the person remained protected. Reporting protected absence as an outcome also makes the study's evidentiary boundary visible to readers. What was not observed should remain distinguishable from what was observed and found neutral.

Silence must be represented as a governed outcome rather than interpreted as neutral experience. A missing report near the endpoint may reflect sleep, comfort, fatigue, delirium, sedation, device removal, clinical urgency, refusal, or loss of capacity. The study should preserve those possibilities in the observation record and return no estimate when they cannot be separated. Imputing peace from nonresponse would turn a humane stop into a favorable result (Little & Rubin, 2019; World Medical Association, 2024). Where feasible, the record should distinguish known reasons for nonresponse from genuinely unresolved missingness without inferring the participant's unobserved

experience. That distinction improves later sensitivity analysis while preserving the no-inference rule.

Independent stop authority is equally important. Participants, authorized representatives where applicable, bedside clinicians, palliative teams, and designated research monitors need practical routes to pause or end observation without negotiating with the hypothesis owner. The stop should take effect before analytic value is weighed, and the reason should be recorded at the level needed for safety and feasibility without demanding intimate explanation. A study that can stop cleanly is not weaker. It is better designed for the realities it claims to study (Council for International Organizations of Medical Sciences, 2016; International Council for Harmonisation, 2026). Stop authority should also be operationally reachable at the moment it is needed, including outside ordinary research hours when terminal care continues. A safeguard that exists only on paper cannot reliably protect either participants or the integrity of the resulting evidence.

3.4 — Consent, Privacy, and Bystander Protection

Consent in this volume is granular because the research object is intimate. Lived-experience data may include self-report, physiology, behavior, clinical records, device streams, family context, staff observations, language, location, sleep, medication, disability accommodation, and terminal circumstances. A signature records agreement at one time; it does not by itself establish comprehension or authorize every later use (Council for International Organizations of Medical Sciences, 2016; National Commission, 1979; Tam et al., 2015; U.S. Department of Health and Human Services, 2018).

Consent as a single event fails when data travel. A participant may understand a bedside interview but not future linkage, accept sensor monitoring but not publication of excerpts, permit coded sharing but not Artificial Intelligence training, or withdraw after derived results exist. The design therefore separates permission states, explains what withdrawal can still change, and tests comprehension of the uses that carry the greatest risk.

Privacy also extends beyond the enrolled participant. Family members, staff, roommates, household members, visitors, community members, and clinicians can appear in data through speech, proximity, relationships, or context. They can carry burden without ever being recruited. That is bystander burden.

Research often hides its own transfers. A study may collect data from one consenting participant while shifting exposure onto a spouse, a child, a nurse, a translator, or a community. The consent form may appear complete while the data ecology is not.

This section therefore treats data dignity as a lifecycle. Permission is given for a use, not for all possible uses. Access is limited by purpose. Retention has an end or a justified retention route. Deletion and withdrawal are explained honestly. Derived results are handled with humility. Future reuse and model training require their own governance.

The result should be a consent architecture that is specific enough to protect people and stable enough to support science. A dataset whose permission is vague is not a stronger dataset. It is a liability waiting to distort trust, recruitment, participation, and public interpretation.

Table 3.2. Data-use lifecycle, permissions, and correction routes.

Stage	Required question	Permission or governance route	Exit or correction mechanism
Collection	What exact data answer the stated question?	Specific consent or approved narrow waiver with minimization	Refuse, pause, or collect less without losing care
Linkage	Which external records are necessary and why?	Separate linkage permission and purpose review	Decline linkage or sever future linkage where feasible
Storage	Who can access the data and for how long?	Role-based access, logs, retention schedule, security review	Correction, access audit, incident response, scheduled retirement

Stage	Required question	Permission or governance route	Exit or correction mechanism
Analysis	What estimand and model use are authorized?	Approved analysis plan and version control	Analysis stop when consent, data quality, or burden gate fails
Sharing	Who receives data and under what constraints?	Data-use agreement, repository review, bystander risk assessment	Withdraw before sharing where feasible, restrict or recall after breach
Publication	What can be shown without exposing persons?	Public artifact review and identification-risk check	Remove, revise, or correct public material when risk or error appears
Future reuse or Artificial Intelligence training	Is the new use materially different?	New consent or governance approval; no automatic conversion	Decline, retire data, prohibit model use, document derived-result limits

3.4.1 — Specific Consent by Use

Use-specific consent should be written as a menu with consequences, not as a dense legal wall. Observation, wearable data, audio, video, clinical-record linkage, family interviews, staff notes, deidentified sharing, publication of examples, future secondary analysis, and Artificial Intelligence training differ in identifiability, sensitivity, reversibility, and social risk. A participant who agrees to one does not agree to all. The protocol

should track permissions in a versioned consent state, not merely in a scanned form. If a later analysis wants a use that was not clearly permitted, the default is renewed permission or abstention, not clever reinterpretation of the original consent.

This specificity protects autonomy. A participant can say yes to a low-burden observation and no to open data sharing. They can allow coded clinical linkage and refuse identifiable quotations. They can permit an analysis for the stated study and decline downstream model training. The study remains viable because consent has options rather than pretending refusal must be all or nothing (Council for International Organizations of Medical Sciences, 2016; National Commission, 1979; National Institute of Standards and Technology, 2020).

Specificity can improve both autonomy and data quality. Participants who understand the use, limits, and withdrawal route can make more stable choices and report concerns earlier. Evidence from clinical trials shows that signatures do not guarantee understanding, so comprehension must be checked in a proportionate way rather than presumed from completed paperwork (Tam et al., 2015).

Artificial Intelligence training needs its own explicit route. A participant who agrees to a research estimate has not granted permission for a model to learn from their text, voice, physiology, or clinical context in ways that may be hard to trace. De-identification alone is not a moral solvent.

Publication is likewise distinct. A chart, graph, quote, case vignette, or public artifact can expose meaning even when names

are removed. Consent should describe what kinds of material may appear publicly and what review or withdrawal opportunity exists before publication where feasible.

The rule is straightforward: each data use must have a lawful and ethical basis, a participant-facing explanation, a refusal route, a governance owner, and a consequence for misuse. Consent that cannot name the use is not consent to that use.

3.4.2 — Capacity and Ongoing Consent

Capacity fluctuation creates a temporal ethics problem. A participant may consent while lucid, become delirious, regain clarity, become fatigued, or communicate only through supported methods. The study must decide in advance which activities require contemporaneous assent, which may continue under a prior directive, which require surrogate confirmation, and which must stop when active dissent appears. A legally authorized representative is not a theory representative. The surrogate's role is to protect the participant's known wishes and interests, not to help the research program reach completion. When capacity returns, the participant's current voice should re-enter the consent relationship as soon as practicable.

Capacity can change over time, especially in terminal, neurological, psychiatric, pediatric, traumatic, or heavily medicated settings. A person may understand the study at enrollment and later become confused, fatigued, sedated, delirious, or unable to communicate. The consent system must be designed for that movement.

Ongoing consent does not mean constant interrogation. It means periodic, proportionate confirmation that participation still matches the person's preference, understanding, and capacity. A low-burden reminder, a simple stop card, a device-removal option, a family-notification rule, or a re-consent checkpoint may be appropriate depending on the study. Evidence that participants often misunderstand material trial information makes comprehension an object to assess, not a box inferred from a signature (Council for International Organizations of Medical Sciences, 2016; Tam et al., 2015; U.S. Department of Health and Human Services, 2018).

Surrogate permission is limited. A legally authorized representative may sometimes permit research under law and review, but the surrogate cannot turn the participant into a proof object. They cannot authorize avoidable harm, comfort delay, humiliating exposure, public meaning, or uses outside the approved purpose. The participant's known preferences and present signs of resistance matter.

Assent and dissent deserve special weight when full legal consent is unavailable. A person who cannot sign a form may still show discomfort, refusal, agitation, withdrawal, or fatigue. Those signals should be treated as participation data only after they are treated as possible refusal. In many cases, they end the procedure.

Re-consent is required when material facts change. A new data use, a new repository, a new model-training plan, a changed device, a more burdensome schedule, an unexpected privacy risk, or a new publication mode should not ride on the old agreement. A changed bridge is a changed permission problem.

Ongoing consent is the temporal form of respect. It recognizes that a conscious stream is not a frozen legal moment and that the burden of participation can change as the person's body, mind, relationships, and risks change.

3.4.3 — Operational Participation Is Not Research Consent

Participation in care, civic life, employment, religious practice, ordinary-life tools, public services, or any applied project is not research consent. Operational records do not become scientific data merely because they are interesting. Public access does not become model-training permission merely because a record can be scraped.

This rule is crucial across the series. *The Science of Fairness* may receive questions from other domains, but it may not convert their records into candidate momentary and interval estimates or terminal evidence without a separate research route. A city record, government service log, note or form from a religious community, Workgame artifact, or transition support file is not a measured cumulative estimate (U.S. Department of Health and Human Services, 2018; Wendler & Grady, 2008).

Operational data are collected for operational purposes. A clinic notes symptoms to care for a patient. A service office records eligibility to route help. A public institution stores a decision to make authority reviewable. Those purposes do not silently authorize scientific inference about inner life.

The difference protects nonparticipants. A person may accept care, submit paperwork, attend a ceremony, contact support, or

use a tool without enrolling in a study. They should not have to avoid ordinary help in order to avoid becoming research material.

If operational data are ever proposed for research, the protocol must pass a conversion gate: purpose compatibility, legal basis, consent or waiver justification, privacy review, de-identification humility, bystander analysis, data minimization, and no-score discipline. Many proposed conversions should fail.

Operational participation is not research consent because burden follows purpose. A record made to help a person should not later carry the burden of proving a theory unless the person and the governance route have specifically allowed it.

3.4.4 — Bystanders and Relational Data

Bystander data are not marginal in this program because lived experience is relational. A participant's record may contain a spouse's grief, a child's voice, a nurse's judgment, a roommate's routine, a family conflict, a chaplain's visit, a household address, or a community marker. The study must decide which relational information is necessary, how it will be masked or excluded, when bystander permission is required, and when the analysis must abstain because privacy cannot be protected. A person should not become research material merely because they loved, treated, lived near, transported, translated for, or appeared beside someone who enrolled.

Bystander protection begins with recognition. The protocol should map who may be captured around the participant and what kind of information could be revealed. It should distinguish unavoidable contextual presence from deliberate collection about

others. It should minimize relational exposure whenever possible (World Medical Association, 2024; Council for International Organizations of Medical Sciences, 2016; National Commission, 1979).

Family reports require particular care. A caregiver can provide valuable context, but they may also experience guilt, grief, pressure, hope, exhaustion, or conflict. Their report is a relational act, not a transparent window into the participant's inner life. It needs consent, framing, and limits.

Staff data also matter. Clinical notes, workflow records, and classifications can expose staff conduct, emotional burden, or institutional pressures. Staff should not be reduced to instruments without labor acknowledgment, privacy consideration, training, and reporting channels.

Relational data raise publication risk. A de-identified vignette can still reveal a family, community, diagnosis, site, or conflict. The more unusual the case, the higher the identification risk. Narrative power is not an excuse for relational exposure.

The bystander rule is a fairness rule: a person may consent to carry research burden for themselves, but they cannot unilaterally donate the privacy of everyone around them. The study must protect the ring of people who can be made visible by another person's participation.

3.4.5 — Minimization, Retention, and Deletion

The retention plan should explicitly cover derived features, analytic code, and consent records. For each object, name the

retention or deletion reason, who may request action, the review authority, and the record left after deletion.

Data minimization asks a simple question before collection begins: what is the least information that can answer the defined scientific question under the approved use? It rejects the habit of collecting everything because future models might find patterns. A project about hidden burden should not create unnecessary data burden.

Retention requires a reason and a clock. Some data may need to remain for audit, replication, safety reporting, or correction. Some should expire. Some should be destroyed when a participant withdraws. Some derived results may remain only in aggregate or locked form. The participant should not have to guess which category applies (National Commission, 1979; National Institute of Standards and Technology, 2020).

Deletion is not always technically or legally simple, and the consent process should not promise what cannot be delivered. It should distinguish raw identifiable data, coded data, de-identified datasets, aggregate statistics, published results, trained model weights, audit logs, and safety reports. Each has a different withdrawal and deletion pathway.

Data retirement is more than deletion. A dataset can become obsolete because an instrument version fails, a consent route is found inadequate, a privacy breach occurs, a population was unfairly recruited, or a model is retired. Retired data should not continue traveling through public artifacts or later analyses as if nothing happened.

Access control is part of minimization. Fewer people should see sensitive data, and each access should have a purpose, role, log, and review route. Curiosity, convenience, donor interest, public excitement, or inter-book usefulness are not access purposes.

3.4.6 — Privacy as a Dynamic Relationship

Privacy risk changes during a study. A data element that appears harmless at collection may become identifying when combined with location, medication, family timing, voice, device telemetry, or a rare clinical trajectory. Governance therefore cannot be exhausted by a one-time classification of identifiers. It must revisit what the dataset can reveal as linkages, models, and external information change.

The relevant unit is often relational rather than individual. A participant's report may reveal that a spouse was present, that a caregiver missed work, that a clinician changed medication, or that a child witnessed a crisis. Those people may never have enrolled, yet their lives become inferable through the participant's record. Data minimization should ask not only what was collected about the participant, but what can be learned about others.

Access is divided by purpose. Collection staff may need contact information. Clinicians may need safety alerts. Analysts may need coded observations. Public repositories may receive only a carefully reviewed derivative. Artificial Intelligence training, commercial reuse, and public release are separate uses, not automatic extensions of research consent. A broad permission cannot carry every future purpose without becoming functionally meaningless (Council for International Organizations of Medical

Sciences, 2016; National Institute of Standards and Technology, 2020; U.S. Department of Health and Human Services, 2018).

Technical controls require accountable roles. Encryption, access logs, secure computation, and de-identification need someone responsible for key custody, approval, anomaly review, revocation, and incident response. Naming tools without decision-makers hides authority behind infrastructure.

Inference risk should be tested adversarially. Teams can attempt re-identification, membership inference, linkage, attribute inference, and extraction from released models or summaries. The goal is not to prove that privacy is perfect. It is to discover which releases create unacceptable pathways and to redesign or withhold them before participants bear the consequence.

Retention should follow scientific need rather than institutional habit. Preserve data as needed for correction, replication, or regulatory obligations; aggregate, transform, or delete them when their purpose ends. Distinguish raw, derived, analytic, and public artifacts in the retention schedule because their value and risk differ.

Correction is part of privacy: inaccurate records can travel farther than disclosed ones. Participants need a route to report errors in identity, context, medication, consent state, or interpretation. Record whether corrections change metadata or analysis, require public notice, or invalidate prior artifacts. Silence cannot correct propagated errors.

Privacy bounds authority. Data held for declared research grant no ownership of a person's inner life or permanent claim on the

record. Legitimacy requires visible purpose, access, contestability, exit, minimization, retention, and deletion.

Map collection, derivation, access, retention, reuse, bystander exposure, and deletion or withdrawal limits. Retained records must remain worth their participant and relational risks (Council for International Organizations of Medical Sciences, 2016; World Medical Association, 2024).

3.5 — Vulnerability, Assent, and Research Proportionality

Vulnerability is not a defect in a person. It is a relationship between a person's situation and the power of a research request. Illness, dependence, poverty, age, disability, institutional status, crisis, language barriers, incarceration, immigration fear, employment hierarchy, clinical reliance, and spiritual pressure can make refusal harder (Council for International Organizations of Medical Sciences, 2016; Emanuel, Wendler, & Grady, 2000; World Medical Association, 2024).

This section does not solve vulnerability by excluding vulnerable people from research. Exclusion can also be unfair when it removes people from studies meant to understand their needs. The problem is not presence. The problem is extraction, pressure, inaccessible communication, and burden that the protocol fails to count.

Participation constraints become validity constraints. If only the healthiest, most supported, most articulate, and most trusting people can enroll or remain, the study describes a selected group. Unequal effort requirements amplify that selection, and costly refusal weakens the meaning of consent.

The design burden therefore rises where refusal is fragile. Materials must be accessible. Aid must not be contingent. Assent must be respected. Surrogates must remain limited. Staff and participant burden must be budgeted. Monitoring intensity must be justified. Recruitment must avoid crisis and desperation.

The causal structure is explicit: research procedures can change the outcome. Monitoring burden can change sleep and physiology. Consent pressure can change expectancy. Clinician behavior can change care. Family anxiety can change the bedside. Staff workload can change adherence. Missingness can concentrate among those most burdened.

A serious protocol therefore specifies prospective participation and workload endpoints before enrollment. It tracks fatigue, distress, time, privacy concern, family involvement, staff workload, device discomfort, and withdrawal patterns. Predefined thresholds trigger pause, redesign, or termination before protocol strain becomes hidden evidence.

Table 3.3. Research-burden causal pathways and design controls.

Research element	Immediate burden pathway	Data-generating consequence	Required design control
Monitoring schedule	Sleep interruption, device awareness, privacy worry	Changed physiology, altered affect report, selective adherence	Minimize schedule, monitor discomfort, allow instant removal
Consent and recruitment language	Expectancy, obligation, prestige, fear of refusal	Demand effects, selective enrollment, underreported distress	Neutral scripts, independent consent support, refusal protection

Research element	Immediate burden pathway	Data-generating consequence	Required design control
Clinician awareness	Treatment timing, extra attention, hesitation, documentation change	Care-path confounding and site effects	Separate care and research roles; record care changes
Family involvement	Anxiety, guilt, interpretation pressure, conflict	Proxy bias, altered bedside environment, missingness after distress	Family burden budget, opt-out, contextual labels
Staff workload	Protocol fatigue, rushed measurement, moral distress	Nonadherence, incomplete data, selective site continuation	Staff time accounting, workload stop threshold, support routes
Public artifact anticipation	Fear of exposure or symbolic use	Self-censorship, withdrawal, public-risk bias	Embargo, artifact review, no individual meaning claims

3.5.1 — No-Desperation Consent

No-desperation consent is violated when research becomes the practical route to care, money, housing, attention, belonging, protection, or hope. The protocol must separate services from enrollment, provide nonresearch routes to support, make refusal visibly safe, and keep compensation proportionate to time and cost rather than need. A person in hardship may consent, but saying no must leave that person no worse off.

Payment and support require care. Reimbursement for time, travel, childcare, communication access, or lost wages can make participation more equitable. Excessive inducement can make refusal less real. The distinction depends on context, income, need, dependence, and the stakes of the study (Council for International Organizations of Medical Sciences, 2016; Emanuel, Wendler, & Grady, 2000; Wendler & Grady, 2008).

Desperation can also be social. A participant may want to please a clinician, a community leader, a religious guide, a family member, a donor, or a public movement. Consent materials should make refusal ordinary and protected, not heroic or disloyal.

Recruitment should avoid language that frames participation as helping prove the Law, advancing humanity, honoring suffering, or joining a special circle of truth. Those phrases convert belief and belonging into pressure. A safer invitation names the study, the burden, the limits, and the right to decline.

No-desperation consent also requires independent care routes. If unmet need is identified, the person should receive appropriate referral or support whether or not they enroll. The research team should not be the only visible door to help.

Voluntariness becomes concrete at the point of refusal. A person must be able to decline or withdraw without losing care, housing, employment, immigration support, spiritual belonging, or any other needed relationship. If that assurance cannot be made credible, the protocol is not ready. Under such pressure, the data may reflect dependence rather than genuine willingness.

3.5.2 — Children and Assent

Research with children and adolescents requires age-appropriate explanation, assent where developmentally possible, meaningful dissent protection, and guardian permission. Their developing agency, dependence on adults, and sensitivity to authority call for a stricter burden threshold. The question must address a child-specific care need or knowledge that cannot responsibly be obtained from adults, with clear justification for the benefit or knowledge sought. Low-risk developmental measurement uses accessible communication and protects the child's freedom to form their own interpretation of the research.

Guardian permission is not enough. Age-appropriate assent, dissent, comfort, comprehension, and communication matter. A child may not understand the abstract hypothesis, but can often understand whether a device hurts, whether a question feels frightening, whether they want to stop, or whether they prefer privacy. The protocol must treat those responses as present authority, not as inconvenient noise beneath adult permission (Council for International Organizations of Medical Sciences, 2016; U.S. Department of Health and Human Services, 2018; Wendler & Grady, 2008).

Children should not be asked to carry existential language. Consent and assent materials should avoid telling a child that their feelings help test whether life is fair. The child's role, if any, should be described in concrete and modest terms: a study of sleep, mood, comfort, communication, or measurement feasibility.

Developmental differences also affect data interpretation. Children's self-report scales, affective expression, language, caregiver reports, neurodevelopmental context, and medical status differ from adult measures. A result in children cannot be imported into the adult claim without calibration and reference-class caution.

Assent is ongoing. A child who tolerated a procedure yesterday may not tolerate it today. Fatigue, illness, developmental stage, family stress, and clinical changes can alter willingness. Stopping should be easy, immediate, and free from adult disappointment.

The chapter's rule is protective but not erasing. Children can be included ethically in research that addresses their needs and respects their voice. They cannot be recruited to make a grand claim emotionally irresistible.

3.5.3 — Disability and Communication Access

Disability access determines who can participate and whose experience enters the evidence. Include nonverbal response routes where needed, and do not substitute a support person's convenience for the participant's will.

Disability and communication difference must not be mistaken for lack of experience. A person who cannot speak fluently, move easily, complete a standard scale, tolerate a device, read a form, or respond at expected speed may still have rich lived experience. Measurement difficulty is not ontological absence.

Accessible research begins before enrollment. Materials may require plain language, sign language, augmentative communication, large print, screen-reader compatibility,

translation, flexible timing, sensory accommodation, participant-chosen support, and non-digital options. Accessibility is part of construct validity because an instrument that excludes or distorts communication cannot claim to measure the same target across participants (International Test Commission, 2018; National Institute of Standards and Technology, 2020).

A protocol that excludes people because they are hard to measure may create a false reference class. The study might then describe only articulate, mobile, compliant, device-tolerant participants and call the result human evidence. That would hide exactly the burden the project claims to reveal.

At the same time, inclusion must not become coercion. Some accommodations require time, staff, privacy, or specialized equipment. If the site cannot provide them safely, it should not recruit and then place the burden of adaptation on the participant. Access failure should trigger redesign, not pressure.

Communication support also raises privacy questions. A caregiver, interpreter, assistant, or device may mediate responses. The protocol must distinguish participant voice from support context and protect the supporter from becoming an unconsented data source. The participant should control, where possible, who assists and what is recorded.

Difficulty communicating does not reduce the person's standing. Any resulting access limit belongs to the measurement method, not to the person.

3.5.4 — Institutional and Clinical Dependence

Dependence changes refusal. A patient may fear disappointing a clinician, a resident may fear staff judgment, a student may fear authority, an employee may fear retaliation, and a service recipient may fear losing access. Ethical review should therefore examine who introduces the study, who collects consent, whether care providers know the decision, what records show refusal, and how complaints move outside the dependent relationship. The cleanest consent process may require independent staff, delayed approach, private refusal routes, and visible assurance that ordinary care or service will not change. The scientific reason is direct: fear of refusal changes selection and response long before the model sees data.

These pressures can operate without intended coercion; prisoners and detained persons face especially strong constraints.

The study must separate authority from recruitment. A clinician who controls care should not be the only person explaining enrollment when a neutral alternative is possible. A supervisor should not recruit subordinates. A service office should not present research while someone is seeking urgent help. Refusal must not affect care, grades, employment, housing, benefits, or access (Wendler & Grady, 2008; World Medical Association, 2024; Council for International Organizations of Medical Sciences, 2016).

Clinical dependence is especially subtle in terminal and serious illness settings. A participant may believe that agreeing to research will make staff more attentive, provide better symptom

relief, or signal gratitude. The consent process must clarify the study's scientific purpose, distinguish possible benefits from guarantees, and make clear that refusal will not reduce ordinary care or staff respect.

Institutional dependence also affects reporting of distress. A participant may underreport discomfort to avoid disappointing staff or seeming difficult. They may keep a device on because a nurse placed it. They may answer in ways they think researchers want. These are not mere social niceties; they are measurement threats.

A dependence-aware protocol includes independent consent support, refusal scripts, complaint pathways, non-retaliation rules, separation between care and research decisions, and monitoring for differential withdrawal. It also records whether participants felt free to refuse in post-contact checks where appropriate.

Institutional dependence does not make research impossible. It makes invisible power visible. A study that cannot show how refusal remains safe should not recruit from that dependent relationship.

3.5.5 — Participant and Staff Burden Budgets

A participation budget should be as concrete as a sample-size calculation. It should estimate minutes, awakenings, device contacts, skin-irritation risk, travel, forms, interviews, family tasks, staff steps, handoffs, after-hours calls, translation, security incidents, and emotional load. The plan needs a ceiling, a monitoring schedule, and an authority able to pause the study

when the design exceeds it. This is an inference condition as well as an ethical one: patterned noncompliance, withdrawal, or skipped procedures can change the study population and the missingness mechanism.

A burden budget is a prospectively specified account of what the study asks participants, families, and staff to carry. It includes time, travel, fatigue, device discomfort, privacy anxiety, emotional strain, sleep interruption, forms, technical troubleshooting, family conversations, clinical disruption, staff labor, and reporting duties.

The budget should be quantitative where possible and descriptive where necessary. Minutes per visit, number of contacts, device wear time, interview length, alerts per week, staff minutes per participant, family calls, adverse distress events, missed measures, and withdrawal reasons can be tracked. Some burdens, such as moral distress or privacy worry, may need carefully designed qualitative reporting (Council for International Organizations of Medical Sciences, 2016; Emanuel, Wendler, & Grady, 2000).

Burden endpoints are not decorative. They are thresholds that can stop, shrink, or redesign a study. A protocol might pause if distress exceeds a declared level, if device removal requests cluster, if staff overtime rises, if family complaints exceed a threshold, if missingness becomes burden-linked, or if no-estimate conditions dominate.

The budget also belongs in the analysis. Excessive study load can produce selection, missingness, nonadherence, altered

physiology, and poor transport across sites. A favorable signal among the easiest-to-observe participants may not generalize; a null after disruptive monitoring may describe the protocol more than the phenomenon.

3.5.6 — Community Partnership and Post-Study Obligations

Ethical responsibility does not begin and end with an individual signature. A study can secure consent while shifting unexamined burden onto families, clinical teams, cultural communities, translators, or institutions whose labor makes the protocol possible. Community partnership can expose those burdens before they become invisible features of the data, but it never replaces individual consent.

Partnership is meaningful only while the design remains reversible. People affected by the study should be able to change enrollment, timing, burden thresholds, communication, data flows, and return-of-results plans. Their role is to inform burden, access, meaning, foreseeable misuse, and practical feasibility, not to certify the truth of the hypothesis or replace accountable clinical, statistical, philosophical, and technical judgment (Council for International Organizations of Medical Sciences, 2016; National Academies of Sciences, Engineering, and Medicine, 2017; World Medical Association, 2024).

Compensation and access should recognize real expertise without turning need into pressure to endorse the project. Travel support, translation, caregiving support, assistive technology, supported communication, and adequate decision time can make refusal and participation more genuine. These accommodations also change

who can be observed and how, so their effects belong in the scientific record rather than being treated as invisible logistics.

Post-study obligations should be declared before enrollment. Participants should know whether aggregate findings will be returned, whether individual feedback is possible, how long data will be retained, who may reuse them, and how corrections will be communicated. No return process may imply a personal terminal interpretation or latent-ledger reading that the science cannot support. Return plans should also specify when findings are too uncertain, preliminary, or group-level to support meaningful individual feedback.

Withdrawal and retained data require a concrete governance route. Participants should know which future uses can still be stopped, which aggregated products cannot practically be reversed, who holds custody, how identity and requests are verified, and how long a response should take. Clinical safety signals also need a prospectively designed response pathway so research findings do not fall between scientific and care responsibilities. Clear responsibility for each request prevents withdrawal, correction, or safety concerns from becoming unresolved administrative handoffs.

Families, staff, and sites need an exit and complaint pathway of their own. The record should state what can be shared, what remains confidential, how care disruption is reported, how devices and local data copies are handled, and who remains available after the research team leaves. Contribution to a study never grants permission to disclose another person's inner life. These pathways should remain accessible after active data

collection ends because privacy, burden, or interpretation concerns may emerge only during later analysis or publication.

Partnership can improve external validity by identifying seasonal routines, cultural scripts, medication practices, communication norms, staffing realities, and care transitions that shape measurement and missingness. It does not make a local sample universal; it makes the local conditions visible enough for later investigators to judge transport rather than assume it. Documenting which local conditions materially affected participation or observation also helps future studies distinguish genuine transport failure from differences in implementation.

The governing principle is reciprocity without transferred authority. People who bear research burdens should have meaningful power over burden, access, communication, correction, and exit, while no participant or community is asked to bless the theory or adjudicate the science. A program worthy of studying fairness should leave those relationships more contestable and more humane than it found them. Reciprocity is strongest when that influence produces visible changes in study practice while scientific conclusions remain answerable to the evidence.

3.6 — Scientific Authority and Domain Boundaries

Scientific authority is narrow. It can define claims, test models, compare rivals, report uncertainty, update evidence status, and correct public overclaim. It cannot replace the independent authority of clinical care, democratic decision-making, constitutional law, religious freedom, ordinary privacy, civic equality, employment rules, insurance protections, or transition governance (Douglas, 2009; National Academies of Sciences, Engineering, and Medicine, 2017).

Findings can inform questions in policy, religion, institutions, and personal practice. Each application evaluates those findings alongside its own evidence, purposes, and accountable decision procedures.

Scientific findings reach other domains through a clear account of their scope and intended use. Cities evaluate applications against civic outcomes; religious communities retain authority over their own doctrines; governments preserve independent eligibility rules; and donors receive accurate accounts of research progress. Scientific verdicts remain the responsibility of accountable researchers and reviewers.

Applied domains can use the burden question to protect nonparticipants, improve records, reduce coercion, and design reviewable systems. Those aims can be evaluated directly through the outcomes of the application.

The science volume gives the series a shared vocabulary for scientific, formal, applied, spiritual, legal, and public-

communication claims. Transition governance and each applied domain retain their respective responsibilities.

3.6.1 — No Policy Shortcut

No policy shortcut means that even strong evidence travels through ordinary public reasoning. A scientific finding may advise a legislature, court, agency, hospital, school, or civic institution, but it does not replace constitutional analysis, democratic accountability, administrative competence, community review, disability access, economic evidence, or legal remedy. A successful research program would create prestige, and prestige can become pressure. A public official could cite the science to justify surveillance, triage, austerity, forced participation, or spiritual symbolism. Evidence can constrain false claims; it cannot become a fast lane around lawful public review.

Scientific findings do not bypass democratic, legal, constitutional, administrative, or clinical review. Even a strong result about a component of the Law would not tell a government what policy to enact, what budget to pass, what right to recognize, or what person to prioritize.

Policy involves values, rights, tradeoffs, institutional competence, distributional effects, feasibility, public participation, law, equity, and accountability. Science can inform those questions by clarifying facts and uncertainty. It cannot erase them by announcing that fairness has been measured (Douglas, 2009; Mitchell, 2009; National Academies of Sciences, Engineering, and Medicine, 2017).

The danger is greatest when policy makers want simple authority. A graph can appear cleaner than a hearing. A model can appear more neutral than a court. A statistic can appear more serious than a person's testimony. This chapter blocks that translation.

Candidate momentary valence estimates, interval contribution estimates, ledger estimates, terminal-signature studies, participation-load models, and endpoint classifications are research tools within a declared context of use. They are not policy scores. They cannot decide benefits, custody, sentencing, immigration, housing, employment, insurance, policing, or access to public trust.

A responsible policy interface would instead use science as constraint and warning. If a public program creates hidden burden, measurement science may help detect it. If a proposed artifact overclaims evidence, the science volume may correct it. If an operational record is misused as research data, the science volume can identify the boundary violation.

No policy shortcut keeps public authority answerable to its own standards. Science may enter the room as evidence, method, and critique. It may not leave the room as unreviewable command.

3.6.2 — No Religious Certification

Religious communities and nonbelievers can engage with scientific findings while retaining freedom of interpretation. Science evaluates empirical claims through its methods; religious and pastoral meanings are considered within their own traditions and personal contexts. This division leaves both forms of inquiry room to develop without requiring either to govern the other.

Scientific reporting may state only the tested empirical relation, its uncertainty, and its branch-matched status. It may not translate a component result into divine agency, providence, karma, grace, spiritual rank, or religious obligation. Those are interpretive claims within voluntary religious life, not outputs of a measurement model.

The boundary protects religion as well as science. If sacred life depends on a future dataset, a negative result becomes a spiritual emergency; if a favorable result is treated as certification, dissenters, nonbelievers, and other traditions can be pressured by a prestige they never accepted. Separation protects voluntary meaning from scientific rank (Douglas, 2009).

The Science of Fairness can say that a claim has or lacks empirical support under defined conditions. It cannot say that a person's suffering had sacred purpose. It cannot say that one spiritual interpretation is higher. It cannot make participation in a religious framework more rational, more loyal, or more required.

Religious communities may still respond to scientific humility. They can learn from burden ethics, no-coercion rules, data dignity, and care before evidence. But those are ethical boundaries and interpretive opportunities, not scientific certification of sacred truth.

Research communication should therefore avoid language that presents findings as spiritual confirmation. It should not say that science has proven a covenant, confirmed a faith, blessed a practice, or shown that a ritual works in cosmic terms. It can state only the scientific status of the tested claim.

No religious certification keeps belief optional and science falsifiable. The Law may invite meaning for some readers, but the research program cannot require meaning from anyone.

3.6.3 — No Civic or Employment Rank

The civic and employment boundary should be written into data-sharing agreements, not left as a moral aspiration. No momentary valence estimator, interval valence contribution estimate, ledger estimate, burden profile, endpoint class, consent choice, withdrawal, missingness pattern, vulnerability marker, or research participation status may become a basis for hiring, insurance, policing, benefits, credit, admission, housing, immigration, workplace evaluation, or public trust ranking. Even aggregate tools can leak into person-level suspicion when dashboards are built carelessly. The study must therefore prevent downstream reuse by contract, access control, audit, technical separation, and public language. A scientific estimate that can ruin a person's ordinary life has already become the wrong kind of instrument.

The technical safeguard is purpose limitation. Every estimate must carry its study purpose, prohibited downstream uses, access roles, retention rule, and audit path. A variable that is valid for one bounded analysis becomes invalid when repurposed as eligibility, loyalty, employability, insurability, credibility, or public trust.

The misuse can begin subtly. A research participant may be treated as more committed; someone who refuses as evasive; a public supporter as more trustworthy; a measured person as more

transparent. Each move converts participation or visibility into social hierarchy (National Commission, 1979).

Employment and insurance uses are especially dangerous. A model that estimates burden, distress, resilience, compliance, honesty, or affective state could be used to route opportunities, premiums, assignments, surveillance, or exclusion. That use is outside the project.

Civic rank is also incompatible with measurement uncertainty. The constructs are latent, bounded by context, vulnerable to calibration failure, and unsuitable for individual worth judgments. Even if a measure is useful in a study, it cannot bear the ethical weight of ranking persons.

A protocol should include nonuse language and data-governance controls. Participants should be told that research estimates will not be returned to employers, insurers, public agencies, schools, religious authorities, donors, or civic platforms as ranking tools. Data-access systems should make that promise enforceable.

No civic or employment rank preserves the difference between making burden visible and making persons measurable. The first can serve fairness. The second would betray it.

3.6.4 — No Artificial Intelligence Sovereignty

Artificial Intelligence may assist with coding, monitoring, anomaly detection, privacy review, translation support, or model comparison only under declared human responsibility. It may not decide consciousness, consent, endpoint, dignity, truth, eligibility, spiritual meaning, or participant credibility. Model outputs must be inspectable, contestable, versioned, and subordinate to human

review with disciplinary competence. This is not hostility to tools. It is recognition that a system trained on partial data can acquire institutional authority faster than it acquires understanding. For this program, any Artificial Intelligence assistant must increase accountability rather than create a new opaque actor between the participant and the claim.

Human governance means more than placing an approval button after an automated output. The responsible investigator must understand the task, data provenance, model version, error profile, limits, and appeal route, and must be able to reverse the decision. A system whose output cannot be meaningfully inspected or contested is not an assistant in this research program.

The reason is not that Artificial Intelligence is useless. The reason is that these systems can compress uncertainty into fluent output, reproduce bias, hide provenance, magnify training-data misuse, and create unwarranted confidence. A language-like answer about a person's suffering can sound humane while having no right to interpret that person (Autio et al., 2024; Douglas, 2009).

In this volume, Artificial Intelligence use requires context labels: what data were used, what task was authorized, what model version was involved, what human review occurred, what errors are known, what appeal route exists, and what the output cannot be used to decide. Without those labels, model output becomes theater.

Artificial Intelligence also needs data permission. A participant's consent to a study does not grant training rights. A clinical note does not become a model corpus by convenience. A public artifact

does not become consent for extraction. Sensitive data require purpose-specific authorization and governance.

No Artificial Intelligence sovereignty includes no automated endpoint adjudication. A model may help identify patterns for human review, but it cannot declare truth-level endpoint, terminal valence closure, participant meaning, or scientific support. Endpoint and verdict decisions remain governed, contestable, and humanly accountable.

The chapter's boundary is compact: Artificial Intelligence can assist the research program only as a tool under explicit limits. It may not become oracle, judge, priest, clinician, or public ranker.

3.6.5 — No Applied Proof

Applied achievements can generate hypotheses, identify practical challenges, and preserve useful practices. A sound housing policy, care protocol, privacy rule, or analytical tool can be evaluated through its own purposes and outcomes as the scientific program develops.

The fit among applied ideas can generate hypotheses about how institutions, practices, and experiences relate. Those hypotheses become useful research proposals when they specify observations and comparisons that can evaluate the suggested connection.

The science volume may receive applied observations as research leads. A public system may reveal burden pathways. Ordinary-life tools may show measurement hazards. Religious practice may raise interpretive questions. Transition trials may expose data risks. These observations can shape research questions, but they do not skip the measurement and rival gates.

Public materials should connect each scientific claim to its evidence. Diagrams identify what their relationships represent, donor pages describe the research supported, and websites distinguish adoption, participation, and research findings. These details help readers understand how the project develops.

3.6.6 — Authority After Publication

Scientific communication continues through summaries, interviews, diagrams, classroom materials, dashboards, and derivative tools. Each format should accurately name the study's object, population, method, and result so readers can follow the finding back to its source.

Every high-reach statement must preserve the level of the underlying verdict. A route-favored result cannot become evidence that every qualifying stream closes; measurement validation cannot become a personal score; and a replicated terminal-window signature cannot become a forecast of an individual death or destiny. The public sentence must not outrun the technical object it summarizes.

Correction routes should be visible beyond the author team. Participants, readers, rival researchers, clinicians, journalists, ethics officers, and data stewards need defined ways to report factual error, misleading artifacts, broken sources, privacy concerns, or status overstatement. The process should identify who reviews the concern, what evidence is required, when a notice is issued, and how the corrected object replaces or points back to the superseded one (National Institute of Standards and Technology, 2020; Tabassi, 2023).

Institutional use remains bounded by the evidence. Universities, funders, companies, religious groups, political actors, and public agencies may cite the work, but citation does not broaden the verdict or transfer scientific ownership. Artificial Intelligence systems may assist search, consistency checking, or hypothesis generation; they may not become sovereign interpreters of persons, issuers of scientific status, or custodians of hidden experiential dossiers.

Public-use monitoring should be proportionate to reach. A registry of high-reach artifacts should record the source chapter and version, status ceiling, responsible human owner, correction route, and current state: active, corrected, superseded, or withdrawn. Archives should preserve prior objects without allowing search systems or derivative tools to present them as current.

Authority can expire when its evidentiary conditions change. An instrument may be superseded, consent for secondary use may lapse, a security incident may alter risk, or an independent replication may overturn the favored model. Review dates and event triggers reconnect public claims to those changes so a once-accurate statement does not become misleading through staleness (Fischhoff & Davis, 2014; Tabassi, 2023). A review can narrow a claim's permitted use while leaving the underlying observation in the record, with the reason for that change attached.

Those affected by public use need a route to contest it. A participant may challenge a disclosure, a clinician may challenge a ranking-prone dashboard, a rival may identify an omitted comparator, and a reader should be able to locate the current

correction without searching through silent replacements. Contestability does not decide truth by vote; it gives error a path to the people responsible for correction. Someone raising a concern should be able to identify the affected artifact directly rather than reconstructing the full research history before review can begin.

Public scientific claims remain inspectable and correctable. Their documented evidence and revision history let contributors across the series assess the findings and use them within their respective domains. Correction notices are most useful when they distinguish the changed conclusion from findings that remain unaffected, allowing readers to update their understanding proportionately.

3.7 — Non-Negotiable Research Red Lines

The final section concentrates the ethical firewall in one place. Its purpose is practical. Later chapters should not reproduce the full list whenever they discuss measurement, endpoints, protocols, models, public artifacts, or verdicts. They should use one local safeguard when a local risk changes and otherwise rely on this chapter (Council for International Organizations of Medical Sciences, 2016; National Commission, 1979; World Medical Association, 2024).

The red lines are not negotiable by result. A favorable study cannot soften them. A donor cannot buy an exception. A public crisis cannot make them optional. A religious community cannot reinterpret them. An Artificial Intelligence system cannot override them. A transition ambition cannot postpone them.

These red lines protect people and the integrity of the evidence. Conditional accounting cannot be used to erase a qualifying counterexample, move an endpoint, or invent an unobserved remainder after the fact. One stream cannot balance another, estimates cannot rank human worth, and failures must remain visible. These safeguards govern research and interpretation; they are not conditions that make a universal hypothesis true.

The firewall therefore does two forms of work at once. It protects persons from the project, and it protects the project from itself. A theory that cannot govern its own temptations should not govern public imagination.

The compact firewall that follows is a reference table for the rest of the volume.

The final line is simple: the science may become stronger, weaker, narrower, inconclusive, or defeated. None of those states authorizes the forbidden uses named here.

Table 3.4. Compact ethical firewall.

Red line	Local meaning for research	Consequence for later chapters
Care before evidence	Care, comfort, safety, access, and dignity outrank measurement and claim status	Use one local sentence when a study risk changes; do not repeat the whole firewall
No harm induction	No induced suffering, deprivation, fear, humiliation, withholding, or path engineering for Law-specific evidence	Route studies to observation, natural variation, independent-benefit interventions, and rival modeling
Comfort-first terminal research	The dying person owes no result, and palliative care outranks endpoint clarity	Use no-estimate, stop, withdrawal, and low-signal labels rather than endpoint theater
Granular consent and data dignity	Observation, linkage, sharing, publication, future reuse, and Artificial Intelligence training are distinct permissions	Maintain purpose limitation, retention rules, deletion routes, bystander review, and no silent conversion
No authority leakage	Science governs claim status only, not law, religion, care, employment, insurance, civic rank, or transition	Defer applied authority to its own domain and block candidate momentary and interval estimators or ledger-like scoring

Red line	Local meaning for research	Consequence for later chapters
No moral payment or worth scoring	Balance requirements are not moral debt; persons are not scores; archives are not souls; failures remain visible	Preserve conditional net accounting; correct moral-desert, control, and evidence-status overclaims

3.7.1 — Balance Requirements Without Moral Desert

Assume exact PTVC, finite positive and negative totals, one qualifying completed stream, and a valid fixed representation with a calibrated neutral origin. At any chosen cut, the accumulated net balance and the signed remainder must sum to zero. A genuinely negative accumulated balance therefore requires a net positive remainder; a genuinely positive accumulated balance requires a net negative remainder. This follows from terminal closure regardless of the mechanism.

The Series Map’s statement “There is no free happiness” expresses the absence of a net positive surplus over a completed conscious stream under this hypothesis. It does not mean joy is wrong, pain is morally owed payment, or suffering is holy. Exact balance challenges a pleasure-only conception of utopia; the series develops its humane social goals through further ethical and practical reasoning.

If exact PTVC is true and the accumulated balance is already negative, a further negative contribution increases the algebraic net-positive remainder required for closure by the same amount. This fixes future positive magnitude minus future negative magnitude, not either gross total separately or an improvement

over a different, unchosen life. It does not establish a strategy, entitlement, or safe and reliable way to obtain a chosen reward.

The required remainder is an arithmetic condition on closure, not moral desert, earned suffering, or justification. It identifies no particular illness, injury, deprivation, or other event that must occur, and implies no event-by-event pairing, timing, conscious knowledge of the balance, or particular mechanism.

Kindness has no automatic valence value merely because it is kind. Any enjoyment genuinely felt by the person helping enters that person's balance like other positive experience. If the balance is already positive, that enjoyment increases the required net negative remainder. If it is negative, enjoyment reduces the positive remainder still needed, unless it carries the balance past zero. The recipient's experience belongs to the recipient's stream. Neither kindness nor enjoyment creates a moral obligation to suffer.

Helping changes the life actually lived. PTVC fixes a terminal difference, not a fixed quota of suffering or a ranking of whole lives. It does not require a particular prevented harm to reappear. It also does not exempt the felt effects of help from the arithmetic. Rights, care, and justice remain independent commitments.

No actually completed qualifying stream can end off balance if exact universal PTVC is true. But changing a genuine accumulated balance changes what the remainder must contain. That leaves a real question about influencing the route, not a demonstrated technique for controlling future happiness. An imagined strategy need not be achievable, and no one's true

balance is assumed known. A realized qualifying counterexample would refute the universal claim, not break a previously exceptionless law.

The project seeks a society capable of understanding PTVc without turning it into a reason for deliberate suffering, coercion, or withheld care. If the hypothesis is universal, informed choices and attempts to exploit it are included in its scope. Safeguards protect people and research integrity; they do not make the Law true. A humane civilization is the project's aim, not a theorem of terminal balance. Research prohibitions do not remove actually realized qualifying streams from the universal claim. Research remains subject to independent ethical review, and deliberate harm is not an endorsed experiment or strategy (Council for International Organizations of Medical Sciences, 2016; World Medical Association, 2024).

3.7.2 — No Cross-Person Balancing

Cross-person balancing often appears in respectable language: net benefit, aggregate welfare, average neutrality, social gain, national readiness, institutional success. Those concepts can matter in policy, but they cannot erase the burden of a particular stream. In research, a cohort mean near zero does not show that each person closed. In ethics, one participant's insight does not justify another participant's suffering. In public communication, one life's peace does not explain another life's grief. The stream-bound character of the Law is therefore also a protection against public arithmetic that hides persons. Comparison can teach. Exchange cannot redeem.

Cross-person balancing would let institutions hide harm. A program could aggregate benefit over one group and suffering over another, then speak as if the suffering disappeared in the total. PTVC is intrastream and nontransferable; research ethics likewise requires attention to who bears risk rather than allowing aggregate gain to erase them (National Commission, 1979).

Report cohort means together with the distribution, heterogeneity, missingness, and stream-level results relevant to the hypothesis. This shows both the overall pattern and how it varies among the contributing trajectories.

The red line also blocks sacrificial rhetoric. A participant, family, community, staff group, or vulnerable population cannot be asked to bear research burden because the project may help humanity later. Future value matters, but it does not make present burden disappear. It must be justified, minimized, consented to, and reported.

Cross-person balancing is especially tempting in public artifacts. A visual might show overall harmony while hiding concentrated injury. A dashboard might show aggregate improvement while one subgroup carries distress. A status report might celebrate participation while staff burnout rises. Those artifacts fail the lens.

3.7.3 — No Human-Worth Measurement

Research variables may describe limited observations under limited assumptions; they may not become measures of worth, trust, holiness, sincerity, employability, civic eligibility, parental adequacy, deserved care, or future potential. Enforce that boundary through purpose labels, access controls, prohibited-use

terms, audit logs, and highly restricted person-level release. Section 3.6.3 governs civic and employment nonuse; this firewall states the general no-worth rule (National Institute of Standards and Technology, 2020; Tabassi, 2023).

3.7.4 — No Archive as Soul

An archive can preserve memory, provenance, consent, correction, and public accountability. It cannot preserve the person as a continuing conscious stream merely by containing records. This matters for terminal research because grief, technology, and public fascination can combine into a powerful temptation: to treat messages, recordings, model reconstructions, or data traces as if they reveal or continue the self after death. The science volume must refuse that implication. Posthumous records may be handled with dignity, restricted access, correction, and family sensitivity. They may not be called the soul, the ledger, the endpoint, the surviving mind, or a substitute for the person who is gone.

Records, public artifacts, governance logs, research datasets, and future archives can preserve accountability, correction, and institutional memory. They remain records. No accumulation of files can resurrect consciousness, certify inner life, or become a proxy for personhood (National Academies of Sciences, Engineering, and Medicine, 2017).

An archive can also tempt endpoint overclaim. A complete record may make observers feel they know what a person was, meant, deserved, or became. The science volume must reject that feeling. The bearer of the formal claim is a separately routed maximal

qualifying conscious stream, not a biography assembled from documents.

Artificial Intelligence intensifies the risk. A model trained on someone's text, voice, image, records, or behavior may simulate style or answer questions. It is not the person. It cannot consent after death. It cannot reveal terminal meaning. It cannot close the ledger.

Posthumous dignity requires record humility. Data retention, family access, publication, memorialization, and deletion should be handled under the permissions and governance set before or legally after death. The more moving the record, the more careful the boundary.

3.7.5 — No Concealed Failure

No concealed failure is the final ethical rule because it helps future studies learn from the complete research record. Null results, rival wins, adverse events, breaches, recruitment problems, burden overruns, model failures, endpoint uncertainty, withdrawn measures, and substantive corrections must remain visible through appropriate channels. Concealment shifts burden onto the next site, the next family, the next dying person, the next staff member, and the next reader who trusts the public summary. Preserving this record is care extended forward in time: it gives later teams the information needed to avoid repeating preventable problems.

Concealed failure is not merely dishonesty. It makes the Law unfalsifiable in practice. If unfavorable outcomes disappear, the public sees only survival. A claim that survives by file drawer is

not answerable; it is curated (Council for International Organizations of Medical Sciences, 2016). Making unsuccessful studies discoverable also helps researchers combine results across sites and choose more informative follow-up designs. A visible record of failure also allows later teams to distinguish isolated setbacks from recurring weaknesses in a method, bridge, or prediction. That distinction can prevent both premature abandonment and unjustified persistence.

The protocol should specify failure reporting before data collection begins. It should state what is reported publicly, what is reported to oversight bodies, what remains protected for privacy, what triggers correction, and what changes claim status. The route should exist before anyone knows the result. Assigning responsibility and a reporting deadline makes this commitment actionable when staff, funding, or institutional priorities change. The protocol should also identify who verifies that required reporting actually occurred and where the resulting record can later be found. Accountability is stronger when disclosure has an owner, destination, and auditable completion point.

Failure visibility also includes public artifacts. If a diagram, summary, website, donor page, or prior chapter becomes inaccurate after a result, it must be corrected, retired, or relabeled. A public artifact is not harmless because it is beautiful. It can carry old authority after the claim has changed. A dated correction notice should identify the affected claim and direct readers to the current explanation, allowing them to follow the change even when older copies remain in circulation. High-reach artifacts deserve priority because their outdated implications can persist

long after the underlying scientific record has changed. Correction should therefore follow both evidentiary importance and the likely reach of the obsolete claim.

Rival wins deserve special protection. A study that favors adaptation, homeostasis, observation attenuation, sedation, frailty, bridge conditioning, or another model has produced knowledge. It should not be narrated as temporary confusion until the Law recovers. It should narrow, retire, or defeat the relevant component as prospectively specified. The comparison should also identify which predictions or observations gave the rival its advantage, turning the result into guidance for the next model or experiment. A rival victory is most informative when the record also shows where the preferred model failed and which assumptions no longer deserve the same confidence. That makes defeat a source of model improvement rather than merely a change in ranking.

Chapter 4 — Technical Synopsis: Claim, Tests, and Verdicts

This chapter maps the PTVC target to its representation, measurement, endpoint, model-comparison, and verdict requirements. It distinguishes derived consequences from proposed tests and identifies the unresolved connections on which stronger claims depend.

The starting point is not a second full statement of the Law but the dependency structure that makes the received target scientifically vulnerable. Section 4.1 supplies the exact finite signed-measure form; this introduction maps the representation, routing, endpoint, observation, recovery, rival, and verdict conditions that must hold before evidence can reach it.

The claim is exact, intrastream, and nontransferable. It permits enormous differences in duration, intensity, temporal order, agency, opportunity, memory, welfare, and gross valence variation. Exact net closure would not imply an easy life, a just society, or low suffering. Those dimensions remain scientifically and ethically independent.

The synopsis next separates status, notation, and dimensions. A symbol may denote a truth-level object, a route state, an observation, an estimand, an estimator, or a verdict label. Units and domains matter because a dimensionless unity gate, an exposure rate, a neutral-relative value, and an accumulated ledger cannot be interchanged without changing the model.

Representation comes before inference. The program must justify sign, neutral origin, cross-sign comparability, scalarity or an identified set, and the exposure convention. A completed-record

recentering that forces zero is prohibited because it builds the answer into the scale.

Bearer and routing come next. The target belongs to one maximal qualifying conscious stream under a prospectively specified ownership rule. Splitting, merging, duplicating, or dropping events after seeing the residual can manufacture apparent closure. Partially identified routing must remain set-valued rather than resolved by convenience.

Endpoint construction is a separate gate. The truth-level endpoint, protocol endpoint, final observation, and biological death are not synonyms. Return, resuscitation, low-access states, observation shutdown, and terminal windows require adjudication rules that do not use the ledger outcome being tested.

Observation and recovery form another layer. Reports, behavior, physiology, neural signals, clinical records, and context are outputs of an observation process, not direct access to the latent ledger. Missingness, measurement reactivity, delayed entry, and unseen prefix or suffix exposure can widen the identified set or yield No adequate estimate.

The candidate signatures are designed to create disagreement among models. Depending on the declared branch, the program may examine reserve-linked drift, innovation contraction, variance shape, endpoint concentration, time alignment, completion potentials, perturbation-compatible compensation, and held-out transport. No single signature is treated as unique to PTVC.

Rivals receive the same information and fitting budget. Homeostasis, adaptation, allostasis, predictive processing, learning, endpoint-conditioned bridges, selection, observation attenuation, medication, frailty, memory, and hidden-state alternatives must be able to generate synthetic data and compete under common scoring rules (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

Model recovery comes before real-data confidence. The analysis must show that it can identify the generating model, detect open-set inadequacy, and avoid manufacturing support when every candidate is wrong. Recovery failure is a diagnosis of the test, not a mysterious property of participants.

The first protocol is therefore deliberately bounded. It defines an eligible population, low-burden data flow, endpoint object, estimands, rivals, missingness plan, safety stops, recovery benchmark, and public reporting rule. SPIRIT 2025 and ICH E6(R3) provide current protocol and quality-by-design disciplines that can be adapted to this unusual target (Chan et al., 2025; International Council for Harmonisation, 2026).

Verdicts remain typed. A result may support a prerequisite, favor a route, remain model-ambiguous, narrow a reference class, retire a mechanism, favor a rival, produce No adequate estimate, or become adverse to a declared target branch. A composite score cannot allow strength in one module to cancel failure in another.

Equivalence language is also bounded. A finite scientific band can be adjudicated with an appropriate equivalence design, but a band-compatible estimate is not exact latent zero (Schuirmann,

1987). Repeated success at finer prospectively nested resolutions can strengthen a case only while the representation, bridge, endpoint, and limiting rule remain stable.

Open problems are kept visible because they organize future work. Neutral-origin identification, mixed valence, stream individuation, complete-domain recovery, unexpected endpoints, policy support, route transport, open-set model recovery, and safe terminal observation remain scientific frontiers rather than gaps to be hidden in prose.

The synopsis ends where the formal core begins. Readers now have a map of the received object, the gates that make it testable, the signatures that could discriminate it, the rivals that could win, and the verdicts that preserve what the evidence actually says. The next Part can develop the mathematics without making the reader rediscover the jurisdiction of every symbol.

4.1 — The Scientific Claim in One View

The synopsis organizes the formal hypothesis, representation assumptions, observation models, endpoint rules, candidate realizations, rival comparisons, reference classes, and decision rules. Naming those layers before introducing notation makes their connections easier to follow (Folland, 1999; Lakatos, 1978; Popper, 1959).

The strong form is deliberately high-risk. Its target is exact latent terminal closure for each qualifying stream on the declared branch. Finite-band compatibility, an estimated atom at zero, probability-one closure under a specified law, and [SET-ALL] closure over every qualifying stream are different claims with different decision rules. The public program does not pretend that a near-zero estimate observes exact equality. It asks whether frozen measurable consequences and validated bridges can bear on the declared target while surviving serious rivals and replication.

The chapter therefore starts with a component-evidence map. A favorable result may update a measurement bridge without updating the strong form. A rival may dominate a signature without defeating every analytic use of the burden-focused lens. A terminal equivalence finding may be unusable if the endpoint was selected after outcome inspection. A beautiful theory may remain metaphysically conceivable while losing scientific status because its empirical bridges failed.

The section also states what no result can authorize. Scientific claim status is not political authority, religious certification,

clinical instruction, civic rank, employment trust, insurance eligibility, public worth, transition readiness, or Artificial Intelligence sovereignty.

Table 4.1 maps claim layers to the evidence that could update them and the evidence that cannot. The table is a status discipline, not a verdict.

The compressed dependency spine can be written as a chain of conditional permissions. Let C_0 be the received formal target, C_1 the representation bridge, C_2 the observation model, C_3 the endpoint rule, C_4 the declared consequence module, whether mechanism-neutral or route-specific, C_5 the rival set, C_6 the inference engine, and C_7 the verdict rule. A public update is licensed only through the weakest surviving link invoked by the target component, not through the most impressive-looking result at the end of the chain.

$$C_0 \rightarrow C_1 \rightarrow C_2 \rightarrow C_3 \rightarrow C_4 \rightarrow C_5 \rightarrow C_6 \rightarrow C_7$$

If any prerequisite gate G_i fails, the permissible update is capped before the failed gate:

$$permittedstatus \leq \min\{G_i : i \leq testedcomponent\}$$

This is the noncompensatory evidence rule. The minimum operator in the displayed shorthand is ordinal over the prospectively specified status ladder, not arithmetic, and it ranges only over gates required by the component being judged. It does not imply that every target-law test requires one candidate realization. A clean endpoint band cannot repair an undefined sign convention; a reserve correlation cannot repair a circular

endpoint; a beautiful simulation cannot repair failed model recovery.

The reader can also read the table as a formal dependency diagram. Formal claim leads to representation; representation leads to observation; observation leads to endpoint; endpoint leads to candidate consequences; candidate consequences lead to rival comparison; rival comparison leads to replication; replication leads to bounded public status. The arrows do not run backward. A later public verdict cannot repair an earlier representational defect. Each arrow can therefore be annotated with the assumption or measurement procedure that carries evidence from one stage to the next.

This matters because many apparently careful theories become unfalsifiable through backward repair. If the endpoint fails, they change the endpoint. If the origin fails, they change the origin. If a rival wins, they rename the rival as the theory. If a reference class fails, they say the class was never meant. The dependency diagram forbids that style of survival. A changed bridge becomes a changed claim version. Recording the revised definition alongside the original keeps the earlier test interpretable and gives the revised proposal a clear starting point.

The component-evidence map also shows how a progressive program differs from a degenerating one. A progressive modification names a failed bridge, proposes a new bridge, and generates a new risky prediction that can be tested before seeing the next result. A degenerating modification merely moves a boundary so the previous failure no longer counts. The scientific conscience of this book is the ability to tell those two movements

apart. A particularly useful next test targets a condition where the revised account and its strongest competitor predict different outcomes.

The strongest positive case therefore rises only when multiple independent components survive together. A measurement bridge that survives calibration, an endpoint rule that survives circularity tests, a reserve relation that survives independent estimation, a rival matrix that lets alternatives win, and a replication system that transports cautiously can together make a program more credible. None of them alone can lift the whole claim. Agreement is especially informative when the checks have different sources of error, reducing the chance that one shared assumption accounts for their apparent convergence.

The same map explains why a single failure can be highly informative. A failure of model recovery may not refute the Law, but it refutes that study's power to adjudicate. A circular endpoint may not refute the Law, but it makes the endpoint evidence unusable. A repeated, valid rival victory in the exact reference class where the candidate was supposed to win may force narrowing or defeat.

Noncompensatory logic means that evidence cannot leap across a failed prerequisite. If sign is unidentified, a terminal curve cannot repair it; if model recovery fails, a favorable information criterion cannot repair it; if care-disrupting observation distorts the record, sample size cannot repair it. Each failure limits the permissible claim at the point where the dependency chain breaks.

Table 4.1. Claim layers, update evidence, and noncompensatory limits.

Layer	What it says	What could update it	What cannot update it
Strong latent hypothesis	Exact terminal valence closure is posited for the received latent cumulative process of a unified conscious stream.	Only a mature chain of component success, rival defeat, endpoint independence, and replication could strengthen its scientific standing indirectly.	A diagram, fitted example, spiritual resonance, applied success, public enthusiasm, or a single equivalence study cannot confirm it.
Representation bridge	The lived-experience target can be represented as a signed, temporally additive rate under declared unity rules.	Psychometric, phenomenological, physiological, and construct validation work can support or weaken this bridge.	Terminal concentration cannot repair a failed sign convention or invalid construct.
Observation model	Candidate momentary estimator, candidate interval contribution estimate, reserve proxies, endpoint proxies, reports, clinical context, and missingness are treated as fallible witnesses.	Calibration, reliability, missingness, sensitivity, and model recovery studies can update it.	A favorable terminal estimate cannot make a noisy or biased instrument valid by outcome.

Layer	What it says	What could update it	What cannot update it
Candidate realization	Reserve coupled or control theoretic mechanisms may generate measurable consequence structures.	Prospective dynamics, variance shape, innovation behavior, and rival comparison can support or retire a realization.	Mathematical construction alone cannot establish that the candidate mechanism operates in nature.
Reference-class prediction	A specified population and endpoint class may show the protocol fixed conjunction of signatures.	Held out prediction and transported replication can update a bounded claim.	A hospice cohort cannot silently generalize to all cultures, sudden deaths, nonhuman animals, or artificial systems.
Public claim status	A result receives a status label: preliminary, replicated, inconclusive, unusable, narrowed, defeated, or abstained.	The declared verdict process and independent review update public language.	Donor interest, media attention, or institutional adoption cannot change scientific status.

4.1.1 — The Received Strong Form

The technical advantage of stating the strong form plainly is that later weakening cannot be mistaken for the original claim. A public program may later narrow to bounded dynamics,

reference-class regularities, or measurement achievements, but those narrower outcomes are not the same proposition. The synopsis therefore writes the strong form without apology and then refuses to treat any early surrogate as if it had already reached that height.

A skeptical reader should be able to underline this sentence and say, this is the target that would need extraordinary support. That clarity is a gift to the project, not a threat. A blurred target might attract easier agreement, but it would make every later verdict untrustworthy because no one could tell what the evidence had actually touched.

The received strong form is the exact terminal-valence-closure hypothesis stated at the latent level of the formal Law. On the primary finite signed-measure branch, one separately routed maximal qualifying stream carries a finite signed phenomenal measure over its complete strict-pre-endpoint domain. Its terminal residual is equivalently the measure of that domain, the difference between its positive and negative Jordan magnitudes, and the left limit of the phenomenal ledger at the truth-level endpoint. The scientific task is to connect this fixed target to observable consequences and the methods needed to evaluate them (Folland, 1999; Lakatos, 1978).

$$Z_i^* := \nu_i(\Omega_i) = V_i^+ - V_i^- = L_i^{\text{phen}}(T_i^* -)$$

$$PTVC_i \Leftrightarrow V_i^+ = V_i^- < \infty \Leftrightarrow Z_i^* = 0$$

The equality is intrastream and nontransferable. It constrains the signed terminal residual while permitting unequal duration, intensity, temporal order, agency, opportunity, memory,

resources, welfare, rights, and gross phenomenal variation. Additive PTV, the bipolar mixed-valence branch, and Generalized Terminal Neutrality remain separate unless an approved bridge establishes equivalence.

On the absolutely continuous primary subbranch, the phenomenal ledger accumulates realized neutral-relative value against experienced exposure. In a physical-time chart, the received representation is:

$$L_i^{\text{phen}}(t) = L_i^{\text{phen}}(S_{i,\theta}^-) + \int_{S_{i,\theta}}^t g_{\theta,i}(s) q_i^{\text{exp}}(s) v_i^{\text{real}}(s) ds$$

A probability-one branch under a declared stream law is a separate modal claim:

$$P_i\{L_i^{\text{phen}}(T_i^* -) = 0\} = 1$$

The display states [P1] closure: the latent integral equals zero almost surely under the specified law. [SET-ALL] instead quantifies over every qualifying stream. The branch label identifies which statement a derivation or analysis addresses.

The strong form is therefore not the first observable claim. Felt valence has no instrument-fixed origin or unit, a study begins after stream onset, and the truth-level endpoint is not delivered by one sensor. A near-zero estimator at the end of an observed window can support only the protocol-fixed measured branch unless representation, complete-domain, endpoint, observation, and measured-to-latent bridges license more.

The most discriminating structural result concerns endpoint timing. Under a declared reference law, suppose an endpoint is

independent of the sigma-field generated by a jointly measurable pre-endpoint ledger path and has a conditional density that is positive almost everywhere on a fixed interval. Exact closure at that endpoint then forces the pre-endpoint ledger to be zero for almost every time in that interval, for almost every eligible path.

$$P_i^0\{L_i(T_i^{\text{exo}}-) = 0\} = 1$$

T_i^{exo} is independent of $\sigma\{L_i(s^-): s \in I\}$ under P_i^0 , and $f_{T_i^{\text{exo}}}(t) > 0$ for Lebesgue-almost every $t \in I$.

$$0 = P_i^0\{L_i(T_i^{\text{exo}}-) \neq 0\} = \int_I P_i^0\{L_i(t^-) \neq 0\} f_{T_i^{\text{exo}}}(t) dt$$

Therefore $L_i(t^-) = 0$ for Lebesgue-almost every $t \in I$ on a P_i^0 -probability-one set of eligible paths.

Endpoint timing has several distinct forms. Section 4.3.4 defines the branch distinctions and anti-tautology conditions; the reserve-coupled route is one candidate realization within that framework.

The strong form receives scientific pressure through branch-matched consequences and validated bridges. Representation failure, circular endpoint construction, unidentifiable route state, failed model recovery, serious rival dominance, or nontransport can narrow or defeat the exact claim version each result actually reaches. Hiddenness does not make the target immune.

If exact PTVC is true, a completed qualifying stream has the proposed terminal balance under its declared representation and endpoint. Observing someone suffer does not establish that person's accumulated balance, explain a particular event, or assign moral payment, desert, or improvement. Care remains

binding under every scientific outcome. The strong form is a research target, not a license over anyone's life.

4.1.2 — The First Empirical Burden

The first empirical burden also protects the program from spectacle. Terminal scenes are emotionally powerful, but their emotional force can overwhelm methodological restraint. Preterminal restrictions ask a colder question: before the ending is known, does the system behave in a way that the candidate architecture predicted and rivals did not predict as well?

The first empirical target is therefore a vector of prospective consequence claims, not one scalar verdict:

$S = \{\text{reserve-linked drift, innovation contraction, variance-shape law, forecast performance under the declared independent-endpoint branch, observation-model robustness, held-out rival superiority}\}$ (Popper, 1959).

A study may report evidence about one coordinate of S while abstaining on another. A fitted negative drift coefficient can support a local dynamical component. Variance shape, reserve coupling, the protocol-fixed endpoint-timing premise, and model recovery receive their own assessments. Component-specific reporting identifies what the result contributes and which comparison should come next.

This order gives the research program an honest first rung. It can begin with dynamics that are difficult but not metaphysical, with instruments that can be improved, with rivals that can be simulated, and with results that can be negative without asking anyone to reinterpret the meaning of death.

The first empirical burden is prospective, comparative structure across this signature vector under frozen rules, before the endpoint is inspected. Terminal zero sits higher in the inference ladder. The program becomes scientifically interesting when the joint pattern is difficult for simpler rivals to reproduce.

Prospective specification makes the study's choices inspectable. Before the relevant outcome is examined, the empirical bridge declares the population, instrument version, endpoint channels, analysis window, smoothing method, estimands, rivals, and decision rules. Later exploratory changes are documented as such.

The first burden is also comparative. A signature has little force if it is compatible with ordinary adaptation, allostatic regulation, endpoint-conditioned bridges, medication, frailty, clinical practice, or observation shutdown. The Law candidate must not merely fit. It must out-predict or out-explain serious alternatives in held-out data after the analysis pipeline has shown it can recover known synthetic generators.

Dynamical shapes, reserve-space relations, forecast errors, innovation behavior, and comparative predictions offer tractable early targets. Their dependence on origin assumptions can be assessed directly, helping identify which features can be compared before absolute terminal level is estimated.

A first result can provide a clear foundation for further work. Suppose a prospectively specified study finds that reserve-linked variance contraction appears prospectively and survives observation-model checks. The finding supports that dynamical consequence within the tested setting, while the terminal-

equivalence analysis reports its own uncertainty. Replication can then test whether the two components develop together.

The first empirical question is not whether one attractive terminal pattern can be found. It is whether the route from experience to evidence survives scale choice, missingness, device effects, clinical confounding, endpoint selection, and public compression. Early studies seek discriminating signatures while exposing those distortions before they harden into claims.

4.1.3 — Component Claims and Dependencies

Dependency logic is also a protection against overcorrection. A hostile reviewer might want one defect to destroy the whole research program, while a proponent might want one success to lift the whole Law. Both reactions are too crude. Component accounting lets the book be severe and fair at the same time.

The lattice should be treated as a burden map. Each row asks who or what would carry the cost if that component were left vague. If representation is vague, participants carry the cost through intrusive but useless data collection. If endpoint is vague, dying persons carry the cost of dramatic but circular interpretation. If rivals are weak, future science carries the cost of false confidence.

The program is a lattice, not a single plank. It includes a formal hypothesis, representation assumptions, observation models, candidate mechanisms, endpoint rules, study designs, rivals, inference tools, replication standards, and public verdict rules. Each component can fail separately. The scientific dignity of the book comes from refusing to let success in one component silently repair failure in another (Folland, 1999).

Representation is one component. It asks whether lived experience can be modeled as a signed, temporally additive target under a declared bearer and exposure rule. Measurement is another. It asks whether momentary and interval estimators, under a declared version, can estimate relevant contributions with known uncertainty. Endpoint adjudication is another component; its anti-tautology and branch-specific timing requirements are developed in §4.3.4.

Candidate realization is also distinct. The route coordinate $L^r(t) = c_{LU} U(t) Y(t)$ may make terminal concentration dynamically approachable, but it is not the received definition of the phenomenal ledger. It is one candidate bridge from formal target to measurable consequences. The bridge can fail while the root hypothesis remains formally intelligible, or it can succeed locally while the exact set-universal form over the declared class remains unconfirmed.

Rival discrimination is a component with its own gates. A model that fits the same pattern after parameter tuning has not earned the status of a model that predicted the pattern prospectively. A rival that wins on held-out prediction under fair comparison must be allowed to change the program. Component claims become meaningful only when rivals are not decorative.

The dependencies are noncompensatory. Endpoint precision cannot compensate for invalid measurement. Measurement reliability cannot compensate for a circular endpoint. A beautiful reserve model cannot compensate for inability to estimate reserve independently. Replication cannot compensate for a public artifact that overstates the result.

When dependencies are blurred, the costs scatter. Participants may undergo needless monitoring; families may absorb anxiety; researchers may chase an uninterpretable signal; readers may mistake component support for support of the whole claim. The dependency lattice is therefore both an inferential map and an ethical map: it shows what each result can bear and who is exposed when the layers are collapsed.

4.1.4 — Reference Classes and Scope

Reference-class discipline is also the antidote to hidden population ranking. A cohort that yields usable data is not a better kind of life. A cohort that yields unusable data is not a lesser one. It is only a domain where the current bridge either works, fails, or has not yet been built.

Public conclusions should state the sample, instrument, and endpoint class actually tested. Those details show readers the scope of the result and the next opportunity for extension.

No empirical result has universal scope by default. A study conducted in one hospice network, under one cultural setting, one instrument version, one endpoint rule, one medication environment, and one recruitment pathway does not silently speak for all conscious streams. The reference class is part of the claim. If it is not named, the result is already overstating itself (Lakatos, 1978; Popper, 1959).

The reference-class ceiling is especially important here because the formal hypothesis reaches beyond any first human cohort. Sudden deaths, pediatric cases, nonhuman animals, advanced dementia, anesthesia, disorders of consciousness, cultural

variation, artificial systems, and future candidate bearers each raise separate representation and endpoint issues. A mature science can expand only by defending transport bridges, not by assuming them.

Scope statements must therefore name population, state space, endpoint class, instrument version, data window, care context, and transport assumptions. A result may say, for example, that in a defined adult palliative cohort under a particular momentary valence estimator version and endpoint adjudication rule, a preterminal reserve-linked variance pattern survived specified rivals. That sentence is long because the claim is honest.

Reference classes also protect against country ranking, clinical ranking, and cultural arrogance. The project must not treat one population's data as evidence that another population is less fair, less balanced, less mature, or less measurable. A transport failure can reveal instrument limits, endpoint limits, cultural calibration needs, or mechanism scope. It is not a hierarchy of lives.

A positive result can sometimes justify expansion. It may motivate a new study in another care context, a different endpoint class, or a distinct culture. But expansion is an empirical bridge, not a rhetorical gesture. Every widening of scope should add a new vulnerability, not merely a broader sentence.

The fairness lens sees reference-class discipline as burden containment. Without it, a narrow study shifts interpretive burden onto people who never participated, never consented, and may not fit the assumptions. Scientific care means refusing to make absent lives carry conclusions drawn from a different world.

4.1.5 — What Support Could Update

Public summaries should identify the component studied, its population, method, and result. Those details let readers understand the finding and locate the work that can build on it.

A study can support a measurement bridge, an endpoint proxy, a reserve-coupled signature, a comparison method, a reference-class prediction, a replication claim, or a decision convention. Name that contribution directly so other investigators can build on the result.

A favorable measurement study can strengthen a witness channel. Correlations with carefully elicited reports, clinical context, and physiological markers in a bounded setting provide evidence for a specified estimator version and inform the design of later studies.

A favorable endpoint study can qualify a rule for a reference class. Agreement with expert adjudication and successful circularity checks strengthen the endpoint procedure for later terminal inference.

Consider a favorable rival-comparison study. If the Law candidate outperforms homeostatic, bridge, frailty, medication, learning, and observation-attenuation rivals on held-out preterminal dynamics, the result may support a conjunction of signatures. The strong form remains exact and latent, but the empirical program has earned more pressure and attention. That is the kind of support this book seeks first.

The update rule is equally important for negative results. If model recovery fails, no real-data result should update the claim. If a

rival wins, the candidate mechanism may be retired. If transport fails, the reference class narrows. If endpoints remain uncertain, terminal claims abstain. An unfavorable result is not a public-relations problem. It is the machinery of scientific honesty.

Support that lands specifically protects human beings from overreach. No one should become more ranked, more exposed, more morally interpreted, more recruitable, or more governable because a component survived. A status update belongs to the claim. It does not attach to the person who generated the data.

4.1.6 — What No Result Can Authorize

Results in this chapter update only the scientific propositions they test. Chapter 3 governs the standing prohibitions on harm, ranking, and authority leakage; locally, each formula, table, model, and caption should name its object, reference class, uncertainty, rivals, and status ceiling.

4.2 — Status, Notation, and Dimensions

Notation is useful only when its status is clear. The same symbol can carry different kinds of burden: a formal definition, a candidate realization, an estimator, a proxy, a design criterion, or an open conjecture. This section gives the reader a status map so that later formulas are not mistaken for empirical findings or root definitions (Durbin & Koopman, 2012; Folland, 1999; Karatzas & Shreve, 1991; Protter, 2005).

Notation note: Chapter 4 uses schematic, often index-suppressed symbols to orient the reader; Chapter 5 supplies the branch-specific stream-indexed definitions. A schematic symbol and its Chapter 5 counterpart are not interchangeable unless the stated branch or bridge identifies them.

The chapter uses a formula-status code. R denotes received definition. CR denotes candidate realization. OE denotes operational estimator. DC denotes design criterion. OC denotes open conjecture. No line may change status inside a paragraph because the prose has become confident.

$$R: L_i^{phen}(t) = v_i(\Omega_i \cap [S_i, t])$$

$$CR: L_i^{rc}(t) := c_{LU} U_i(t) Y_i(t), c_{LU} > 0,$$

$$OE: \hat{L}_i(t_n) = \sum_{j \leq n} \Delta \hat{L}_{ij}$$

This status code is more than editorial discipline. It prevents a common failure in speculative science: the display equation is treated as if it were a discovered relation simply because it is

compact. In this volume, a formula must carry its assumptions, its context of use, its proxy status, and its route to defeat.

The dimensional problem is not cosmetic. A valence rate, a time integral, a unitless reserve, a normalized process, a momentary valence estimator, and an accumulated contribution cannot be multiplied or compared without assumptions. When those assumptions are unclear, a diagram can look cleaner than the science is. The synopsis therefore marks dimensions and unresolved bridges before it presents signatures.

The origin problem connects three choices: the reference point for phenomenal neutrality, the onset of the accumulated history, and the relation between a measured neutral band and the latent quantity. Reserve-product realizations add a fourth question: how the closing product relates to the received valence ledger. Explicit definitions make these questions available for mathematical analysis and measurement studies.

The section closes with open bridges rather than hidden repairs. Process-class mismatch, initial-condition compatibility, endpoint-reserve synchronization, whole-life ledger ignorance, scalarization, and the conservative-collapse trap remain problems that must be carried into later chapters. A synopsis that hides them would make the book easier to sell and weaker to read.

Table 4.2 is the compact dimensional and status map for the chapter. It is meant to be consulted whenever a later formula seems to be doing too much work.

The origin problem can be made concrete with a simple transformation. Suppose a momentary valence estimator $x(t)$ is

transformed into $x^*(t) = a + b x(t)$, where b is positive. Differences are preserved up to scale, but the zero changes whenever a is not zero. A terminal value that looked neutral under x may not be neutral under x^* . Without an independently meaningful zero, terminal equality can move with the analyst's convention.

The same issue compounds under integration. If a rate estimate is shifted by a constant offset, the accumulated estimate changes by that offset multiplied by included conscious time. Over a long window, a small arbitrary centering choice can dominate the accumulated ledger. This is why a study cannot create the Law's neutral origin by subtracting a sample mean or by centering a questionnaire for convenience.

The empirical program can still test less origin-sensitive structure. Slopes, forecast errors, variance shapes, reserve relations, and rival-discriminating dynamics may retain meaning under transformations that would undermine absolute terminal level. That is why the synopsis places prospective preterminal structure before terminal equality. The order is not evasive. It is an identification strategy.

Formula status should therefore travel with every symbol. The phenomenal ledger $L^{\text{phen}}(t)$ is a received formal object. The route coordinate $L^{\text{rc}}(t) = c_{\text{LU}} U(t)Y(t)$ is a candidate realization. A momentary valence estimator is an operational estimator, and an interval contribution estimate is context-bound under a declared exposure and time rule. A neutrality band is a design criterion. A verdict label is a public-status rule. These objects never carry the same authority.

A diagram can accidentally erase those statuses by drawing all objects with the same color and line. A table can erase them by putting measured estimators beside latent variables without warning. A chapter can erase them by saying the ledger when it means the measured running estimate. This synopsis names the statuses so the rest of the volume has less excuse to blur them.

The unresolved reserve-unit problem belongs in the same family. Mathematical reserve can be normalized, but physiological reserve is estimated through noisy, multidimensional clinical and biological signs. The bridge between normalized U and clinical U must be defended. Otherwise a reserve-coupled signature may look precise while the object called reserve has changed from line to line.

The viability ratio Ψ is especially fragile. It can be algebraically useful because it expresses ledger magnitude relative to remaining reserve, but as U approaches zero even small estimation error can explode. A chapter that uses Ψ must specify windows, errors, and abstention rules. It may not convert Ψ into a public urgency score.

Dimension checking is therefore a protection against hidden burden. Without it, the burden of ambiguity is passed to the reader, the reviewer, and eventually the participant whose data may be used to support a claim that the symbols never licensed.

Table 4.2. Scientific objects, status, dimensions, proxies, and failure conditions.

Object	Compact meaning	Status	Unit or scale concern	Observable proxy	Failure condition
$F(t)$	Latent valence rate contribution while the stream is unified.	Received formal object	Rate per time; sign and origin require representation assumptions.	No direct proxy; candidate momentary estimator is an estimator only after calibration.	No defensible signed, temporally additive target.
$g\theta(t)$	Unity gate that determines whether experience is included in the stream ledger.	Received formal object	Dimensionless inclusion or weight; threshold and soft-gate choices remain open.	Unity proxies from consciousness-state adjudication.	Endpoint or inclusion rule becomes circular or nonrecoverable.
$L(t)$	Latent cumulative phenomenal ledger.	Received formal target	Accumulated valence over time; origin problem remains binding.	measured cumulative estimates, never direct observation.	Scale, origin, or aggregation cannot be justified.

Object	Compact meaning	Status	Unit or scale concern	Observable proxy	Failure condition
T	Truth-level stream endpoint, fixed without terminal-ledger outcomes; stopping-time treatment requires a declared filtration and justification .	Received endpoint concept and empirical adjudication target	Not a calendar instant given by one sensor; adjudication windows matter.	Endpoint proxies and expert adjudication channels independent of the ledger.	Endpoint selected by or algebraically tied to the ledger outcome.
U(t)	Biological or functional reserve in the candidate product realization.	Candidate realization component	Unit conflict and depletion scale require formal change control.	Reserve proxies, frailty measures, clinical trajectory, physiological reserve indicators.	Reserve cannot be independently estimated or is only disease severity in disguise.

Object	Compact meaning	Status	Unit or scale concern	Observable proxy	Failure condition
Y(t)	Signed arithmetic reference process in the candidate reserve product $L^{rc}(t) = c_{LU}U(t) \cdot Y(t)$.	Candidate realization component	Signed real-valued process; not geometric and not restricted to positive values.	Inferred only through model fit under assumptions.	Reference process cannot be distinguished from bridge conditioning or ordinary control.
Rate estimate (t)	Momentary fallible estimator of valence-rate-like burden on a versioned scale.	Operational estimator	Versioned scale; calibration, response shift, and sign conventions bind use.	Physiological estimator plus validation and challenge stack, not inner life itself.	Estimator is unstable, biased, noninvariant, or invalid for the reference class.
Interval estimate	Integrated contribution unit derived from candidate momentary estimator over time under a declared version.	Operational accumulated estimate	Interval contribution, not a worth score; version and uncertainty travel with it.	Time-integrated candidate momentary estimator-derived estimate with uncertainty.	Additivity, uncertainty, or version continuity fails.

Object	Compact meaning	Status	Unit or scale concern	Observable proxy	Failure condition
Ψ	Viability ratio $\frac{ L^{rc} }{(c_{LU}U)'$ for $U > 0$, in the reserve realization.	Derived diagnostic under candidate relation	Numerically fragile near U approach ing zero; errors-in-variables problem.	Estimated only under windowed or stabilized analysis.	Unstable denominator, proxy error, or endpoint window makes inference unusable.

4.2.1 — Received Definitions

The received definitions are the target definitions carried forward into each analysis. This volume states them in the technical synopsis and develops their full specification in Chapter 5. The term received identifies the object a study is designed to investigate. A revised definition creates a revised target, so its implications for measurement and inference are recorded explicitly.

That distinction keeps criticism clean. A scientist may object that $F(t)$ cannot be represented, that $g\theta(t)$ is underdefined, or that $L(t)$ lacks an identifiable origin. Those objections attack the received target or its bridge directly. The book does not defend a substitute object merely because the substitute is easier to measure.

Received definitions are the fixed target objects used throughout this volume. The bearer is a separately routed maximal qualifying conscious stream, not the body, biography, legal person, social identity, or record. The currency is phenomenal valence under a

prospectively fixed representation, sign, neutral origin, and exposure rule. The ledger is latent. The domain is complete and strict-pre-endpoint on the primary branch. The endpoint is the truth-level endpoint. Candidate momentary and interval estimators are research objects, not instruments already validated (Durbin & Koopman, 2012; Folland, 1999; Karatzas & Shreve, 1991).

The science volume can analyze these definitions, pressure their operational use, and show what must be measured, but it cannot silently rewrite them. If a later chapter discovers that a definition needs formal amendment, that problem belongs to formal change control. A scientific chapter may identify the failure and state its implications; it may not pretend the root object has changed because a study design prefers a different one.

The received definitions also come with public-risk boundaries. The unified stream is not a public identity. The latent cumulative process is not an administrative account. Candidate momentary and interval estimators are not human-worth scores. The endpoint is not a spectacle. Scientific evidence is not legal, religious, or civic authority. These boundaries travel because the definitions would be dangerous without them.

A reader can think of received definitions as the coordinates of the research map. Coordinates do not prove that the destination exists. They let investigators say where they are trying to go and what kind of error would mean they are no longer studying the proposed object. Without received definitions, every failed test could be escaped by renaming the target.

The key received object is the phenomenal ledger, a signed measure accrued over the declared phenomenal-event domain. On the absolutely continuous physical-time branch, the ledger uses the experienced-exposure density $g_{\theta,i}(t)q_i^{\text{exp}}(t)$ and realized neutral-relative value $v_i^{\text{real}}(t)$. This is a formal target, not a sensor output, questionnaire total, or social record.

Dimensional reading follows from that factorization. The product $g_{\theta,i} q_i^{\text{exp}} v_i^{\text{real}}$ has ledger-per-clock-time units on the declared chart; integration yields accumulated phenomenal value. A momentary estimator may approximate only a versioned local component, and an interval contribution estimates an increment, not the person, a score, or a hidden moral balance:

$$\Delta L_{i,[a,b]} = \int_a^b \vartheta_i(s) d\hat{\tau}_i(s)$$

$$\Delta L_{ij} = \vartheta_i(t_j) \Delta \tau_{ij}, \hat{L}_i(t_n) = \sum_{j=1}^n \Delta L_{ij}$$

L denotes the latent target under the formal hypothesis. $\hat{L}$ denotes its estimate under a versioned observation model, carrying uncertainty from missingness, sign conventions, and context of use. The measurement relation connects these two objects in the analysis.

The inherited definitions keep the scientific object honest. They direct attention to experience rather than outward appearance, to stream unity rather than administrative identity, and to an independently specified endpoint rather than a dramatic scene

selected after the fact. Their value lies partly in what they refuse to simplify before evidence begins.

4.2.2 — Candidate Realizations

Candidate realizations make room for mathematical exploration. A model can derive signatures, reveal incompatibilities, and identify conditions that distinguish it from alternatives. Those consequences turn a broad hypothesis into specific questions.

The reserve product is therefore presented with both force and restraint. It is powerful because it links terminal dynamics to a declining capacity variable. It is restrained because reserve, normalized process, and endpoint synchronization are not gifts from notation. They have to be estimated, justified, and compared.

Candidate realizations are proposed ways the received formal object might generate measurable consequence structures. They are not root definitions. The principal current route coordinate is $L^{\text{rc}}(t) = c_{\text{LU}} U(t)Y(t)$, where a declared reserve state and signed normalized coordinate generate drift, innovation, and dispersion restrictions. Its value is that it exposes the route to measurable signatures. Its danger is that compact notation can be mistaken for a discovered mechanism (Karatzas & Shreve, 1991; Protter, 2005).

The reserve route has a specific scientific burden. $U(t)$ must be independently meaningful, not merely a symbol chosen to vanish at the endpoint. $Y(t)$ must be a signed arithmetic reference process, and c_{LU} must carry a declared scale convention. The relationship between L^{phen} and L^{rc} must be derived, assumed, or

marked open. Endpoint-reserve synchronization must be tested rather than built into the definitions.

On the reference route, reserve is nonincreasing with $dU_i(t) = -r_i^U(t)dt$ and $r_i^U(t) \geq 0$, while the signed normalized coordinate follows:

$$dY_i(t) = \sigma_i(t)dW_i(t), L_i^{rc}(t) = c_{LU}U_i(t)Y_i(t).$$

With $U_i(t) > 0$, the product rule gives:

$$dL_i^{rc}(t) = \frac{-r_i^U(t)}{U_i(t)}L_i^{rc}(t)dt + c_{LU}\sigma_i(t)U_i(t)dW_i(t).$$

The empirical signature is joint, not single. On the positive, absolutely continuous reserve branch, the integrated restoring coefficient diverges as reserve tends to zero. Pointwise strengthening of the restoring coefficient $\kappa_i^U(t) = r_i^U(t)/U_i(t)$ requires an additional rate or monotonicity premise; vanishing innovation requires $\sigma_i(t)U_i(t) \rightarrow 0$. Endpoint-conditioned bridges can produce pull toward zero, but reserve-linked prediction asks whether the declared drift and innovation signatures track an independently estimated route state under common observation and rival models.

A candidate realization can be powerful because it produces fingerprints: drift dominance, innovation contraction, variance compression, time-scaling relations, and viability-ratio behavior. But each fingerprint has rivals. Ordinary control systems can pull states toward set points. Bridges can condition paths on endpoints. Disease severity can couple reserve and affect. Observation loss can shrink measured variance. A realization earns attention only through discrimination.

Candidate control models play a different role. Completion-potential, conditioned-path, reserve-coupled, homeostatic, predictive, and reinforcement-learning accounts can explain parts of experience dynamics. Some may be Law-candidate mechanisms, some may become rivals, and some may be retired. The synopsis marks them as candidate mechanisms, not settled physiology.

A conservative-state representation requires a separate justification. Defining valence as the derivative of a state function makes the integral a boundary difference; imposing equal initial and final values would additionally force closure. The target cannot gain empirical support from those imposed conditions. An independently specified potential remains available as a model or rival, subject to a validated phenomenal bridge.

The fairness lens treats candidate realizations as offers of vulnerability. A mechanism is not added to make the Law safer. It is added to let the Law lose in more precise ways. If the mechanism cannot be measured or separated from rivals, it cannot support a discriminating empirical claim. If closure is imposed by construction, that imposed result is not empirical support; independently testable path predictions remain available for comparison.

4.2.3 — Operational Proxies and Estimators

Report the momentary-to-interval estimator chain with its uncertainty, context, channel coverage, and no-estimate states. That information lets later analyses use the estimate under the conditions it can support.

This is also where the anti-score rule becomes technical. A score usually tempts users to rank, sort, and administer. A research estimator instead carries purpose limitation, uncertainty, contestability, and prohibited use. The same number can become either a tool or a harm depending on the governance that surrounds it.

Operational proxies and estimators are the tools by which a study witnesses what it cannot directly see. The momentary valence estimator is a context-bound momentary estimate, not inner life itself. The candidate interval contribution estimate is an accumulated contribution derived under a versioned integration rule, not a unit of worth. Unity proxies, reserve proxies, endpoint proxies, clinical observations, active reports, behavioral context, and records all have limited roles and must be kept distinct (Särkkä, 2013).

A generic observation layer can be written as a state-space model rather than a direct readout:

$$X_k(t) \sim p_{\phi,k}(X_k(t)|F(t), U(t), \theta(t), C(t), M(t))$$

$$\hat{v}_i(t) = m_{\psi}(X_{i1}(t), \dots, X_{iK}(t), C_i(t), M_i(t)) + \varepsilon_i(t)$$

Here $C(t)$ denotes context and $M(t)$ marks medication, device, clinical, and observation conditions. The formula is deliberately broad. It makes clear that the momentary valence estimator is an estimator shaped by a model, not a natural instrument that automatically inherits the authority of the latent target.

The naming discipline matters. First-person reports, family context, clinician observation, behavior, and qualitative materials

can validate, challenge, or contextualize a momentary valence estimate. They are not automatically channels used by the momentary valence estimator by default. Treating every witness as a channel would create a spurious total instrument and invite surveillance creep. The estimator must remain narrower than the person.

Every operational object needs a version. Instrument version, channel weights, calibration rules, sign conventions, missingness treatment, uncertainty propagation, endpoint proxy definitions, and data-retention rules should be frozen for a study. If the version changes, the claim version changes. A result obtained under one bridge should not be retroactively folded into another.

Estimators also carry response-shift and context burdens. A person's language, medication, culture, disability, fatigue, delirium, sleep, fear, and relationship with researchers can change what a report or physiological channel means. A proxy that works in one state or reference class may fail in another. The synopsis therefore treats proxies as research questions, not solved instruments.

A compact momentary-to-interval estimation example helps. A participant has four observation windows. The momentary valence estimator estimates a momentary burden signal with uncertainty. The candidate interval contribution estimate integrates those estimates across time, marking missing windows, device removal, medication changes, and confidence. The result is not the person's ledger. It is a fallible estimate of a study-defined contribution on a versioned scale.

A broader multimodal alternative makes the bridge clearer. This illustration is distinct from the received physiological candidate described in §6.5.1. Imagine a thirty-minute window with a brief report channel, a physiological channel corrected for medication and movement, and a clinical-context channel marking a pain episode, support contact, or rest. The separately declared model specifies which observations inform the signed estimate and how each channel's uncertainty is represented.

At each minute, this illustrative multimodal model combines the declared channels. A report missing because the participant declined a prompt is not replaced by zero. Refusal, fatigue, sleep, distress, and device burden enter the observation model; unresolved missingness widens uncertainty or yields no estimate for that minute.

If the momentary valence estimator has been calibrated as a rate-like estimate, the interval valence contribution estimate for the thirty-minute interval is the time accumulation of those minute estimates. The covariance between minutes matters. A series of correlated errors does not shrink simply because the data table has many rows. The interval contribution travels with uncertainty and with a label showing which channels were active.

The running measured cumulative estimate begins at the study-window origin. Its graph represents accumulation during the observed window; a complete-history analysis adds an independently identified or bounded prior contribution.

Now suppose reserve is estimated independently from functional decline, clinical trajectory, and physiological reserve markers. If

the windowed measured cumulative estimate shows drift and innovation behavior linked to that reserve estimate, the result can enter the candidate-signature analysis. If reserve was partly computed from the ledger itself, the coupling would be less informative or circular.

A different artifact appears when a smoother uses information from after a candidate endpoint to reconstruct the preterminal path. The resulting curve may begin bending toward neutrality before the endpoint because future data have leaked backward through the analysis, not because participants followed a prospective completion dynamic. The correct response is a no-look-ahead audit and a filtered analysis, not admiration for the smooth curve.

A well-built bridge between momentary and interval valence estimators is therefore an instrument of restraint. It does not promise to see all of inner life. It tells the study when it is seeing enough to ask a bounded question and when it should withhold claim language.

An estimator can simplify the participant so aggressively that its apparent precision becomes a design defect. Sleep disruption from a device, pressured reports, relational data gathered without consent, informative missingness, or a model that compresses uncertainty into one clean trace all change the bridge between experience and evidence. Those changes belong in the analysis, not outside it.

4.2.4 — Dimensions and Rate Consistency

A dimensional map makes the notation easier to interpret. For each quantity, specify whether it is a rate, interval contribution, reserve coordinate, or ratio, and state the corresponding units.

The unresolved reserve-unit conflict is not a reason to abandon the program. It is a reason to route the program honestly. Later formal work may choose a normalization, a dimensional bridge, or a family of admissible transformations. Until then, the text should not pretend that all quantities already live on one coherent physical scale.

Dimensions connect each expression to a quantity that readers can interpret and researchers can check. $F(t)$ is a rate-like formal contribution over time. The unity gate is dimensionless or weighting-like. $L(t)$ accumulates over time. $U(t)$ is a reserve quantity in a candidate realization. $Y(t)$ is the normalized signed reference process in that realization. The candidate momentary valence estimator is an estimator on a declared scale. The candidate interval contribution estimate is an integrated estimate. Ψ is a derived ratio and becomes fragile near vanishing reserve (Durbin & Koopman, 2012; Folland, 1999; Karatzas & Shreve, 1991).

The reserve-scale convention should be explicit. The reserve-coupled realization uses a positive route-scale constant c_{LU} , allowing U to retain its declared reserve unit while Y carries the complementary unit. A normalized submodel may set $c_{LU}=1$, but that is a declared gauge choice rather than an empirical finding:

$$L_i^{rc}(t) := c_{LU} U_i(t) Y_i(t), c_{LU} > 0,$$

The reserve-normalized coordinate is:

$$Y_i(t) = \frac{L_i^{rc}(t)}{c_{LU}U_i(t)}, \Psi_i(t) = \frac{|L_i^{rc}(t)|}{c_{LU}U_i(t)} = |Y_i(t)|.$$

The notation should not let U mean biological capacity in one paragraph, ledger scale in another, and time-to-death in a third. A dimension table is not pedantry. It is the line between a formal model and a suggestive metaphor.

The product $L^{rc}(t)=c_{LU} U(t)Y(t)$ specifies a dimensional relation. If U carries reserve units, c_{LU} and Y together convert them into ledger units. Gauge rescaling leaves the product unchanged, so claims about the separate factors require an external anchor.

Rate consistency matters for integration. A momentary level cannot be accumulated like a rate without a time rule. If the momentary valence estimator estimates a valence-rate-like contribution, then the interval valence contribution estimate requires declared time intervals, missingness rules, and uncertainty propagation. If the momentary valence estimator estimates a state level instead, the integration claim changes. The title of the estimator does not solve the unit problem.

The viability ratio $\Psi=|L^{rc}|/(c_{LU} U)$ is useful only under the candidate route and only above a validated reserve floor. As U approaches zero, small reserve error can dominate the ratio. The synopsis therefore treats Ψ as a fragile diagnostic requiring windowing and errors-in-variables analysis, not as a terminal truth meter.

Terms adopted from physics, control theory, or neuroscience should retain a clear definition and mathematical role. Where a

term enters empirical work, specify its measured indicators, units, and comparison model.

The fairness lens sees rate consistency as anti-burden work. Bad units shift interpretive burden onto future readers, analysts, and participants. They make disagreement look philosophical when it is actually a measurement error. A humane science of felt experience owes its participants dimensions that can be checked.

4.2.5 — Initial Conditions and Study Windows

A terminal window can contain valuable information about changing dynamics. Complete-history analysis also represents the contribution before enrollment, using historical information, justified bounds, or sensitivity analysis as available.

Diaries, health records, speech, behavior, and public archives may enrich a participant's history. Each enters the analysis with its documented coverage, missingness, sign interpretation, and context.

Stream onset and study enrollment define different starting points. A late-life study combines its observed window with an unknown pre-enrollment contribution, represented through an explicit estimate, bound, or sensitivity analysis (Karatzas & Shreve, 1991; Protter, 2005).

An origin transformation makes the danger visible. If an estimator shifts the rate origin by a constant over a unity-one interval, the accumulated estimate shifts with time. A neutral-looking endpoint can therefore be created or destroyed by origin choice. The program must test structures that are less dependent on arbitrary

origin when possible, then treat terminal level claims as more assumption-sensitive.

The reserve route adds an initial-condition compatibility problem. If L^{phen} and L^{rc} are asserted to be the same pointwise object at stream onset, their initial values must agree. A realization that chooses a convenient Y initial state without an explicit bridge changes the route rather than solving it.

On the exact path-bridge branch, the initial identity is:

$$L_i^{\text{phen}}(S_i^\theta -) = L_i^{\text{rc}}(S_i^\theta -) = c_{\text{LU}} U_i(S_i^\theta -) Y_i(S_i^\theta -).$$

If the phenomenal convention additionally sets the initial ledger to zero and reserve is positive, this identity constrains the initial Y state. Other branches may use an offset, a reduced-form route, or an explicit initial ledger, but the choice must be declared before terminal fitting.

Study windows also change reference class. A palliative cohort with forty days of observation is a study of local terminal dynamics under a defined care context, not a whole-life ledger. It may estimate drift, variance, reserve coupling, missingness, and endpoint behavior during that window. It may not infer total lifetime balance without a bridge that no first study possesses.

Initial-condition honesty makes partial support possible. A late-window study might support a preterminal consequence while abstaining from terminal-level equality. It might show a rival dominates late dynamics while leaving earlier-life mechanisms untouched. It might reveal that pre-enrollment uncertainty is too

large for any terminal-level statement. These are legitimate outcomes.

A study window is not a life. Treating a late observable interval as though it represented the complete stream overstates what participants supplied and obscures which portion of the trajectory was actually informative. The correct result names the window, the unobserved history, and the assumptions connecting one to the other.

4.2.6 — Open Formal Bridges

Open bridges define a research agenda. Naming them gives future formal work a precise direction and keeps each dependency available for review.

Open formal bridges are not footnotes. They are the places where the research program could break before data become decisive. The integral definition and the reserve product belong to different process classes unless a bridge is supplied. Origin, unit, scalarization, endpoint, reserve, and representation assumptions must be declared. A study that ignores the bridges may produce clean results for the wrong object (Särkkä, 2013).

The process-class discrepancy is central. The received ledger is written as a unity-gated integral over time. The candidate reserve realization writes the ledger as a product of reserve and a signed reference process. The product can be useful, but the equivalence of these descriptions is not automatic. The bridge may be an assumption, a derivation, or an open conjecture. Its status must be labeled. A useful derivation would show how changes in reserve and the reference process combine to reproduce the ledger's

increments under the same initial conditions and time convention. A bridge that reproduces increments but not the same domain or initial condition would establish a related construction, not identity with the received ledger.

Endpoint-reserve synchronization is another bridge. If $U(t)$ approaches zero at the same time the endpoint T occurs, the product construction can force L toward zero. That can be a candidate mechanism only if reserve is independently defined and not chosen because it vanishes where the endpoint is declared. Otherwise the construction risks making closure true by design. Tracking both factors near the endpoint helps determine whether the reference process remains bounded or grows rapidly enough to offset the decline in reserve. A useful test asks whether the same reserve definition predicts closure timing in held-out streams where endpoint location was not used to calibrate the reserve measure.

The Logical Fork also remains open. If the endpoint is independent and the terminal ledger distribution remains continuous and nondegenerate, exact terminal equality is not expected by chance. The program must therefore identify what premise changes: terminal degeneracy, atom formation, boundary control, endpoint-state coupling under declared rules, or another mechanism. Each option has different signatures and risks. Comparing these options under a shared observation model can identify which differences in timing, distribution shape, or boundary behavior are detectable with the planned measurements. These branches should be compared on observable implications

that diverge before the endpoint, because terminal fit alone may leave their generative differences unresolved.

Scalarization is an open bridge because lived experience may be multidimensional. Pain, calm, fear, meaning, relief, dignity, fatigue, attachment, and bodily distress do not collapse into one dimension without a value-laden or empirical rule. The formal model uses a signed contribution, but the empirical bridge must justify how channels become a single estimator without erasing structure. Where scalarization is nonunique, the empirical object may be a set of admissible residuals rather than one number, preserving uncertainty at the representation layer.

4.3 — Measurement and Endpoint Dependency Chain

The research program has an order. Representation comes before integration. Calibration comes before comparison. Bearer classification comes before endpoint inference. Endpoint rules come before outcome inspection. Filtering comes before smoothing. Observation processes enter the generative model rather than being swept into missingness after the fact (Borsboom, 2005; Little & Rubin, 2019; Rubin, 1976; Särkkä, 2013).

The chain uses a separate decision at each prerequisite: signed representation, measurement calibration, endpoint adjudication, observation quality, and model comparison. Later inference proceeds when the prerequisites on which it depends meet their criteria.

The chain is also ethical. Endpoint science touches people in vulnerable situations, but the protection here is not simply a warning. No-crisis recruitment, burden budgets, palliative priority, consent scope, device withdrawal, and staff workload affect data quality because they affect who enters, who remains, what is observed, and how signals change. The ethics chapter owns the full firewall; this section shows where it enters the dependency stack.

The reader should notice that the endpoint firewall has two walls. The constructional wall prevents defining truth-level endpoint by the ledger or by a zero result. The inferential wall prevents selecting, smoothing, or adjudicating the endpoint after seeing the outcome in a way that builds the conclusion into the test. Both walls have to hold before terminal inference can be discussed.

Table 4.3. Dependency chain as a noncompensatory gate system: later success cannot repair earlier failure.

Gate	Pass condition	If it fails	What cannot compensate
Representa tion	Signed, temporally additive target is defensible for the reference class.	Ledger inference is unavailable or must be narrowed.	No endpoint pattern or large sample can repair it.
Calibration	Origin, sign, scale, invariance, and response shift are handled by frozen rules.	Comparison across time, persons, or sites loses warrant.	No smoothing or model selection can make the scale valid after the fact.
Bearer	The unified stream is adjudicated with confidence appropriate to the study.	The endpoint may not be assigned to the correct object.	Terminal concentration cannot identify the bearer.
Endpoint	truth-level stream endpoint is defined prospectively through non-ledger channels.	Neutrality becomes circular or uninterpretable.	A clean final curve cannot rescue a circular endpoint.
Observatio n process	Missingness, device removal, visit timing, sedation, and clinical escalation enter the generative model.	A favorable pattern may be observation artifact.	More participants cannot remove structured bias by volume alone.

Gate	Pass condition	If it fails	What cannot compensate
Model recovery	The pipeline recovers known synthetic generators under realistic error.	Real-data model comparison is not trustworthy.	A better information criterion on real data cannot substitute for recovery.
Rival comparison	Strong rivals are specified, fit, and allowed to win.	Support remains local or rhetorical.	One dramatic signature cannot replace direct rival pressure.
Replication and transport	Independent sites and populations reproduce bounded component claims.	Status remains preliminary or reference-class limited.	A single mature site cannot authorize universal language.

4.3.1 — Representation Before Integration

Representation also asks whether mixed affect can be treated as a scalar without distortion. Many experiences contain relief and pain, fear and love, grief and gratitude, exhaustion and peace. Scalarization may be useful for a bounded estimand, but it is a component assumption, not an obvious fact about experience.

Scalarization must specify what information is discarded, which rival interpretation that loss permits, and whether a vector or identified-set representation better answers the study's question.

Before integrating, the program specifies what is being added, its sign, its time basis, its unity condition, and its uncertainty. Those representation choices give temporal addition a defined meaning (Borsboom, 2005; Folland, 1999).

A minimal scalarization can be written as:

$$F_w(t) = w^\top z(t), w \in W, L_w(T) = \int_0^T g_\theta(t) w^\top z(t) dt$$

If several admissible weights remain plausible, the identified terminal set is:

$$L(T; W) = \{L_w(T) : w \in W\}$$

A result is scalarization-sensitive when the sign, equivalence-band conclusion, or rival ranking changes across W . In that case the proper outcome is narrowing or abstention, not a more confident paragraph.

The representation problem is deeper than choosing variables. Physiological arousal can accompany fear, joy, effort, fever, pain, medication, or social contact. A report can be shaped by language, shame, sedation, or hope. Behavior can express burden or conceal it. The signed target must therefore be built from validation, challenge, and context, not from channel convenience.

The most dangerous shortcut is to integrate a score whose sign is not stable. If high values sometimes mean burden and sometimes mean restoration, then a cumulative total can cancel unlike things by arithmetic rather than experience. The program must declare channel transformations, anchors, response-shift rules, and exclusion conditions before the interval valence contribution estimate is computed.

Representation also decides what is left out. If meaning, dignity, trauma, disability, culture, or communication access changes the interpretation of signals, the model must either include the issue

or restrict the reference class. A silent omission is not neutral. It shifts burden onto people whose experience is harder to measure.

A study may find that the proposed signed target is unsuitable for a population or state. It then reports that result and develops an alternative representation before proceeding with accumulation.

Representation should preserve what matters about the experience before any integral is computed. The aim is not to grind a life into a single number, but to define a signed target whose interpretation, uncertainty, and limits remain visible. Representational fidelity therefore precedes mathematical convenience.

4.3.2 — Calibration Before Comparison

Calibration is also a history problem. A person's use of language, bodily awareness, and emotional scale may change after illness, trauma, medication, aging, cultural migration, or terminal proximity. A stable number across time can hide a changed meaning, and a changed number can hide a stable experience under a changed reporting frame.

Calibration is an ongoing state documented by interval, instrument version, response-shift checks, and uncertainty. This record lets later analyses use each measurement under the conditions in which it was evaluated.

Comparison requires calibration. A measured value today cannot be compared with a measured value next week, another site, or another person unless the scale has a declared relationship across those contexts. The same number may not mean the same burden after illness progresses, after medication changes, after language

shifts, after response styles adapt, or after a sensor is replaced (Rubin, 1976; Särkkä, 2013).

The origin problem becomes operational here. A neutral point can be set by rules, but the rule must be defended. A personal baseline may support within-stream change while failing across-person comparison. A population anchor may support site harmonization while missing local meaning. A terminal band may be useful for equivalence only if fixed before outcomes are known.

The affine-origin problem can be stated in one line. If $x^*(t)=a+bx(t)$, with $b>0$, then the study-window integral transforms as:

$$\int_{t_0}^{t_1} x^*(t) dt = a(t_1 - t_0) + b \int_{t_0}^{t_1} x(t) dt$$

The effect of origin uncertainty differs by estimand. Analyze its influence on dynamical restrictions, comparisons, and absolute terminal levels separately, and carry the resulting uncertainty into each conclusion.

Calibration also includes uncertainty propagation. If the momentary valence estimator has uncertainty, the interval valence contribution estimate inherits it. If the endpoint is uncertain, the terminal estimate inherits it. If reserve proxies are noisy, reserve-linked slopes inherit it. A clean final table without uncertainty is not clearer. It is less honest.

Response shift is a special hazard. People may change the meaning of their ratings as illness, adaptation, fear, acceptance, fatigue, or hope changes. A scale may appear stable because participants learned the instrument rather than because experience

kept the same metric. The program must model, test, or restrict around response shift before comparison.

Calibration failure can narrow rather than end the program. A method may work within a person but not across persons, within one culture but not another, or within active reports but not in delirium. The status update should say exactly which comparisons remain licensed.

A bad calibration rule usually fails unevenly. Language, culture, disability, development, and clinical condition can be mistaken for noise when the instrument is really losing invariance. Calibration before comparison is therefore both a scientific requirement and a protection against systematic misrepresentation.

4.3.3 — Bearer Before Endpoint

The bearer question also guards against archive drift. A sufficiently detailed record can make observers feel that the stream is still present, especially when speech, images, and Artificial Intelligence reconstructions are available. The scientific bearer is not the archive. The archive may inform history or context; it does not continue the stream by being vivid.

Endpoint discipline therefore begins with respect for the thing that could end. If the stream is uncertain, endpoint confidence should be uncertain. If the stream is partitioned, interrupted, or returning, a single endpoint label may be premature. Scientific dignity means letting ambiguity remain visible instead of forcing a clean ending.

An endpoint can close only the object it belongs to. The object is a separately routed maximal qualifying conscious stream, not merely a body, chart, legal person, family story, or device record. Before a terminal event can be interpreted, the program must have a qualified bearer model, exhaustive routing rule, and continuity class appropriate to the study (van der Vaart, 1998).

Bearer adjudication is not metaphysical ornament. Sleep, anesthesia, coma, delirium, dementia, dissociation, developmental thresholds, nonhuman animals, and artificial systems can all challenge the boundary of the stream. A terminal endpoint assigned to the wrong bearer is not a noisy result. It is a category error.

Bearer uncertainty should travel visibly. A study can declare confidence classes: high-confidence unified stream, uncertain continuity, possible partition, temporary interruption, or insufficient evidence. Those classes then control which endpoint and ledger claims can be made. A terminal estimate without bearer confidence is under-specified.

This gate also protects public dignity. No person should be treated as less worthy because the science cannot classify the stream with confidence. Uncertainty about bearer status is a limit on the claim, not a ranking of the person, family, species, or system.

Stream classification distributes uncertainty across the entire analysis. Families may supply context, clinicians may judge state, researchers may quantify confidence, and participants may still be misclassified. Naming those roles before endpoint inference

keeps a terminal timestamp from concealing unresolved bearer uncertainty.

4.3.4 — Endpoint Before Outcome Inspection

The endpoint firewall must also survive incentives. Researchers, donors, public readers, and institutional partners may all prefer a clean terminal picture. That preference can subtly influence window choice, smoothing, censoring, and exclusion. A prospectively specified endpoint rule is a defense against the project’s own desire to be right.

A technical reader should be able to audit the endpoint path without trusting the author’s virtue. The rule, data channels, thresholds, uncertainty classes, adjudicators, disagreements, revisions, and analysis consequences should be visible. Trust grows when it is not required.

The endpoint must be defined before the outcome is inspected. If the truth-level endpoint is selected by looking for the moment when the measured cumulative estimate is nearest zero, the program has defined the conclusion into the test. This is the tautology firewall in operational form. Endpoint channels must be prospectively declared and not algebraically identical to the ledger estimator (Hernán & Robins, 2020).

On a declared first-hitting endpoint branch, with a specified endpoint filtration and regularity conditions ensuring the stopping-time property, the endpoint rule can be written as:

$$T_{\theta}(\omega) := \inf\{t \geq 0: \theta_t(\omega) \in E_{\theta}\}, \quad \omega \in \Omega_{\theta}$$

$$\{T_{\theta} \leq t\} = \{\omega \in \Omega_{\theta}: T_{\theta}(\omega) \leq t\} \in \mathcal{F}_t^{\text{endpoint}}$$

$$T_{\theta} = \Phi_{\theta}(\theta_{[0,\infty)}).$$

Constructional separation does not require stochastic independence. Any shared causes or residual dependence between endpoint channels and the ledger must be represented in the joint model.

Endpoint discipline contains a universal anti-tautology requirement and branch-specific timing premises. Universally, the truth-level endpoint must be prospectively defined and adjudicated independently of the ledger value whose closure is tested; defining the endpoint as the first or last zero makes closure an identity. On a declared independent-endpoint branch, timing independence from the ledger-generated information set and the protocol-fixed support assumptions are additional premises. State-coupled timing, first hitting or absorption, endpoint atoms, singular carriers, continued experience, and endpoint-inclusive value remain distinct branches. Windows, smoothing rules, thresholds, and exclusions must be frozen before outcome inspection in every branch.

Clinical reality makes the rule hard. Dying is not always a single observable instant. Resuscitation, sedation, coma, low-signal periods, device removal, family decisions, and record gaps can create multiple plausible windows. The program must specify how uncertainty is represented rather than pretending precision that care cannot provide.

Endpoint failure is a valid verdict. If the endpoint cannot be adjudicated independently, no terminal inference should be drawn. A study may still inform measurement burden,

observation processes, care feasibility, or preterminal dynamics, but it should not speak about terminal concentration.

This rule also blocks the archive-as-soul drift. Records of last moments are not the person and do not survive as consciousness. Endpoint evidence is a research artifact under consent and governance. It should not be turned into spiritual proof, public spectacle, or a final narrative about a life.

A clean endpoint is never worth a compromised deathbed. If classification procedures intrude on comfort, family presence, or clinical judgment, the protocol has failed before the model is fitted. Endpoint discipline therefore begins with care-compatible observation and a standing right to return no estimate.

4.3.5 — Filtering Before Smoothing

Filtering also gives the program a way to lose prospectively. A smoothed reconstruction can often be made to look orderly because the endpoint is already known. A filtered forecast has to speak before the ending. That temporal humility is one reason filtered performance carries more evidentiary force.

Smoothing still matters, especially in clinical states where reports are sparse and later information clarifies earlier uncertainty. The rule is not to forbid smoothing. The rule is to label it, restrict its claim, and prevent it from impersonating prediction.

Filtering and smoothing answer different questions. Filtering uses information available up to a time point to estimate or forecast the current state. Smoothing uses information from before and after a time point to refine a retrospective estimate. Both can be useful, but they cannot be confused. A prospective prediction cannot use

future information and still count as prospective (Rubin, 1976; Särkkä, 2013).

The distinction can be written in conditioning notation, with $\mathcal{Y}_t := \sigma(Y_s : s \leq t)$ denoting the information generated by observations through t :

$$\hat{L}_{\text{filter}}(t) = \mathbb{E}[L(t) \mid \mathcal{Y}_t]$$

$$\hat{L}_{\text{smooth}}(t) = \mathbb{E}[L(t) \mid \mathcal{Y}_T]$$

Every figure should therefore label its information set as observed, filtered, forecast, smoothed, endpoint-aligned, retrospectively adjudicated, or simulated. A prespecified smoothed analysis may support retrospective adjudication, quality control, or teaching; its evidentiary role remains retrospective.

The distinction matters because terminal alignment is powerful. If trajectories are smoothed after the endpoint is known, they can appear cleaner, more convergent, and more law-like than they were in real time. That may be acceptable for retrospective description if labeled. It is not acceptable as evidence for prospective restriction unless the analysis separates the two.

Filtering before smoothing also protects model comparison. A Law candidate may perform well in retrospective smoothing and poorly in real-time forecasting. A bridge rival may look similar after alignment but differ prospectively. The program needs both comparisons, but it must not let retrospective elegance masquerade as prediction.

A study can fail this gate if the pipeline cannot reproduce what information was available at each time. Missing timestamps, undocumented endpoint adjudication, late transformations, and untracked imputation can make a dataset unsuitable for prospective claims. The right response is no inference or retrospective-only status, not narrative rescue.

4.3.6 — Observation Process as Data

Because measurement can change behavior and care context, contact burden belongs in the observation process rather than outside the model.

The observation process is part of the data-generating system. Device removal, visit timing, family presence, clinical escalation, sedation, fatigue, refusal, staff workload, and the participant's tolerance for contact can all shape what is observed. Treating these as mere missingness after the fact hides a causal pathway that may mimic the target signature (van der Vaart, 1998).

The applicable dependency chain is noncompensatory: target, calibration, burden limits, reserve qualification when a reserve-coupled route is tested, endpoint rule, model recovery, prospective prediction, rival comparison, and component verdict must pass before any downstream inference that depends on them. A failed target, calibration, burden, endpoint, or recovery gate blocks the downstream inference. This is substantive because device intrusion, family anxiety, staff overload, and clinical escalation can otherwise masquerade as properties of the latent process.

The observation process also explains why absence has many meanings. No report can mean comfort, sleep, fatigue, inability, refusal, delirium, sedation, shame, family filtering, clinical urgency, or technical loss. A design that treats absence as neutral has already chosen one story without evidence.

For the candidate reserve coordinate $L^{\text{rc}}(t) = c_{\text{LU}} U(t)Y(t)$, a useful observation model is:

$$\begin{aligned} L_{\text{obs}}(t) &= L^{\text{rc}}(t) + \varepsilon(t) \\ \text{Var}(L_{\text{obs}} \mid U = u) &= c_{\text{LU}}^2 u^2 \text{Var}(Y \mid U = u) + \text{Var}(\varepsilon \mid U = u) \\ &\quad + 2c_{\text{LU}} u \text{Cov}(Y, \varepsilon \mid U = u). \end{aligned}$$

The additive-noise floor can bias the estimated variance exponent downward, making a reserve-coupled process look more bridge-like. More observations sharpen the wrong answer if the floor remains uncharacterized. The response requires an observation model, sensitivity analysis, and abstention when the floor dominates. Where feasible, estimating the floor from independent calibration or control measurements gives the correction a separate empirical basis rather than allowing it to inherit the terminal structure being tested.

The strongest first protocols should make observation marks analyzable objects. Device removals, prompt refusals, response latency, family presence, clinical interruptions, staff workload, care changes, and participant-requested pauses should be recorded as part of the generative process. They may reveal that the study is not viable before they reveal anything about the Law. Predeclaring how each mark enters the primary and sensitivity analyses, including any stratification, observation-process

modeling, or abstention rule, turns these events into reproducible design information rather than post hoc judgment.

Observation intensity can collapse near the endpoint. If the most distressed, medicated, or low-reserve periods are less likely to produce usable momentary valence estimator windows or reports, measured variance may shrink even when latent experience has not. A favorable-looking terminal pattern can therefore be a visibility pattern. The program must model observation gain. Because changing observability can alter apparent location, dispersion, and temporal dependence together, the analysis should carry the observation model through the full candidate signature rather than correct variance alone.

Observation also affects ethics. Devices that disturb sleep, questionnaires that increase worry, and interviews that change family behavior can alter the measured state. Research burden is both a moral cost and an input into internal validity. The protocol should distinguish burden created or amplified by measurement from burden already present in the clinical state, because the former represents observation reactivity introduced by the study.

Every estimate should carry observation marks: active report, passive physiological observation, device-off, medication-changed, family-present, clinician-interrupted, burden-stopped, endpoint-uncertain, or no-estimate. These distinguish absence of signal from absence of experience. These marks should remain available in analysis so a quiet segment caused by device loss cannot be pooled with a quiet segment observed under full coverage. A protocol-fixed rule for how each mark enters the primary and sensitivity analyses prevents the same observation

failure from being reclassified opportunistically after outcomes are known.

A study may produce valuable observation-process results even when the Law-specific inference abstains. It may show that a device is too burdensome, that missingness is informative, that staff workload makes the protocol infeasible, or that endpoint windows are too sparse. Such findings improve future research by revealing burden. Such results should be reported as feasibility or observation findings in their own right rather than buried beneath an abstained primary verdict.

Observation is selective in ways that often track vulnerability. The exhausted participant, overloaded clinician, or family member who can no longer support the protocol may vanish from the record just when the system is under greatest strain. Modeling the observation process makes that selection visible instead of converting it into a deceptively quiet dataset. Burden-linked dropout should therefore enter the estimand and sensitivity plan, not be treated merely as a loss of statistical precision.

Observation intensity can be modeled as a process with its own history and predictors. The probability of a usable report at time t may depend on earlier symptoms, treatment, reserve, family presence, staff workload, and previous prompts. A joint model of the latent trajectory and marked observation process makes those relationships explicit and supports sensitivity analysis across alternative missingness assumptions (Rubin, 1976; Little & Rubin, 2019; Hernán & Robins, 2020). Joint models should report which predictors affect observation intensity independently of the

latent state, because those variables can help diagnose selection without becoming outcome proxies.

Observation-specific negative controls can help separate visibility from experience. Device battery loss, scheduled maintenance, staffing transitions, benign changes in prompt timing, and channels that should respond to contact burden but not to the latent Law-specific state can reveal whether apparent contraction follows the measurement system. State-space filtering and smoothing may summarize such patterns, but the filtered estimate available at time t must remain distinct from the retrospectively smoothed estimate that uses later data (Durbin & Koopman, 2012; Särkkä, 2013). Comparing these controls across device versions and sites can reveal whether the apparent terminal pattern tracks biology or the changing visibility of the measurement system. A control that changes visibility without plausibly changing experience is especially valuable because it directly tests whether the apparent signature survives altered observation gain.

4.4 — Candidate Signatures and Rival Matrix

A single signature is never enough. Mean reversion can come from ordinary homeostasis. Variance compression can come from observation shutdown, sedation, frailty, or event alignment. Endpoint concentration can come from conditioning, selection, smoothing, or post hoc bands. Reserve linkage can come from disease severity shared by affect and physiology. The PTVC candidate must therefore win as a prospectively specified conjunction, not as a favored reading of one pattern (Doob, 1957; Durbin & Koopman, 2012; Gneiting & Raftery, 2007).

This section presents the candidate signatures in the order in which they become progressively more demanding. Reserve-linked drift and innovation contraction are prospective dynamic restrictions. Variance shape and time scaling add form. Terminal concentration and equivalence sit higher in the ladder because they are more assumption-sensitive. Rival mapping accompanies each signature so the positive case does not outrun the discriminating work.

A strong rival matrix makes the comparison informative. At comparable predictive accuracy and calibration, a model that explains the pattern with fewer independently unsupported assumptions merits preference in that domain. Repeated superiority across the declared conjunction should lead to the corresponding narrowing, mechanism retirement, or theory-level verdict. This structure lets a demanding test improve the field whichever model succeeds.

The current research program draws on a substantial empirical foundation in neighboring fields and has a defined next step. Affect regulation, reward learning, relief, cross-modal valuation, biological integral feedback, lifespan change, and consciousness assessment provide measured phenomena relevant to the program. They contribute representational plausibility, mechanism feasibility, measurement opportunities, and quantitative alternatives. Their importance is clearest when each finding is assigned its actual role.

The measurement agenda is concrete: evaluate momentary rate estimates; test interval composition under realistic missingness; identify neutral-origin anchors; estimate reserve independently; and qualify endpoint proxies through separately specified consciousness channels. Each task provides a focused opportunity for empirical work.

Law-specific predictions are narrower and more demanding. Exact complete-stream phenomenal reconstruction is not required for every informative test. A protocol-fixed PTVC-linked route or consequence model may imply observable restrictions on history dependence, continuation choice, recovery dynamics, endpoint-relative behavior, or cross-species trajectories before a complete ledger is identified. Prospective reserve-linked drift, innovation contraction after observation correction, variance-shape restrictions, forecast performance under a declared independent-endpoint branch, fixed-band measured equivalence, and held-out superiority to rivals are examples. The derivation, empirical bridge, and rival set must be fixed before the relevant data are examined. A successful signature first supports the specified route

or consequence model. It bears on PTVC only when the tested restriction follows from PTVC under independently justified bridge assumptions, and only to the scope licensed by that implication. The program should therefore pursue both direct measurement bridges and indirect discriminating tests against strong learning, adaptation, homeostatic, selection, and observation-process rivals.

Cross-field convergence becomes more informative when its structure is explicit. Triangulation combines approaches with different major sources of bias and asks whether their results support a common causal interpretation (Lawlor et al., 2016). For PTVC, this suggests a concrete synthesis: derive a shared restriction from one declared realization, then test its consequences in independently sampled observational, behavioral, physiological, and sleep settings. Allow each channel its own validated measurement relation. Record overlapping participants and shared preprocessing so the same evidence is not counted twice.

The gain comes from a common model predicting the joint observations under fixed assumptions. An adequate comparison gives learning, regulation, context, and observation-process rivals the same information and tests the additional restriction on protected data. This turns the recurring shape of phenomena into a specific scientific challenge.

The next milestones are explicit: qualify momentary and interval phenomenal-valence measurements in bounded settings; establish origin, cross-sign scale, exposure, and endpoint bridges; recover

the competing models under realistic observation; and obtain independent, prospectively specified comparisons.

Read the rival matrix together with four evidence roles: observed scientific findings; the components those findings make plausible or measurable; the additional bridges and predictions required by a declared PTVC realization; and results that would compare that realization with its alternatives. This map lets each achievement retain its full value and gives the reader a precise route from established science to a stronger test.

The section includes an adversarial synthetic case because a superficially favorable terminal pattern is easy to create. If observation intensity collapses near the endpoint, noisy extremes can disappear. If endpoints are aligned after the fact, trajectories can resemble bridges. If sedation changes both report and physiology, apparent concentration may be a clinical artifact. The synopsis shows these possibilities before any real study is praised.

Table 4.4. Pairs candidate signatures with the rivals most likely to mimic them. The positive case depends on the conjunction, not on any one row.

Candidate signature	Law-candidate interpretation	Strong rivals	Discriminator
Reserve-linked drift	State-dependent relaxation steepens on a declared subbranch where r^U/U increases as reserve declines.	Ordinary homeostasis, allostatic control, endpoint-conditioned bridges, medication effects.	Independent reserve estimation plus prospective held-out drift relation.

Candidate signature	Law-candidate interpretation	Strong rivals	Discriminator
Innovation contraction	Stochastic innovations shrink on a declared product subbranch where σU decreases.	Observation attenuation, sedation, device removal, frailty-linked signal loss.	Observation model checks and residual innovation analysis after proxy error.
Variance shape	Variance contracts according to reserve-time scaling rather than generic event alignment.	Brownian bridge conditioning, terminal alignment, noise-floor bias, frailty selection.	Reserve-space and time-domain exponents estimated with noise-floor deconvolution.
Terminal concentration	Measured endpoint distribution concentrates near a protocol-fixed neutral band.	Post hoc endpoint choice, smoothing, response dropout, clinical scripts, social desirability.	Prospective endpoint, no look-ahead smoothing, and predeclared equivalence band.
Reference-class transport	The conjunction persists across bounded populations and endpoint classes.	Site practice, culture, recruitment pathway, care model, instrumentation.	Multisite prospectively specified replication and transport analysis.
Adversarial favorable pattern	A late curve appears to approach neutrality.	Observation gain collapse or endpoint conditioning created the approach.	Synthetic recovery must show the pipeline identifies the rival branch.

4.4.1 — Reserve-Linked Drift

The drift signature should be stated in terms of conditional relation, not narrative decline. A person approaching death may become calmer, more agitated, less communicative, more medicated, or more variable for many reasons. Reserve-linked drift becomes meaningful only when the statistical model links changes in the estimated ledger to independently estimated reserve under a specified dynamic form.

Reserve is a candidate state variable. Its estimated value changes the route model's predictions; it does not determine a person's completeness, worth, or availability for research.

Reserve-linked drift relates the route coordinate's pull toward neutrality to reserve. In the signed arithmetic reference version, the drift is $-(r^U/U)L^{rc} dt$. A steeper conditional drift slope requires r^U/U to increase over the declared regime. Its predicted relation to independently measured reserve and innovation behavior supplies the joint comparison developed below (Doob, 1957; Durbin & Koopman, 2012; Gneiting & Raftery, 2007).

Under the reference candidate, the local drift and local diffusion functions are:

$$b_L(\ell, t) = -\frac{r^U(t)}{U(t)}\ell, \quad s_L(t) = c_{LU}\sigma(t)U(t)$$

The associated one-dimensional forward equation, conditional on a known reserve path and a justified Markov closure, is:

$$\partial_t p(\ell, t) = -\partial_\ell \{b_L(\ell, t)p(\ell, t)\} + \frac{1}{2}\partial_{\ell\ell} \{s_L^2(t)p(\ell, t)\}$$

If U is hidden, stochastic, or coupled to observation, L alone is not generally a Markov state. The appropriate object is then a joint state-space model, not a decorative Fokker-Planck line. The synopsis includes the equation to show the burden, not to skip it.

The positive intuition is simple: remaining biological or functional reserve constrains how much imbalance can continue to move. If the candidate realization is correct, late dynamics should not look like unconstrained wandering. They should show a coupling between reserve and corrective movement. The coupling specification and fitted parameters must be fixed without tuning to the evaluation endpoint or held-out ledger outcomes, then evaluated prospectively under the declared joint model.

Drift alone cannot separate the Law from serious rivals. Ordinary homeostatic models also pull states toward set points. Brownian bridge-like models can create endpoint-directed drift by conditioning. Medication and clinical care can induce state-dependent changes. A drift estimate without variance, innovation, endpoint, and rival context is too weak to bear law-language.

A simple Brownian bridge to zero has a state-dependent pull:

$$dB(t) = -B(t)/(T - t) dt + \sigma dW(t)$$

The pull strengthens near T , so drift toward zero is not enough to distinguish the Law candidate. Without additional structure, the conditioned bridge does not supply the same independently estimated reserve-coupled innovation contraction. The discriminating conjunction must therefore include variance

shape, reserve coupling, the protocol-fixed endpoint-branch premises, and held-out prediction rather than a single slope.

Reserve must be estimated independently. If reserve is merely a transformed version of the ledger, the signature is circular. If reserve is only disease severity and disease severity also changes affect, shared cause can mimic coupling. The analysis must include clinical state, treatment, observation intensity, and proxy error.

A favorable drift finding could support the candidate realization in a bounded reference class. An unfavorable finding could motivate revision or retirement of the reserve-coupled mechanism. Both outcomes guide the comparison of routes and identify which predictions merit the next test.

Reserve language is technically useful only while it remains a model variable. It is not a measure of worth, courage, eligibility, prognosis, or priority for care. The construct belongs to a candidate mechanism evaluated under consent and governance; it does not classify the person in whom it is estimated.

4.4.2 — Innovation Contraction

Innovation contraction should also be compared to censoring. If high-variance participants exit the observable dataset because of transfer, withdrawal, device intolerance, or sudden decline, the remaining observed trajectory can look compressed. This is not contraction of the underlying process. It is selection in the observed sample.

A good study therefore reports both within-stream innovation estimates and who remains observable at each time. The set of

observed streams is part of the result. A narrowing sample may be more important than the variance number it leaves behind.

Innovation contraction is the companion to drift on a separately declared candidate subbranch. Stochastic innovation in the reserve-coupled route coordinate scales through $c_{LU}\sigma_i(t)U_i(t) dW_i(t)$. Contraction requires the product $\sigma_i(t)U_i(t)$ to decline, and vanishing terminal innovation requires $\sigma_i(t)U_i(t) \rightarrow 0$; reserve decline alone is insufficient. The observation model must also exclude manufactured contraction. This is a route-specific consequence under those premises, not a unique fingerprint (Karatzas & Shreve, 1991; Protter, 2005).

For reserve-space variance under RC-1:

$$V_{L,i}(u, x, t) := \text{Var}(L_i^{rc}(t) | U_i(t) = u, \Xi_i^\circ(t) = x) = c_{LU}^2 u^2 V_{Y,i}(u, x, t).$$

This identity is exact conditional on $U=u$ under $L^{rc}=c_{LU} UY$. It becomes an empirical claim only when U is independently estimated, Y has a stable conditional second-order structure, and the observation process has been separated from latent variance. Otherwise the slope can be a sensor-gain artifact.

The positive case is that terminal approach should become less volatile in a specific way, not merely calmer by description. A shrinking innovation term predicts relationships among reserve proxies, residual variance, and time-to-endpoint. Those relationships can be compared with bridges, homeostatic models, frailty, medication, sedation, and observation attenuation.

Observation attenuation is the nearest danger. A device may record less variation because it is removed, because the

participant moves less, because reports cease, because sedation suppresses channels, or because data processing filters out extremes. That would look like innovation contraction while saying more about visibility than experience. The observation process must be modeled explicitly.

Innovation contraction should therefore face a resolution sweep rather than one favored window. The analysis should vary sampling interval, aggregation rule, and instrument channel under prospectively specified limits, then ask whether the route-specific relation transports within uncertainty. A biological relation may weaken predictably under coarser measurement; an artifact may reverse, disappear, or track one instrument version only.

A favorable finding would be component support only if contraction survives proxy error, observation marks, and rival recovery. An unfavorable finding may reveal that the reserve product is wrong, that reserve is poorly measured, or that the window is dominated by observation artifacts. The verdict must name which gate failed.

4.4.3 — Variance Shape and Time Scaling

Time scaling also affects visual communication. A graph plotted against normalized time-to-death can make lives with very different trajectories appear commensurable. That may be useful for an exploratory figure, but it must be labeled as endpoint-aligned and not mistaken for a prospective clock. The axis is part of the claim.

Every candidate consequence must declare its clock. Calendar time, experienced time, reserve time, declared hazard time, and

endpoint-aligned time can reveal different structures and different artifacts. A robust prediction must state which clock carries the estimand, why that clock is scientifically motivated, which transformations preserve the claim, and which clock changes would count against the proposed route.

Variance shape is more discriminating than a generic claim that variance declines. RC-1 predicts reserve-space contraction because $L^{rc}=c_{LU} UY$ implies conditional scaling in relation to U under stated assumptions. The observable boundary exponent also depends on normalized-state dispersion and on the declared route clock. No universal time exponent follows from the product alone (Vehtari, Gelman, & Gabry, 2017).

If $U_i(t)=c_U[d_i^{rc}(t)]^\beta\{1+o(1)\}$ and the conditional normalized-state variance scales as $c_Y[d_i^{rc}(t)]^\gamma\{1+o(1)\}$, then:

$$Var(L_i^{rc}(t)|U_i(t), \Xi_i^\circ(t)) = c_{LU}^2 c_U^2 c_Y [d_i^{rc}(t)]^{2\beta+\gamma}\{1 + o(1)\}.$$

The route-space exponent is $2\beta+\gamma$. A value of 2β requires $\gamma=0$ or an independently justified locally constant normalized-state dispersion. Neither β nor γ is universal; both are estimands or declared route assumptions.

For a normalized illustrative case with $c_{LU}=1$, $U(t)=U_0(1-t/T)$, $Y(0)=0$, and $dY=\sigma dW$:

$$Var[L(t)] = U_0^2 \sigma^2 t \left(1 - \frac{t}{T}\right)^2$$

This illustrative variance peaks at $t=T/3$ and then contracts. It demonstrates terminal-regime compression under the stated

special case, not monotone whole-life smoothing or a universal exponent.

The exponent depends on its coordinate. A log-variance slope against reserve and a log-variance slope against clock time coincide under the relevant linear-depletion conditions; nonlinear depletion, state dependence, shared disease drivers, and proxy error can change that relation. The analysis estimates the slope on its declared scale.

Variance shape also separates the Law candidate from endpoint-conditioned bridges. A bridge may show variance that peaks and then contracts because paths are conditioned on an endpoint. The reserve-coupled candidate predicts contraction tied to independently estimated reserve. Discrimination requires checking whether variance follows reserve, time alignment, endpoint conditioning, or observation gain.

Noise floors matter here. Additive measurement noise can flatten late variance and bias exponent estimates. If subtracting the noise floor produces unstable or negative variance, the analysis should abstain. A clean exponent calculated from a biased estimator is worse than uncertainty because it looks precise.

A favorable variance-shape result could strengthen the conjunction if it is prospective, reserve-linked, noise-characterized, and rival-tested. A variance decline alone should not update the Law. An unfavorable or unstable shape may retire a predicted signature, narrow the reserve model, or force new measurement work.

A variance curve carries a network of assumptions with it. Reserve, time-to-endpoint, observation density, noise, rival dynamics, and selection all shape the pattern. The curve becomes scientifically useful when those dependencies are explicit and its interpretation is correspondingly conditional.

4.4.4 — Terminal Concentration and Equivalence

Equivalence also requires a meaningful null. The program should not treat failure to reject non-neutrality as evidence for neutrality. It must specify an equivalence band, measurement error model, power or precision target, and sensitivity analysis. A weak study that cannot distinguish anything has not found balance.

Terminal concentration is most persuasive when it arrives as the end of a route already traveled. If representation, calibration, endpoint, observation, rival, and recovery gates are intact, then a terminal pattern can add force. If those gates are broken, the same pattern becomes a warning sign about the design.

Terminal concentration and equivalence are the strongest and most assumption-sensitive targets in the public program. Measured endpoint estimates may concentrate near a prospectively specified neutral band, but that is not direct observation of exact latent closure. It is an empirical consequence on a fallible scale under a declared endpoint and observation model (Doob, 1957; Durbin & Koopman, 2012; Gneiting & Raftery, 2007).

An equivalence analysis specifies its estimand, operational scale, acceptance band, measurement-error model, and decision rule

before outcome inspection. It evaluates whether the data establish the declared degree of closeness at that resolution.

Terminal concentration inherits all prior gates. Representation, calibration, bearer, endpoint, filtering, observation process, model recovery, and rival comparison must already be strong enough. A favorable terminal band cannot compensate for failure upstream. This is why terminal-level claims appear after preterminal signatures in the synopsis.

The following is a population concentration claim about the measured terminal estimator, not an equivalence-test decision or direct sight of exact closure:

$$\Pr(-K \leq \hat{L}(\hat{T}) \leq K \mid \text{observation model, endpoint model}) \geq 1-\alpha$$

This probability claim depends on K , α , the endpoint estimator, the observation model, and the reference class. Here α is the permitted tail probability. The analysis estimates that probability with quantified uncertainty. An equivalence test separately evaluates its declared estimand against a prespecified band under an appropriate decision rule.

The strongest rival dangers are endpoint conditioning, post hoc smoothing, observation loss, clinical scripts, medication, sedation, family pressure, and frailty selection. Each can create apparent convergence. A terminal result that does not compare against these rivals should be treated as preliminary at best and unusable if endpoint or observation gates fail.

A terminal-concentration result updates the tested reference-class consequence when the required measurement and endpoint conditions hold. The direction and strength of the comparison

guide the specified decision about that consequence, its candidate route, or a broader branch reached through a valid entailment.

Terminal concentration is an empirical question, not a narrative claim about the meaning of a person's final days. Last-window data are especially vulnerable to treatment effects, observation shutdown, family scripts, and selective visibility. The analysis has to protect comfort first and treat the ending as evidence only within the narrow protocol that produced it.

4.4.5 — Rivals by Signature

The matrix should also include the possibility that a rival wins in one layer while the Law candidate remains useful in another. Adaptation may explain short-term recovery while failing to explain reserve-linked variance shape. Observation attenuation may explain terminal calm while leaving earlier dynamics open. Fair comparison is not a duel where only one sentence survives.

Generous model development makes the comparison informative. Give each serious rival enough flexibility, data access, and testing resources to represent its explanation fairly. A well-specified comparison teaches the field which structures best predict the observations.

Every candidate signature has a rival family. Homeostasis can produce local return toward set points; opponent processes can produce rebound; predictive and active-inference accounts can produce error correction and control; reinforcement learning can produce policy adaptation; Brownian bridges and Doob transforms can produce endpoint-conditioned paths; frailty, medication, sedation, and observation shutdown can produce late

contraction. The rival matrix must distinguish these mechanisms rather than treating a shared shape as unique (Doob, 1957; Durbin & Koopman, 2012).

Rivals should be generative, not merely named. A generative rival produces synthetic data with declared parameters, observation processes, endpoint behavior, and missingness. The pipeline must show that it can recover the rival when the rival generated the data. Without this step, model comparison on real data can become an aesthetic contest among formulas.

The rival map should be signature-specific. A rival that mimics variance contraction may not mimic reserve-linked drift. A rival that mimics endpoint concentration may not match innovation behavior. A rival that fits one cohort may fail transport. The Law candidate gains force only from a conjunction whose members fail against different alternatives.

An adversarial synthetic case belongs in the synopsis. Imagine a dataset where late momentary valence estimator variance shrinks and terminal estimates fall near the neutral band. On inspection, observation intensity declines sharply, sedating medications increase, and endpoint alignment is retrospective. A bridge or observation-attenuation model recovers the data better than the Law candidate. The correct verdict is rival dominance or unusable terminal evidence, not cautious support.

Rival success contributes scientific knowledge. When adaptation, homeostasis, or predictive control provides a better calibrated explanation under the declared comparison rules, the result guides the scope of the PTVC candidate. Repeated outcomes across the

joint prediction inform whether that candidate should be retained, revised, or retired.

A preferred hypothesis earns trust by constructing the alternatives that could defeat it. Critics should not have to reverse-engineer the strongest homeostatic, adaptive, bridge, selection, or observation-artifact model after publication. The rival set belongs inside the program, with enough information and flexibility to win.

4.4.6 — The Discriminating Conjunction

The conjunction should be prospectively specified as a gate structure, not reconstructed as a story after results. Which components are necessary, which are exploratory, which are decision-critical, and which are sensitivity checks should be stated before analysis. Otherwise any favorable subset can be narrated as the real test after the fact.

This is where the project's ambition becomes disciplined. It is willing to ask for a pattern that ordinary rivals should struggle to reproduce, but it is also willing to lose if those rivals reproduce it. The conjunction is therefore both the positive case and the defeat route.

The discriminating conjunction is the book's first positive empirical target. No single pattern is enough. The conjunction requires independent reserve coupling, prospective endpoint separation, observation-model robustness, model recovery, held-out prediction, variance-shape discipline, and rival comparison. It is a compound claim because the serious rivals are strong in different places (Vehtari, Gelman, & Gabry, 2017).

A useful conjunction might say: under a declared reference class and instrument version, preterminal dynamics show reserve-linked drift, innovation contraction, and variance-shape restrictions; the endpoint is prospectively adjudicated by non-ledger channels; observation attenuation and clinical confounds are modeled; generative rivals are recovered when true; and the Law candidate outperforms rivals on held-out forecasts. That is the level at which support becomes scientifically interesting.

The conjunction is deliberately vulnerable. It can fail through measurement invalidity, reserve proxy error, endpoint circularity, observation collapse, rival dominance, nontransport, model-recovery failure, or ethical burden. A failed member is not repaired by success elsewhere. The status update names the failed prerequisite.

The conjunction also makes positive results narrower and more valuable. If the full set survives in one bounded population, the result supports that reference-class prediction. It does not support all conscious streams. It creates a reason to replicate, expand, and challenge, not a reason to announce validation. The next replication should preserve the successful conjunction rather than selecting only its strongest coordinate, because the joint restriction is what earned the result.

This standard prevents the book from becoming a pattern-recognition exercise. Humans are good at seeing significance in curves. Scientific claim status requires a rule declared in advance that says which patterns matter together, which rivals were allowed to win, and what the public statement will say if the conjunction fails. Predeclared failure of any indispensable

coordinate should lower the verdict even when the remaining plots look persuasive.

A conjunctive signature package keeps attractive findings from hiding qualifications in prose. Requiring the major conditions together states the evidentiary price of support before public compression. This structure also makes later synthesis cleaner, because independent studies can compare the same multicomponent criterion rather than retrospectively chosen highlights.

4.5 — The First Protocol in Miniature

This section walks through a humane, bounded, late-life observational study in miniature. Population, data flow, estimands, intercurrent events, rivals, recovery, adverse branches, and public reporting are specified together, giving researchers an integrated design to examine and develop before enrollment (International Council for Harmonisation, 2019; International Council for Harmonisation, 2026; Lakens, 2017; Nosek et al., 2018).

The miniature studies dynamics and measurement within a defined late-life window. Recruitment occurs outside crisis, care proceeds as clinically indicated, devices are used only while tolerated, and endpoint rules are specified before trajectory evaluation. Those choices make the initial study concrete and proportionate.

Simulation has several distinct jobs before real-data selection: verify code against known identities, calibrate finite-sample behavior, expose parameter nonidentifiability, estimate design power, and stress the observation and endpoint rules under controlled failure. These jobs should be declared separately so a convincing illustration is not mistaken for recovery evidence.

The protocol's most important feature may be its adverse branch. A study can return nulls, unstable estimates, endpoint failure, burden stops, measurement collapse, rival dominance, or no-estimate outcomes. Those are not failed products. They are scientific results when they are declared, preserved, and allowed to change the program.

Table 4.5 compresses the first-study route. It is a schematic, not a protocol approval, and it does not authorize research without ordinary expert, legal, clinical, and ethical review.

Table 4.5. First protocol in miniature: stage, scientific action, and stop or decision rule.

Stage	Scientific action	Stop or decision rule
Enrollment	Define an adult, comfort-first palliative reference class and approach only through non-crisis pathways.	Abstain when urgency pressure, site burden, or selection distortion makes the intended reference class uninterpretable.
Observation	Collect versioned momentary estimates, context, reserve or horizon proxies, treatment changes, and observation-process marks.	Pause or stop when monitoring disturbs comfort, sleep, family interaction, or staff workflow; mark affected data unusable.
Endpoint	Adjudicate the truth-level stream endpoint prospectively through non-ledger channels, confidence classes, and a no-estimate option.	Return no terminal inference when endpoint confidence fails or outcome information has entered the adjudication.
Estimands	Estimate preterminal drift, innovation variance, reserve coupling, observation effects, and measured endpoint concentration.	A late-window result may update only the declared component; it cannot stand for the complete life.

Stage	Scientific action	Stop or decision rule
Rivals and recovery	Demonstrate model recovery in synthetic worlds, then compare homeostatic, bridge, frailty, medication, learning, and observation rivals under common rules.	Recovery failure blocks model-winner language; rival victory narrows or retires the candidate route.
Release	Report scope, uncertainty, burdens, adverse branches, rival performance, and prohibited interpretations.	Permitted outcomes include bounded component support, narrowing, rival-favored, unusable evidence, or No adequate estimate.

4.5.1 — Population and Enrollment

The miniature protocol begins with a bounded population rather than a universal claim. A humane first terminal-dynamics study might enroll adults in a palliative reference class where observation can occur without crisis recruitment and where care teams can refuse or pause research without penalty. The narrow class is a strength: it states exactly which care environment, endpoint process, and participation pathway the first inference can address (International Council for Harmonisation, 2019; International Council for Harmonisation, 2026; Lakens, 2017).

The reference class should also include the care system. A study in a well-staffed hospice with stable relationships, trained research staff, and strong privacy infrastructure is not the same as a study in an overstressed hospital or fragmented home-care environment. Site conditions affect participation, observation, and data quality.

Enrollment is therefore a scientific design choice as much as an ethical one. It determines which lives become visible to the model, which participation demands are acceptable, which endpoints can be adjudicated, and which generalizations remain forbidden until transport is tested.

Recruitment materials describe the observed period and the study's questions about measurement, dynamics, endpoints, and competing explanations. Any inference using pre-enrollment history is identified separately, together with the information that supports it.

No-crisis recruitment is a scientific as well as ethical condition. A person approached in acute distress, uncontrolled pain, family panic, or urgent clinical uncertainty may be less able to refuse freely, and the recruitment context may select a distorted sample. The study should use stable clinical pathways, repeated opportunities to decline, and independent care-team permission.

Inclusion and exclusion should be defined through care compatibility and scientific interpretability. Device tolerability, communication needs, cognitive fluctuation, family involvement, staff capacity, and clinical instability all shape the data. When a subgroup cannot participate without added risk or unmanageable workload, the design narrows or changes instead of forcing representation through pressure.

Enrollment also includes bystander handling. Family members, caregivers, clinicians, and roommates may appear in context, speech, timing, or observation records. They do not become

research participants by proximity. Their data must be minimized, separated, consented where needed, or excluded.

A humane protocol makes the distribution of work explicit. Participants can refuse; families are protected from unchosen roles; clinicians retain care priority; staff workload is measured; and the design can shrink or stop before intrusion becomes harmful. Feasibility includes the people who make the study possible.

4.5.2 — Data and Context

The miniature data plan should include versioning. Instruments change, sensors update, staff training evolves, and clinical workflows shift. A result tied to one measurement version should not silently merge with another. Version labels make the evidence reusable without pretending it is timeless.

Context also includes silence. A nonresponse may mean rest, exhaustion, refusal, delirium, distress, device failure, privacy need, or death. The study should not assign one meaning by convenience. Silence is a data problem with human dignity at its center.

The miniature dataset contains more than momentary valence estimator values. It includes physiological channels used in the momentary valence estimator, active reports when appropriate, reserve proxies, medication timing, sleep and rest context, care events, family presence where consent allows, device status, observation intensity, and endpoint-related marks. Context is not noise. It is how the model knows what kind of signal it is seeing (Lakens, 2017; Nosek et al., 2018).

Data and context remain witnesses, not the latent object. The candidate momentary estimator and interval estimate inherit the versioning, uncertainty, and channel-role rules in §4.2.3; contextual reports may challenge or validate the estimator without silently becoming part of it.

Treatment records are essential because medication and care can mimic target signatures. Sedation, analgesia, oxygen changes, delirium treatment, infections, hydration shifts, and clinical escalation can change physiology and reportability. A terminal pattern that ignores treatment context is under-modeled.

Observation marks should be attached to windows rather than buried in a data appendix. A window may be observed, filtered, forecast, smoothed, endpoint-aligned, simulated, missing by refusal, missing by device burden, missing by clinical priority, or no-estimate by design. The label determines what claim the window can support.

Data minimization remains active. The protocol collects what the estimand and rival comparison require, not every intimate detail that might someday interest a model. Future reuse, linkage, and model training require separate permissions. The dataset is research material under governance, not a general archive of a life.

Context should sharpen interpretation rather than justify unlimited capture. Medication changes, sleep, symptoms, and care events may explain a signal; unrelated conversations, household activity, or bystander behavior do not become research data merely because sensors can reach them. The miniature

protocol collects the minimum context needed for its declared question.

4.5.3 — Primary Estimands

The study estimates defined dynamic quantities under its research model. Clinical teams evaluate care and individual needs through their own assessments, informed by relevant contextual observations.

Public wording identifies the component estimand and the scientific question it answers. The description keeps the study's unit, population, and purpose clear to readers.

The first study needs estimands, not hopes. Primary estimands might include reserve-linked drift slope, innovation variance as a function of reserve, variance-shape exponent with time-to-endpoint, observation-gain parameters, forecast error under the declared endpoint-timing branch, and measured terminal concentration within a prospectively specified band. Each estimand answers a different question (Schuirmann, 1987; Wilson & Collins, 2019).

A compressed estimand vector for the first study is:

$$\eta = (\kappa_U, \gamma_{innov}, \beta_{var}, \delta_{end}, \Delta ELPD_{Law-rivals})$$

κ_U indexes reserve-linked drift; γ_{innov} indexes reserve-linked innovation contraction; β_{var} indexes time-domain variance scaling; $\delta_{endpoint}$ indexes terminal equivalence under the observation model; and $\Delta ELPD$ compares held-out predictive performance against prospectively specified rivals. The joint

decision evaluates their predicted relations and each required component.

The ordering matters. Preterminal dynamic estimands should be primary before terminal-level equivalence because they are less dependent on arbitrary origin and whole-life initial conditions. Terminal concentration may be secondary or high-level, depending on endpoint and measurement gates. The protocol should not let the most dramatic outcome become primary after seeing it.

Estimands must carry reference class and scale. A drift slope in one instrument version, one care context, and one endpoint class is not a universal parameter. A candidate interval accumulation over a forty-day window is not a lifetime ledger. A terminal mean is not an individual closure probability. The estimand name should prevent overreading.

Uncertainty belongs in the estimation and reporting of each estimand. If reserve is noisy, endpoint timing uncertain, or momentary valence estimator calibration unstable, the analysis should propagate that uncertainty. A point estimate stripped of its measurement model may look clean while losing the very information needed for verdict status.

An estimand can also remain unestimated. If the endpoint gate fails, terminal concentration is not estimated. If observation collapses, preterminal dynamics may become no inference. If model recovery fails, rival comparison may be withheld. These outcomes should be written into the protocol before the data arrive.

An estimand is also a promise about use. It states what participant data will answer, which intercurrent events matter, and how the result will be interpreted. Precision at this stage reduces the chance that observations gathered for one purpose will later be converted into an opportunistic claim.

4.5.4 — Rival Set and Recovery

Recovery should include near-miss designs. The analysis should test cases where the Law candidate and a bridge rival produce superficially similar endpoint behavior but differ in preterminal variance, observation marks, or reserve relation. Near-misses are more useful than easy separations because real data will rarely be kind.

The synthetic fixtures should be archived with versioned code in a governed research repository. The book can explain assumptions, diagnostics, and pseudocode, but runnable science needs artifacts that independent teams can inspect, challenge, and rerun. Prose alone does not make a computational program reproducible.

The rival set should be prospectively specified as generative alternatives. A homeostatic mean-reversion model, an endpoint-conditioned bridge, an observation-attenuation model, a frailty and medication model, an adaptive-learning model, and a safe-control baseline should all be able to generate synthetic data. The PTVC candidate must face them before the pipeline interprets empirical data (Gneiting & Raftery, 2007; Nosek et al., 2018; Wilson & Collins, 2019).

Model recovery is the gate that makes comparison credible. The analysis pipeline should receive synthetic datasets generated by each rival and by the Law candidate under realistic missingness, noise, endpoint uncertainty, and observation marks. If the pipeline cannot recover the true generator often enough, real-data selection is not interpretable.

The recovery requirement is operational:

$$M_j \rightarrow O_\phi \rightarrow \{M_1, \dots, M_J\} \rightarrow \hat{f} \text{ with calibrated uncertainty}$$

Recovery tests should include adversarial mixtures. Real participants may not be generated by a single pure model. Observation attenuation may combine with homeostasis. Medication may combine with bridge-like endpoint alignment. Reserve coupling may exist but be weaker than assumed. The pipeline should know when it is uncertain rather than forcing classification.

The rival set should include positive-terminal-drift baselines and no-closure baselines. A serious program must let the data say that terminal dynamics move away from neutrality, or that no structured closure pattern appears. A model space that lacks defeat options is not a model space. It is a protection device.

Rival success changes public language. If the bridge model wins, the result favors an endpoint-conditioning explanation over the defeated candidate route. If observation attenuation wins, the result pressures measurement, not the Law directly. If homeostasis wins, the reserve-coupled mechanism may narrow. The verdict should name the component that lost.

Rivals deserve scientific parity, not rhetorical courtesy. Weak comparators make the preferred model look strong while leaving outsiders to supply the missing skepticism. Strong generative alternatives make the result worth reading because the program has genuinely risked losing.

4.5.5 — Adverse and Unusable Branches

Interpret terminal trajectories together with medication, communication capacity, participant condition, and changes in observation. Including those processes in the model makes the graphical result and its uncertainty easier to assess.

In the favorable synthetic branch, the endpoint is adjudicated without ledger variables, reserve proxies decline under a prospectively specified low-reserve rule, the fitted Law candidate recovers the joint drift-diffusion pattern, and held-out prediction beats the bridge and homeostatic baselines.

In this synthetic branch, a successful result supports the pipeline's recovery and discrimination under the specified generator. It is not empirical support for PTVC or for a natural reserve mechanism. Independent execution can reproduce the computational result; empirical component support requires a separately conducted study with the relevant measurement, endpoint, and comparison gates satisfied (Lakens, 2017; National Academies of Sciences, Engineering, and Medicine, 2019).

In the adverse synthetic branch, terminal values cluster near zero only after device removal, sedation escalation, or endpoint alignment. The Law candidate fits the visible end, but the observation-attenuation rival explains why excursions

disappeared. The correct output is unusable or rival-dominant evidence, not a polished success story.

This is why the no-estimate outcome is protective. It protects the participant from having uncertainty converted into a story, and it protects the theory from surviving by using data that no longer satisfy its own design.

The protocol specifies responses to withdrawal, sleep disruption, family burden, endpoint uncertainty, observation loss, calibration problems, and comparative model outcomes. Each branch identifies its appropriate action, including a No adequate estimate result when the target is unavailable.

Adverse branches should be predeclared as decision paths. If device burden crosses a threshold, monitoring stops. If care teams report interference, the study pauses. If endpoint channels conflict, terminal inference abstains. If observation gain collapses below a usable level, variance claims are withheld. If synthetic recovery fails, model comparison is not reported as decisive.

When evidence is unusable, the protocol action should be concrete: quarantine the affected analysis, record the failed prerequisite, prevent pooled salvage under a new label, assess participant and privacy consequences, and issue a correction if a public claim escaped. The dataset may still teach about feasibility or failure, but it does not update the protocol-fixed target.

An adverse branch can still teach. It may reveal that a proposed device is too burdensome, that the reference class is too fragile, that missingness is informative, or that a better endpoint proxy is

needed. That knowledge belongs in the research record, but it does not become support by reframing.

The protocol should also protect participants after adverse events. Withdrawal, deletion requests, data retirement, incident reporting, family communication, and staff support must be planned. A study that can collect data but cannot handle distress, breach, or withdrawal is not ready for this subject.

Adverse and unusable branches belong in the main result. When a device conflicts with care, missingness becomes dominant, endpoint adjudication fails, or model recovery collapses, the stopping path is itself evidence about feasibility. Concealing it would transfer the same failure to future participants and readers.

4.5.6 — Bounded Public Result

A bounded public result names uncertainty plainly. It states what the model estimated and what the study could not see: earlier life history, unobserved internal states, excluded populations, ambiguous endpoints, and rivals outside the protocol-fixed set. These limits belong to the result.

The best public result is modest enough to be true and clear enough to matter. It gives scientists a reason to replicate, critics a target, and readers no permission to rank, console, pressure, or explain another person's suffering.

A bounded public result states the component, reference class, instrument version, endpoint rule, uncertainty, rival outcome, adverse events, and prohibited uses. It does not expand because the audience wants a larger story. A first study might report preliminary support for reserve-linked dynamics in one declared

reference class, or abstention because endpoint adjudication or a protocol-fixed timing premise failed (Fischhoff & Davis, 2014; Nosek et al., 2018; Spiegelhalter, 2017).

Use specific verbs and source roles when reporting neighboring findings, measurement results, and proposed predictions. State each result once, with its population, method, and outcome.

The result must also name what did not change. Component support authorizes no clinical decisions, policy, religious doctrine, legal status, employment rank, civic trust, ordinary-life scoring, or Artificial Intelligence interpretation of persons. Negative results do not weaken care. State these limits once in the result or release note, not a disclaimer page.

A bounded result should include nulls and rival wins. If an observation-attenuation model explains the terminal pattern better, the release should say so. If the momentary valence estimator versioning failed, the release should say no claim update. If a burden stop ended data collection, the release should record the stop as evidence about feasibility.

The release should not be upgraded by donors, media, aesthetics, or public enthusiasm. Every detachable artifact should carry a source result, version, date, maximum status, correction trigger, and withdrawal path. The public surface may compress the explanation, but it cannot compress away the condition that controls the verdict. Visual beauty is not warrant.

A bounded public result should state exactly which component changed status. Readers must never be invited to interpret lives

through evidence lacking that authority, so the protocol ends with a narrow, reversible statement rather than a triumphal headline.

Table 4.6. Neighboring evidence, open questions, and PTVC status.

Evidence category	What is currently available in neighboring science	What remains open for this program	Status for the Law
Affective dynamics	Affect changes over time and can show adaptation, rebound, inertia, and regulation.	Whether those dynamics instantiate the declared ledger target and reserve-coupled signatures.	Observed affective dynamics and candidate mechanisms.
Consciousness-state research	Markers and expert adjudication can sometimes distinguish wakefulness, sleep, anesthesia, coma, and other boundary states.	Whether unity proxies can define endpoints without circular dependence on the ledger.	Empirically tested consciousness-assessment methods.
Psychometrics and measurement	Latent-variable modeling, reliability, calibration, invariance, and response-shift methods can improve construct discipline.	Whether candidate momentary and interval estimators can become valid estimators for the specific reference classes and endpoints.	Empirical measurement foundations and qualification methods.

Evidence category	What is currently available in neighboring science	What remains open for this program	Status for the Law
Palliative and clinical research	Comfort-first observation and longitudinal symptom research can be conducted under ethical review.	Whether terminal dynamics can be studied without burdening care or distorting signals.	Observed clinical trajectories and practical study-design experience.
Statistical model comparison	Equivalence testing, sensitivity analysis, Bayesian companions, predictive validation, and model recovery provide tools.	Whether those tools discriminate the Law candidate from strong rivals under realistic error.	Established tools for estimation and model comparison.
Law-specific evidence	Formal predictions and proposed study designs.	Test the central predictions through prospective comparison, replication, and clearly reported outcomes.	Next milestone: prospectively specified comparative results.

4.6 — Verdicts, Stop Gates, and Open Problems

A scientific program should define verdict language before evaluating data. This volume defines a formal target, develops conditional results and candidate realizations, and specifies measurement, endpoint, rival, and study requirements; the evidence reviewed here does not establish PTVC as an empirical law. The literature reviewed in this volume supports component methods, mechanisms, rivals, and feasibility, not the complete-stream equality itself. The verdict system below therefore governs future PTVC evidence and current component findings alike: preliminary component support, replicated component support, inconclusive or unusable evidence, narrowing, mechanism retirement, rival dominance, abstention, and theory-level defeat (Gneiting & Raftery, 2007; Lakatos, 1978; Mayo, 2018; National Academies of Sciences, Engineering, and Medicine, 2019).

The verdict ladder is noncompensatory. A result cannot jump over failed prerequisites. Replication cannot repair a circular endpoint. Elegant statistics cannot repair invalid measurement. A donor-facing graphic cannot upgrade a null. A public response cannot turn a rival win into support.

The verdict rule is deliberately categorical. It maps the data and the state of each prerequisite gate into one of the protocol-fixed outcome labels.

Its inputs include prospective specification fidelity, measurement validity, endpoint admissibility, model recovery, rival comparison, ethics, privacy, and transport.

The section also gives abstention dignity. If origin, sign, scale, endpoint, observation, recovery, ethics, privacy, or rival-separation gates fail, the correct verdict may be no inference. That is not timidity. It is the refusal to turn poor data into a story. The program becomes stronger when it can say that a study should not update any claim.

Open problems remain inside the scientific program rather than being hidden in back matter. The detailed register at the end of the chapter assigns formal bridges, dimensional interpretation, process classes, endpoint construction, branch-specific timing premises, transport, recovery, observation error, and public updating to explicit unresolved states. Naming that work prevents a synopsis from converting incompleteness into decorative certainty.

The decision tree begins before statistics. If consent, privacy, capacity, assent, surrogate boundaries, or data-use limits fail, the study cannot produce a supporting public claim. If participant or family burden exceeds the declared budget, the protocol pauses or stops. A humane stop is not an interruption of science. It is one of the outcomes the science promised to respect.

If ethics and permission hold, the tree moves to representation. If the state cannot be represented as a signed and temporally interpretable target, the study may report phenomenology, feasibility, or qualitative data, but it should not compute a ledger. If representation survives, the tree moves to calibration, scale, uncertainty, and response shift.

If calibration fails, comparison fails. The study may still teach the next instrument how to improve, but it may not claim cross-time, cross-person, or terminal valence closure inference. If calibration survives, the tree moves to bearer and endpoint. If stream identity or endpoint adjudication is unresolved, terminal claims are withheld.

If endpoint and observation modeling survive, model recovery becomes the next gate. A workflow that cannot recover the right generator from synthetic data should not be trusted to name the right generator in real data. The correct verdict is abstention from model-winner language until recovery improves.

If recovery succeeds, the candidate and rivals compete on held-out filtered prediction, prespecified terminal estimands, observation robustness, and transport. A Law candidate that wins only after smoothing with endpoint information has not won the prospective test. A rival that wins on the declared criteria should receive the public verdict, even if the result is disappointing.

At the program level, the decision combines results across independently motivated bridges and rival comparisons. Revisions contribute when they add testable predictions; a sustained absence of predictive progress can justify retiring the affected scientific claim.

Table 4.7. The verdict ladder. Its purpose is to make support, narrowing, abstention, unusable evidence, rival dominance, and defeat available before any result is known.

Verdict	Concrete condition	Public wording discipline
Preliminary component support	One prospectively specified component survives measurement checks and specified rivals in a bounded reference class.	Say which component and reference class, not that the Law is validated.
Replicated component support	Independent sites reproduce the same bounded component under compatible instruments and endpoint rules.	State replication scope and remaining transport limits.
Narrowing	Evidence supports a component only under a smaller population, endpoint class, or measurement version.	Change the claim version visibly; do not reinterpret the old claim as unchanged.
Mechanism retirement	A candidate realization fails while the broader formal hypothesis remains open.	Retire the mechanism without declaring victory elsewhere.
Rival dominance	A protocol-fixed rival explains the target signatures with better held-out performance and fewer strained assumptions.	Credit the rival and specify what Law claim loses standing.
Inconclusive evidence	Data are adequate but do not distinguish candidates within the protocol-fixed sensitivity bounds.	Say unresolved, not supported.

Verdict	Concrete condition	Public wording discipline
Unusable evidence	Origin, endpoint, sign, observation, recovery, ethics, or privacy gates fail.	Say no inference; do not mine the dataset for narrative.
Abstention	The correct scientific action is to withhold claim update because prerequisites did not hold.	Treat abstention as an honest result.
Theory-level defeat	A gate-valid counterexample rejects the declared universal branch; alternatively, repeated bridge failure, uninformative replacements, and strong rival dominance can exhaust the empirical program.	Withdraw scientific law-language for the affected claim.

4.6.1 — Preliminary and Replicated Component Support

Replication should also include failure memory. A second study should not merely repeat the first success conditions. It should carry forward the first study's problems, adverse branches, rejected rivals, and uncertainty. Otherwise replication becomes ceremony rather than correction.

A mature evidence program should be able to say: this component is preliminary, this component is replicated, this component failed transport, this mechanism is retired, and this question remains open. Such plural verdicts will sound less dramatic than proof, but they will be far more useful.

Preliminary component support means that a declared component survived its initial gates in a bounded reference class. It may be measurement support, endpoint support, reserve-signature support, model-recovery support, rival-separation support, or protocol-feasibility support. The statement names the supported component and its tested scope (Gneiting & Raftery, 2007; Lakatos, 1978; Mayo, 2018).

Replicated component support requires independent confirmation under compatible rules. A second analysis of the same site is not enough. A transported result should preserve instrument version or explicitly bridge it, use compatible endpoint rules, declare reference-class differences, and include rival comparison. Replication is a design of vulnerability, not a ceremonial second number.

Component support can accumulate. Measurement may improve first, endpoint discipline second, dynamic signatures third, rival separation fourth, replication fifth. The strong form remains indirect throughout. A mature program may make the strong form more scientifically credible by strengthening the bridges that expose it to loss, but credibility is not the same as confirmation.

Component support should be published with failure routes. The same report should say what would have turned the result into narrowing, abstention, or defeat. A result without its defeat conditions is not ready to travel publicly because readers will supply triumph where the method left uncertainty.

Support also has a time horizon. A result may be preliminary until external replication, source verification, data audit, code review,

endpoint adjudication review, and public-artifact review are complete. The pressure to release early should not alter the label. The label protects the reader from the project's own excitement.

Support should attach only to the component tested. Using participant data for a stronger public claim than the design can bear converts observation into meaning that was never supplied. Component-level language respects both the evidence and the people whose time made it possible.

4.6.2 — Inconclusive and Unusable Evidence

The distinction between inconclusive and unusable also helps public trust. Critics often suspect that ambitious theories convert every result into support. A visible unusable-evidence category shows that the project can refuse its own data when the bridge is broken.

The same category helps future researchers. A study that fails because of device burden, endpoint ambiguity, or observation attenuation teaches design constraints. The lesson should be retained, but the data should not be forced to answer the original question.

Inconclusive evidence and unusable evidence are different verdicts. Inconclusive evidence passes the basic gates but does not distinguish the candidates strongly enough. Unusable evidence fails a prerequisite: invalid measurement, circular endpoint, broken consent scope, observation collapse, failed model recovery, privacy breach, or ethical interference. The distinction protects science from false neutrality (Mayo, 2018;

National Academies of Sciences, Engineering, and Medicine, 2019).

An inconclusive result can still update design. It may show that a sample is too small, an equivalence band too narrow or too wide, a reserve proxy too noisy, a rival set too underdeveloped, or a window too short. The claim status may remain unchanged while the next protocol becomes sharper.

Unusable evidence should not be mined for narrative. If the endpoint was chosen after outcome inspection, no terminal claim should be made. If the momentary valence estimator calibration failed, no measured cumulative estimate inference should be drawn. If participant burden altered the state, the data may serve a burden report but not a Law-specific result. No amount of interpretive eloquence repairs a failed gate.

The program should publish unusable paths in controlled form. Hidden unusable evidence creates publication bias and lets future teams repeat harms. Public registration, restricted data notes, adverse-result trees, and negative-result logs can preserve the lesson without exposing private material.

Abstention belongs near this verdict. Sometimes the correct scientific answer is that no claim should be updated. This may feel unsatisfying to a public audience, but it is better than turning ambiguous data into confidence. Abstention is the discipline that keeps the program from becoming self-sealing.

Uncertainty needs an accurate label. Calling unusable evidence merely inconclusive can preserve false hope; calling inconclusive evidence a defeat can overstate what the design learned. The

verdict vocabulary protects readers and propositions alike by distinguishing absence of information from information against a claim.

4.6.3 — Narrowing and Mechanism Retirement

Narrowing can be progressive when it increases risky content. If a broad claim narrows to a specific reference class and then predicts new patterns there, the program has become sharper. It becomes degenerative when narrowing merely protects the claim from adverse results without new exposure.

Mechanism retirement should be written with recognition of what was learned. A failed mechanism may have helped design a better study, clarify a rival, or identify an open bridge. The scientific value is retained even when the mechanism is not.

Narrowing is a successful form of losing. A claim may become smaller because a reference class failed, an instrument did not transport, an endpoint rule worked only in one state, or a signature survived only under specific care contexts. Narrowing preserves what the evidence can bear and removes what it cannot (Popper, 1959; Vehtari, Gelman, & Gabry, 2017).

Mechanism retirement is more specific. A candidate realization may fail while the formal hypothesis remains open. The reserve product might fail to outperform rivals. A queue or horizon mechanism might explain only some dynamics. A predictive-control rival might absorb a proposed signature. Retiring a mechanism should be visible, not hidden inside new language.

Narrowing requires version control. A changed measurement bridge is a changed claim version. A changed endpoint rule is a

changed claim version. A changed reference class is a changed claim version. The program may improve by changing, but it must not call the changed claim the same result.

A narrow claim can be more valuable than a broad vague one. If the program learns that a preterminal dynamic signature appears only under certain endpoint classes and not others, the science has gained structure. The public claim becomes smaller but more contentful. That is progress if it is named honestly.

Mechanism retirement also protects the formal root from premature abandonment. A failed candidate product does not automatically defeat every possible realization. But repeated mechanism retirement without novel risky predictions can exhaust empirical content. The program must not use endless replacement to evade loss.

A narrowed claim should carry its revision history with it. The data, model failures, and rival victories that forced the change remain part of the scientific record. Without that memory, the same risk can return under a new label and appear novel.

4.6.4 — Theory-Level Defeat

The defeat rule also stops category drift. The project may not call the Law a deep law in inspirational prose and a heuristic when the tests fail. If the scientific claim loses its empirical bridge, the public scientific language must change, even if the analytic lens remains useful elsewhere.

Whatever the theory-level verdict, the program can leave better methods for burden detection, care, privacy, and measurement.

Those contributions give future research and practice a useful foundation.

One gate-valid counterexample can reject a declared set-universal [SET-ALL] branch when its stated identification and inferential prerequisites hold. That logical result does not by itself refute a probability-one [P1] branch, which is defined under a declared probability law and may permit exceptional trajectories of probability zero. Separately, program-level scientific retirement can follow when independently motivated bridges repeatedly fail, replacements produce no novel risky prediction, serious rivals dominate the declared conjunction, and the empirical program no longer yields distinct testable consequences (Gneiting & Raftery, 2007).

For retirement through program exhaustion, assess the following conjunction:

Program exhaustion if: bridge failures persist + rivals dominate + replacements add no risky prediction + transport fails under defended reference classes

The verdict follows the declared test and its reference class. A counterexample meeting a universal branch's identification conditions can reject that branch; retirement through program exhaustion follows the cumulative pattern specified above.

The strong latent form has an asymmetry. No finite sample can confirm a universal per-stream equality, but credible counterexamples or repeated failure of the measurable consequence structure can refute or scientifically retire strong versions. The program must keep that asymmetry visible. Support

accumulates conditionally; defeat can be more decisive when prerequisites are valid.

Defeat can have levels. A reference-class prediction can be defeated while another remains open. A candidate mechanism can be defeated while the formal hypothesis remains metaphysically conceivable. A public empirical claim can lose scientific status while a fairness-oriented analysis remains useful as an analytic burden question. The verdict should specify which object is defeated.

The Science of Fairness exists to discover which aspects of PTVC are borne out by the world and how strongly the evidence supports them. Its verdict rules allow support, narrowing, and theory-level defeat when warranted. The final verdict chapter develops the public language for those outcomes; this synopsis gives readers the criteria before decisive results arrive.

Care and participant dignity remain the foundation of the research program through every scientific verdict. Findings guide the hypothesis and its methods; participants retain the same respect and support throughout.

A theory that asks participants, critics, and rival models to accept vulnerability must accept vulnerability itself. Theory-level defeat names the point at which the strong form no longer deserves protection by local repairs. That reciprocity is not humiliation; it is the price of scientific standing.

4.6.5 — Publication and Safety Stops

Publication stops are design constraints, not last-minute public-relations checks. A figure that becomes misleading when cropped

is redesigned. A result sentence that requires several remote caveats is narrowed. A release whose source verification, endpoint adjudication, model recovery, privacy review, or adverse-event record is incomplete waits. Public timing is part of scientific status.

The strongest safe artifact is not timid. It is memorable because the contribution is clear and trustworthy because the condition that limits it travels with the claim. Beauty, compression, and confidence are welcome when they orient attention toward the evidence rather than performing the evidence's work.

Once released, a result remains conditional on its source, endpoint, bridge, recovery, privacy, and adverse-event record. If any of those change, the public claim must be corrected, relabeled, or withdrawn with a visible history. Publication is not a one-time gate; it is an ongoing claim-status obligation (Gneiting & Raftery, 2007; Lakatos, 1978).

Safety stops protect participants and surrounding persons before scientific ambition. Device burden, distress, sleep disruption, family pressure, staff overload, clinical interference, privacy breach, security incident, or consent withdrawal can stop a protocol. A stopped study may disappoint the analysis plan, but it preserves the ethical foundation required for any future science.

Public-artifact stops are also necessary. A diagram, summary page, donor note, website, social excerpt, or media caption can overstate the science even when the paper is careful. Every artifact should pass hostile-cropping review: if a single image or

sentence can be lifted as proof, score, consolation, recruitment pressure, or authority over persons, the artifact fails.

Data stops must distinguish deletion, retirement, retained derived results, restricted access, and model-training permission. Withdrawal does not always erase already aggregated scientific products, but future use must follow the consent and governance rule declared at enrollment. A model cannot inherit permission merely because a dataset existed.

Publication and safety stops should be nonpunitive. They are not signs that a site failed morally. They are the designed brakes of a program that studies vulnerable phenomena. A mature infrastructure expects to pause, correct, retract, and learn.

Publication pressure can convert unresolved problems into costs borne by participants, staff, families, and future readers. Prospective stops prevent that transfer. A study halted for safety, unusable data, or failed recovery may be a more valuable contribution than an overclaimed release.

4.6.6 — Open Theorem and Identification Register

The technical synopsis ends with an explicit register of what remains unsolved. Open theorems, identification limits, measurement gaps, and protocol dependencies receive named statuses, owners, next actions, and defeat conditions rather than being dispersed through repetitive caution (Mayo, 2018; National Academies of Sciences, Engineering, and Medicine, 2019).

An open theorem identifies formal work to complete; an identification question specifies empirical work. The reserve-product relation should be recorded as derived, assumed, or open.

Complete-history coverage, operational equivalence, and prospective forecasting each receive the conditions and evidence appropriate to that task.

The register begins with process class, origin, transformation, units, and reserve meaning. It records whether the additive ledger and multiplicative reserve product are linked by derivation, assumption, or signature only, and which preterminal features survive admissible rescaling.

Endpoint-reserve synchronization is tracked separately. Reserve may not be defined to vanish at the endpoint and then offered as discovered closure; timing, support, and any independence assumptions are fixed without using the tested ledger outcome, and residual dependence is modeled.

Scalarization and observation identifiability share another entry. The protocol may defend a scalar bridge, restrict the class, or report an identified set, while testing whether observation marks distinguish latent contraction from visibility loss caused by device removal, report cessation, sedation, care changes, or staff burden.

Model recovery precedes real-data adjudication. The pipeline must recover candidate generators, serious rivals, mixtures, endpoint conditioning, observation attenuation, medication and frailty effects, and no-closure baselines under realistic missingness and proxy error, using thresholds fixed before real data are scored.

Transport is recorded by population, culture, instrument, endpoint class, care context, and model version. Failure narrows the claim or exposes measurement dependence; it is not explained away. A

transport failure should also identify whether the break occurred in representation, measurement, endpoint construction, or model behavior, because each implies a different successor study.

Negative and null results retain branch-matched status. With valid prerequisites, failure may narrow a class, retire a route, favor a rival, or count against the target under an explicit entailment. When a required protocol or implementation gate fails, the affected evidence is Unusable; when passed gates leave the target undefined or without either identification or a valid bound, the result is No adequate estimate. Keeping these labels separate prevents uncertainty about the method from being misreported as evidence for or against the target.

Public artifacts receive their own status ceiling, owner, hostile-crop review, and correction route. Summaries, diagrams, interviews, donor pages, and excerpts can change the practical meaning of evidence after analysis. The artifact record should retain the exact technical verdict it compresses so that later corrections can trace back to the responsible analysis.

Repeated bridge failure without new risky predictions triggers exhaustion rather than another rescue. Exhaustion is therefore a property of a versioned research program, not a metaphysical proof that every conceivable formulation is false.

Part II — PTVC Formal Core

A scientific hypothesis becomes answerable only when its objects are separated from the instruments, mechanisms, and stories that surround them. Part II performs that separation for Per-Stream Terminal Valence Closure. *The Law of Fairness* supplies the public question and shared vocabulary. This volume specifies the technical meaning and develops the scientific exposition, mechanism-neutral consequences, tests, rivals, and verdict architecture for empirical work.

The Part begins with the bearer. PTVC concerns separately routed maximal qualifying conscious streams, not bodies, legal persons, biographies, data records, households, populations, or archives. That choice creates hard problems of unity, ownership, split, fusion, pause, continuation, and endpoint identity. It also protects the formal claim from cross-person transfer and protects persons from being treated as entries in a social ledger.

The next formal task is phenomenal representation. The primary additive branch uses a finite signed phenomenal measure over the complete strict-pre-endpoint domain. A bipolar branch preserves primitive positive and negative components and their overlap. Generalized Terminal Neutrality admits richer typed terminal functionals, but it remains a separate hypothesis family until a bridge theorem establishes equivalence.

Exactness enters through origin, sign, units, and exposure. A positive change of units can preserve zero; an arbitrary translation usually cannot. A questionnaire midpoint, population mean, adaptation level, or fitted terminal center does not become a phenomenal neutral origin merely because it is convenient. The

science must identify the origin independently or abstain from exact-zero adjudication.

Time is equally structural. A phenomenal contribution is a rate or measure over experienced exposure, not a stack of disconnected scores. Reparameterizing the clock requires the matching transformation of the rate. Delayed observation creates an unknown prefix rather than a new stream, and a study-relative baseline cannot reset the cumulative past.

The endpoint is not the last data point. The truth-level stream endpoint, protocol stopping event, estimated endpoint, physiological event, loss of responsiveness, and observation shutdown are different objects. The primary branch uses a complete strict-pre-endpoint domain. Endpoint-inclusive atoms, jumps, continued experience, and revised routing belong to separately declared branches.

Reference-class closure, probability-one closure, support containment, all-policy closure, all-intervention closure, and compositional closure specify different scopes. Naming the scope directly makes each result and opportunity for extension precise.

Chapter 6 then turns the formal object toward measurement without allowing measurement to usurp it. Representation, route state, observation, estimand, estimator, decision rule, and verdict occupy different layers. An estimator can be reliable and still answer the wrong question. A rich set of sensors can improve prediction while leaving the neutral origin or complete-stream history unidentified.

Mixed valence and partial identification receive full treatment because false precision would be especially damaging here. Some data may support only vectors, partial orders, or identified sets over scalarization weights. The appropriate output may be a range, a branch-specific result, or No adequate estimate. Scientific seriousness is not measured by how often the program produces one number.

The observation kernel includes response, context, memory, communication, devices, missingness, and gain. Near endpoints, the probability and quality of observation can change exactly when the theory becomes most vulnerable. Silence, immobility, sensor dropout, sedation, and clinical workflow can manufacture apparent calm. Those possibilities belong inside the model, not in a final limitations paragraph.

Chapter 7 asks what exact closure would imply before any mechanism is chosen. Prefix feasibility, remaining directional capacity, completion sets, endpoint support, and boundary accessibility create necessary conditions that candidate routes must satisfy. The equal-and-opposite net remainder is a conditional mathematical requirement, not a known personal forecast, moral desert, or a safe means of obtaining a chosen reward.

The random-endpoint problem supplies one of the program's hardest tests. Under a prospectively declared baseline law with independent diffuse timing, almost-sure exact zero at the endpoint imposes severe restrictions on the pre-endpoint ledger. State-coupled timing, first-hitting termination, endpoint atoms, singular support, continued experience, and routing change remain live

branches, but each must be declared and tested rather than invoked after failure.

Candidate routes are then allowed to compete. Native dynamics, conditioned bridges, admissible-history selectors, interventions, observation selection, global constraints, local controllers, and reserve coupling can produce similar terminal-looking trajectories for different reasons. Equal-information and equal-scoring comparison is therefore a scientific obligation, not a gesture of politeness toward rivals.

The reserve-coupled route is developed through a declining nonnegative reserve, a signed arithmetic reference process, a positive scale constant, an explicit product rule, linked drift and innovation restrictions, and observation-noise analysis. These features define a candidate realization with specific predictions and decision criteria.

This Part develops the hypothesis from its compact statement into an explicit map of definitions, assumptions, and consequences. That map connects the formal proposal to the measurement, experimental, and comparative work in the chapters that follow.

The formal core connects a bearer to a domain, a domain to a signed measure, a signed measure to an observation model, and observations to an estimand, estimator, and verdict. Part II specifies the transitions among those objects. Their explicit relationships make exactness usable across the participating disciplines (Borsboom, 2005; Manski, 2003).

The same architecture also clarifies what remains valuable under loss. If additive PTV C proves too coarse, the bipolar branch may

preserve component structure. If scalarity fails, identified sets may replace point estimates. If the reserve route loses, reachability, endpoint-support analysis, and equal-information rival comparison remain useful. A rigorous formal Part is therefore not a fortress built around one conclusion. It is a map of how the research program can learn without hiding what failed (Mayo, 2018; Lakatos, 1978; National Academies of Sciences, Engineering, and Medicine, 2019).

By the end of the Part, the reader should be able to audit any later formula or diagram by asking six questions: Which branch is active? What object does each symbol denote? Which assumptions are definitions and which are empirical? What observation bridge is required? Which rival receives the same information? What result would force narrowing, abstention, or retirement? Those questions turn a striking terminal claim into an inspectable scientific program and prepare the transition from formal architecture to the science of lived experience.

Chapter 5 — PTVC: Hypothesis, Branches, and Scope

A formal hypothesis is not one sentence. It is a dependency architecture. The terminal equality may be memorable, but its scientific content depends on the bearer, representation, domain, origin, sign, units, endpoint, scope, and change rules that give the equation a determinate meaning.

This chapter specifies PTVC's exact technical meaning while preserving the public question and vocabulary introduced in *The Law of Fairness*. The following sections define the objects needed for scientific exposition, analysis, testing, and adjudication. When a successor branch, endpoint, or representation is proposed, the change is named, versioned, and propagated to every affected theorem, protocol, figure, and verdict.

The first object is the qualifying stream. PTVC is intrastream and nontransferable. Bodies, biographies, legal persons, records, families, and populations may supply observations or contexts, but they do not replace stream ownership. Split, fusion, pause, and continuation remain scientific questions whose answers determine the ledger's domain.

The second object is the finite signed phenomenal measure. On the primary additive branch, positive and negative Jordan magnitudes are finite and equal at the complete strict-pre-endpoint boundary. The equality constrains one net relation while leaving gross variation, temporal order, duration, agency, welfare, rights, and biography radically unequal.

The third object is the bipolar branch. Mixed valence can contain positive and negative components at once, and a scalar net residual may erase coactivation and overlap. The bipolar

representation therefore preserves component totals and temporal structure long enough for scalarization to become a testable assumption rather than an automatic subtraction.

The fourth object is Generalized Terminal Neutrality. A richer terminal functional can be useful when the science does not support one scalar representation. Yet generality cannot become an escape hatch. A prespecified functional must expose a risky neutral set, and equivalence to additive PTVC requires a bridge theorem.

The fifth object is scope. A formal target can be proposed for one reference class, almost surely under one probability law, throughout one support, under every policy, under every intervention, or compositionally across streams. Those are different claims with different evidence burdens.

The sixth object is past-fixity. Later evidence can change what researchers know about earlier experience; it cannot change the earlier experience itself. Future complementarity is about a future signed increment, not retroactive moral or phenomenal repricing.

The seventh object is endpoint domain. The truth endpoint is not the last measurement, first zero crossing, protocol stop, or physiological event by definition. The primary branch uses the strict-pre-endpoint domain, while endpoint atoms and continued experience require separate branches.

These distinctions make the formal statement harder to support and easier to respect. They also make failure informative. Origin may be unidentified, scalarity may fail, routing may remain

ambiguous, endpoint support may exclude the route, or the reference class may narrow.

The chapter will use mathematics as a transparency device. Every formula has a role: received target, derived identity, branch definition, non-implication, decomposition, or change rule. No display is allowed to become evidence through visual polish.

Concrete examples show how pooled means, centered scales, mixed states, delayed entry, and terminal jumps affect the mathematical interpretation. Each example identifies the assumption being examined and the resulting consequence.

Critics and builders should leave with precise questions for formal and empirical work. The branch labels identify whether a result concerns additive PTVC, a different terminal formulation, or a candidate realization.

The chapter develops one equality into a family of precisely defined claims and tests. That structure gives each version of the hypothesis a clear scientific question.

Formalization earns scientific value by restricting movement, not by making the page look authoritative. A definition fixes what later evidence is about. A branch declaration records which alternatives are live. A bridge theorem states what must be proved before two formulations may be treated as equivalent. A modal quantifier tells the reader whether the claim concerns one realized stream, almost every stream under a law, every admissible continuation, or every member of a declared class. When those roles are separated, notation becomes a map of vulnerability rather than a shield against criticism (Suppes, 1957; Mayo, 2018).

Consider three studies that all report a terminal estimate near zero. One represents experience with a scalar signed measure over a complete strict-pre-endpoint domain. Another records separate positive and negative components whose overlap is scientifically meaningful. A third uses a generalized terminal functional that is invariant only under a specified family of transformations. The numbers can look similar while the scientific claims differ. Chapter 5 prevents the apparent agreement from erasing branch, representation, domain, and bridge obligations.

The chapter also establishes a discipline of counterexamples. A one-sign stream pressures the origin and sign conventions. Duplicate ownership shows why a formally additive total can be invalid even when its arithmetic is flawless. Overlapping positive and negative components expose information hidden by a net residual. Endpoint-inclusive contributions distinguish a left-limit claim from a terminal-jump claim. Nonadditive path functionals show why an attractive scalar equation cannot be assumed to cover every admissible phenomenology. Each counterexample removes an illicit shortcut and leaves a more inspectable object. Counterexamples are most valuable when they force an explicit branch decision, because that converts a conceptual objection into a downstream change that can itself be tested.

This architecture is deliberately outcome-resilient. If the additive branch narrows, the bipolar branch may preserve component science. If scalarity fails, a generalized or set-valued formulation may remain testable. If complete-domain exposure cannot be identified, local additive structure may still support bounded studies. The scientific loss is therefore recorded at the smallest

warranted level. That is more demanding than declaring the whole program alive or dead, and more useful to the fields that must measure, compare, and reproduce its components (Manski, 2003; National Academies of Sciences, Engineering, and Medicine, 2019). This modularity also lets repeated losses accumulate within one dependency until retirement is warranted without erasing findings that remain valid elsewhere.

The chapter ends with change control because formal exactness is temporal as well as logical. A future revision must identify the object that changed, the authority for the change, the equations and protocols affected, and the conclusions that no longer transport. A research program may improve its definitions, but it may not retroactively claim that every earlier test addressed the successor object. Versioned formalism is how an ambitious hypothesis remains corrigible without becoming movable. A successor version should therefore begin with a delta statement naming the changed definition before any new evidence is compared.

5.1 — Truth-Domain Streams, Ownership, and Maximality

The first formal task is not the terminal equation but the carrier to which it could apply. A complete-history claim needs a prospectively declared qualifying bearer, an ownership rule for phenomenal events, a continuation relation, and a maximality convention. Without those objects, the same experience can be counted twice, omitted, or reassigned after the outcome is known (Bayne, 2010; Bayne & Chalmers, 2003).

This section treats stream identity as a truth-domain problem rather than a synonym for organism, brain, biography, account, or data record. Those objects may supply evidence, but none automatically determines which phenomenal events belong to one separately routed stream. The protocol must preserve that distinction even in ordinary cases, because fission, fusion, pause, copying, restoration, and nested candidates expose any hidden ambiguity.

Ownership must enter exactly once. The formal model permits either a domain already restricted to stream-owned events or a common exposure base with one explicit allocation or unity gate. Applying both can apply the ownership restriction twice and distort the represented contribution. Leaving residual ownership unclassified would turn an exact equality into an artifact of selective accounting.

Maximality is therefore relational. It means maximal under the declared continuation-and-ownership rule, not the largest organismic, anatomical, legal, social, or computational aggregate.

The six subsections below move from bearer and routing to event domains, unity gates, difficult continuations, and the division between root ownership and scientific use (Bayne, 2010; Bayne & Chalmers, 2003).

Table 5.1. Truth-domain objects and first-use rules.

Object	Status in this chapter	First rule for use
Unified conscious stream	Received bearer	Do not substitute body, biography, legal person, public record, or social identity.
$r_i(t)$	Latent composite contribution rate on an absolutely continuous chart	Define from realized density and one declared exposure convention; withdraw pointwise notation when the measure has unmatched atoms or singular mass.
$g_{0,i}(t)q_i^{\text{exp}}(t)$	Declared exposure-density factors	Encode unity or ownership at most once and preserve units under time reparameterization.
$L_i^{\text{phen}}(t)$	Latent phenomenological ledger	Formal target, not an observed total or public record.
T_i^*	Received endpoint concept	truth-level stream endpoint, not ledger crossing, body death, or convenience time.
$Z_i^* = 0$	Strong latent hypothesis	Exact closure claim, not a public empirical finding.
$L_i^{\text{rc}}(t) = c^{\text{LU}} U_i(t) Y_i(t)$	Candidate realization	Candidate route with bridge, dimensional, endpoint-coincidence, and retirement obligations; not the primitive definition.

Object	Status in this chapter	First rule for use
$\hat{L}(t)$	Estimator family	Belongs downstream; never substitute for $L(t)$.

5.1.1 — Qualifying Bearers and Unified Streams

The unified conscious stream is the proposed bearer of the received Law. It is not the body considered biologically, the person considered legally, the biography considered narratively, or the record considered administratively. The formal claim is attached to the stream of unified felt experience, because the ledger is supposed to integrate what is lived, not what is externally attributed (Bayne, 2010; Bayne & Chalmers, 2003).

This distinction matters even before hard cases appear. A body may continue while a qualifying conscious stream has irreversibly ended. A legal person may remain while consciousness is absent or profoundly uncertain. A biography may be socially intact while lived unity is interrupted, fragmented, or inaccessible. A record may be complete while the inner stream remains unknown.

The chapter receives the stream as a formal target, not as an established scientific object. Later chapters must ask how unity could be detected, how pauses and returns should be handled, how partition should be adjudicated, and how nonhuman or artificial candidates should be treated. Those questions are downstream. Here the only safe move is to state the object and prevent substitutions.

The fairness lens asks who bears the burden when a bearer is misnamed. If the body is treated as the bearer, terminal research

may confuse physiology with experience. If biography is treated as the bearer, memory and public identity may overrule present consciousness. If a record is treated as the bearer, the archive can become a false soul. The stream concept is a safeguard against those transfers.

A scientist may object that the stream is not directly observable. That objection is correct and useful. The received bearer is latent, and its adjudication requires proxies, confidence classes, edge-state rules, and abstention categories. A latent bearer can still be a scientific target if the book states what would count as evidence about it and what would force narrowing.

The unified conscious stream is therefore a received reference point, not an easy empirical object. Every later measurement, endpoint, and verdict must state whether it bears on the stream itself, a proxy for it, or a different object.

A useful technical test for this subsection is substitution pressure. Replace the phrase unified conscious stream with body, brain, person, biography, legal identity, or record, and ask whether the formal claim would still be the same claim. It would not. Each substitution changes the bearer and therefore changes the reference class of every later equation. The received object may prove hard to adjudicate, but difficulty of adjudication is not permission to substitute an easier object without declaring a formal change.

5.1.2 — Ownership, Routing, and Nonduplication

Ownership is the rule that assigns each phenomenal event to one declared stream-history branch. The assignment is not inferred

from where a datum is stored or which body produced it. It is a truth-level relation that the protocol represents fallibly. A sensor trace, testimony, or medical record may be evidence about ownership without becoming ownership itself (Bayne, 2010; Gazzaniga, 2000).

Two formally admissible encodings are especially important. On a restricted-exposure branch, the phenomenal measure is already limited to events owned by the stream. On a common-base branch, one frozen allocation or unity weight assigns exposure and signed components. The same ownership relation may not be multiplied into the exposure, valence rate, gate, and quadrature weights several times.

Nonduplication becomes decisive when candidates overlap. A component stream and a whole-system stream may both look plausible; two restored copies may inherit the same memories; a split history may support several continuations. The protocol must either give distinct ownership, apportion events under a declared rule, or retain unresolved typed slack. It may not let the same event close several ledgers.

Residual ownership cannot be hidden in one signed remainder. Unresolved positive variation, negative variation, exposure, atoms, and singular mass have different consequences. They remain separate coordinates with explicit bounds. When those coordinates are too wide for adjudication, the scientifically honest result is Model-ambiguous or Inconclusive evidence rather than a conveniently balanced total.

Routing also constrains maximality. A qualifying instance is maximal only relative to a prospectively fixed continuation relation that preserves event ownership. Maximality does not mean the spatially largest system, the longest biography, the most detailed archive, or the most socially recognized identity. Those substitutions change the carrier and therefore change the claim (Parfit, 1984; Schechtman, 1996).

Fission, fusion, copying, and restoration may redistribute a fixed token or history weight under a declared branch. The routing relation specifies those historical allocations and distinguishes them from the successor streams' future phenomenal contributions. Informational continuity and future accumulation are modeled as separate quantities.

A useful audit case begins with one recorded episode that is accessible to two candidate continuations. If both candidates receive the full episode, ownership is duplicated. If neither receives it, ownership is incomplete. If the allocation is chosen after terminal residuals are inspected, the result is selected. Only a frozen allocation, explicit unresolved set, or justified quotient avoids those failures.

Scientific use therefore requires an ownership register: carrier, branch, allocation rule, unresolved coordinates, continuation relation, adjudicator, version, and abstention condition. The register is not a dossier about a person. It is a model-control object that prevents the program from manufacturing closure by moving events between streams.

5.1.3 — Maximal Event Domains

The phenomenal domain is the complete set of stream-owned experiential events on which the signed measure is defined. It is not merely a calendar interval, a sequence of survey rows, or the portion of life that left a record. A complete-history hypothesis cannot substitute observation coverage for the truth domain without changing its quantifier (Folland, 1999; Kallenberg, 2002).

A maximal event domain must exhaust the declared stream under the chosen routing rule. It includes ordinary intervals, isolated events when the measure has atoms, and any singular component admitted by the representation. A density along clock time is one convenient branch, not the definition of the domain itself.

The distinction matters because event structure can be richer than sampled time. Experiences may cluster around transitions, occur during intervals with weak reportability, or be represented by measures that are not absolutely continuous with respect to the chosen clock. Treating every contribution as a smooth time series would erase those possibilities before measurement begins.

Delayed entry does not restart the domain. Enrollment, device activation, first diary response, or hospital admission marks the beginning of an observation window. The pre-enrollment phenomenal domain remains part of the complete target, even when it can be represented only by bounds or remains unidentified.

Domain selection can manufacture neutrality. Excluding hard-to-observe intervals, dropping positive or negative atoms, or ending

the domain at the first convenient zero changes the object being summed. A valid protocol freezes inclusion rules without access to terminal residual, endpoint surprise, or completion-model output.

Nonvacuity is equally important. A qualifying stream must have a nonempty declared phenomenal domain unless a zero-exposure class is separately defined as degenerate. Otherwise exact closure could be satisfied by an empty object that says nothing about lived experience.

A practical domain manifest should list the event carrier, sigma-field or generating algebra, exposure measure, ownership restriction, admissible atoms and singular components, entry and exhaustion rule, and unresolved mass. Each line names a possible failure point rather than decorating the notation.

The domain survives only if its meaning transports from formal statement to simulation, protocol, analysis, and public explanation. A study that tests a sampled-window estimand may be valuable, but it must not be reported as direct adjudication of the complete maximal domain.

5.1.4 — Unity Gating and Qualifying Intervals

A unity gate marks when and to what degree the declared bearer qualifies under the chosen stream criterion. It is an inclusion or weighting object, not a judgment of personhood, worth, care priority, sincerity, or social standing. Low confidence about unity calls for wider uncertainty or abstention, never reduced dignity (Bayne & Chalmers, 2003; Bayne, 2010).

Hard gating is mathematically simple: an interval is included or excluded. Consciousness science rarely offers such clean boundaries. Sleep, anesthesia, delirium, fragmented access, covert awareness, and rebinding may require a family of thresholds or a soft gate whose values express graded evidential support rather than graded human value.

The gate must be identified independently of the terminal residual. If the same valence estimator both decides whether an interval counts and supplies the value being accumulated, unfavorable intervals can disappear by construction. Unity evidence and valence evidence may share data sources, but their algebraic roles and validation targets remain distinct.

Apply §5.1.2's nonduplication rule to unity gating. On a restricted-exposure branch, ownership is already in the domain; on a common-base branch, one gate may supply allocation. A second ownership multiplier in the rate or quadrature weights would duplicate the same relation.

Qualifying intervals need endpoint discipline. A gap in reportability is not automatically a pause in experience, and a pause is not automatically the end of a stream. The gate family should therefore be estimated with rules for return, reversible loss of access, threshold hysteresis, and uncertainty around the first and last qualifying times.

Gate uncertainty propagates into every downstream object. It changes interval contributions, cumulative residuals, endpoint windows, and the set of compatible histories. A protocol that reports a point ledger while treating a disputed gate as certain

understates uncertainty at the very layer that determines what enters the sum.

A useful stress test compares two pipelines on the same synthetic history. One uses an independently calibrated unity gate; the other tunes the gate after inspecting terminal residuals. Similar apparent closure in the second pipeline is not corroboration. It is a demonstration of how selection can imitate the target.

The correct output may be a set of ledger paths indexed by admissible gate families, or No adequate estimate if the target cannot be identified or validly bounded. That outcome is scientifically informative because it locates the failure at stream qualification rather than mislabeling uncertainty as neutral experience.

5.1.5 — Split, Fusion, Pause, and Continuation

Split, fusion, pause, and continuation are not exotic decorations around a simple bearer. They determine how the universal carrier is counted. A probability-one closure statement is meaningful only after the reference class, routing branch, maximal instances, and event ownership have been fixed (Parfit, 1984; Schechtman, 1996; Bayne, 2010).

The next display states the branch-specific probability-one target under a declared probability law and carrier event. It is a formal claim, not an observed frequency and not a substitute for routing decisions.

$$Q^b(FPTVC^b) = 1$$

A pause differs from an endpoint because continuation remains admissible. Sleep, reversible anesthesia, temporary loss of report, and interrupted access may preserve one stream under a declared relation, or they may remain ambiguous. Biological continuity alone does not settle the question, and observation shutdown cannot decide it by default.

Fission requires the protocol to state what happens to the parent instance and how successor ownership begins. Fusion requires the corresponding rule for predecessor instances and the fused continuation. The science volume does not obtain permission to trade residuals across branches merely because they share memory, tissue, code, or causal history.

Copying and restoration create a related trap. Informational sameness does not prove numerical identity of phenomenal ownership. A restored system may be a continuation, a new branch, or an unresolved candidate under the declared ontology. The result must remain conditional on that ontology rather than selected by whichever routing closes most cleanly.

Return after an apparent ending is a direct falsifier of a badly defined protocol endpoint. Resuscitation, renewed responsiveness, recovered access, or later evidence of continued experience can show that the study stopped too early. The estimate or adjudicated classification of the truth-level endpoint is revised only through the protocol-fixed adjudication rule, not through retrospective convenience.

Difficult routing cases should remain in the analysis as branch-indexed objects or explicit unresolved sets. Dropping them

because they are complicated creates survivorship in the formal carrier. Pooling them under one presumed identity can be equally damaging. Both errors can produce false confidence about closure.

Routing uncertainty is itself a scientific result. When continuation, ownership, or maximality cannot be adjudicated, the program records Model-ambiguous or No adequate estimate and preserves the case for later theory revision. Ambiguity is not permission to choose the branch with the preferred terminal value.

5.1.6 — Root Ownership and Scientific Use

This chapter specifies the formal object that the rest of the book investigates. Representation, measurement, inference, candidate mechanisms, rival comparison, replication, and revision all refer to this stated target. The bearer, domain, endpoint, currency, and quantifiers remain explicit so that readers can follow each derivation and identify what a study tests (Folland, 1999; Kallenberg, 2002).

That boundary is a defense against semantic drift, not a ban on scientific criticism. Research may show that a branch is too coarse, a bridge is unidentifiable, or an endpoint class is empirically inadequate. Such findings can justify a formal change request, a successor object, a narrowed claim, or a withdrawn route. They cannot justify changing the target silently while preserving its public name.

A received-object concordance should accompany every operational descendant. For each symbol and branch, it should identify the truth-level meaning, the protocol approximation, the

observation bridge, the estimand, the estimator if one exists, and the conditions that force abstention. The concordance makes it possible to locate a failure without absorbing every discrepancy into generic model misspecification.

Independent teams should be able to reconstruct the same target from the frozen packet. If one team treats biological death as the truth endpoint, another uses the last report, and another defines the endpoint as first hitting zero, they are not applying different methods to one hypothesis. They are studying different endpoint constructions, one of which may make closure tautological.

Operational descendants should remain traceable to the same formal target. Public explanations may simplify the notation, but technical derivations and empirical tests must restore the assumptions needed for the object actually under study.

Scientific creativity begins from this fixed point. Researchers may propose vector extensions, endpoint-inclusive branches, nonadditive functionals, revised routing, or new candidate mechanisms. Each proposal is welcome as a typed successor with its own identifiers, bridges, predictions, and failure conditions. Visible succession permits genuine discovery while preventing the current hypothesis from inheriting evidence earned by a different object. Successor proposals should also state which earlier counterexamples they resolve and which new counterexamples they expose themselves to.

The practical standard is simple: receive first, test honestly, and revise visibly. A stable target lets critics challenge assumptions, reference classes, or bridges directly instead of arguing against a

moving collection of metaphors. It also lets a failed module teach the program exactly what failed without forcing either dogmatic preservation or opportunistic rescue (Cronbach & Meehl, 1955; Lakatos, 1978; National Academies of Sciences, Engineering, and Medicine, 2019). That continuity also lets later datasets remain comparable, because a revision can be evaluated against the same frozen target rather than retroactively redefining earlier evidence. That stability makes disagreement cumulative: later teams can argue about evidence against the same object instead of unknowingly testing different targets.

5.2 — Finite Signed Phenomenal Measure and Exposure

This section defines the primary signed measure first and introduces density or rate notation only on branches where absolute continuity justifies it. The distinction keeps measure-level claims separate from later physical-time representations.

Time-indexed ledger and rate notation require a declared exposure chart; §5.2.3 gives the absolute-continuity conditions under which a physical-time contribution rate exists.

Write $r_i(t)$ for the declared composite contribution rate $g_{\theta,i}(t)q_i^{\text{exp}}(t)v_i^{\text{real}}(t)$. Physical time, unity-weighted exposure, subjective time, and protocol time are not interchangeable. Units and rates must transform with the clock, and ownership may enter only once. A polished cumulative curve cannot repair a missing exposure convention.

The display below is a chart identity on the absolutely continuous branch, not the primitive definition of the signed measure and not an empirical finding. The final warning concerns path class: an ordinary integral of a regular rate has finite variation, whereas later candidate routes may contain diffusion or jumps. Any bridge between those objects requires its own assumptions, units, and testable consequences.

$$\begin{aligned} r_i(t) &:= g_{\theta,i}(t)q_i^{\text{exp}}(t)v_i^{\text{real}}(t), \\ L_i^{\text{phen}}(t) &= L_i^{\text{phen}}(S_i^\theta-) + \int [S_i^\theta, t]r_i(s)ds \end{aligned}$$

5.2.1 — Signed Phenomenal Measure

On the primary branch, the latent phenomenal object is a finite signed measure v_i on the complete measurable domain (Ω_i, Σ_i) of

one separately routed maximal qualifying stream. The measure assigns signed contribution to phenomenal event sets. It is not initially defined as a questionnaire score, a mood state, or a regularly sampled time series (Folland, 1999; Kallenberg, 2002).

Countable additivity is not licensed by arithmetic convenience. An empirical representation needs a premeasure or additive-conjoint gate: disjoint unions must preserve the relevant ordering and magnitude relations on a generating algebra, and extension to a signed measure must be coherent on the declared domain. Failure at this gate favors an ordinal, vector, bipolar, or nonadditive branch rather than a manufactured measure (Luce & Tukey, 1964; Krantz et al., 1971; Folland, 1999).

The measure-theoretic formulation separates event ownership from clock choice. Ω_i carries the stream-owned phenomenal events; a later time chart pushes the measure onto an ordered axis. This makes it possible to distinguish a truth-level contribution from the particular cadence, window, or device used to observe it.

Density and physical-time rate notation are available only on the absolutely continuous subbranches specified in §5.2.3; atoms or singular components remain measure-level objects. Realized density, conditional predictor, proxy, and estimator remain notationally distinct.

The cumulative ledger $L_i(t)$ is a prefix evaluation of v_i under the declared chart. It inherits its meaning from the measure and domain. It is not a separate metaphysical substance and not a public or private record anyone can inspect directly. Its value changes only through stream-owned phenomenal contribution under the chosen representation.

Finiteness means finite total variation over the complete domain. It rules out undefined subtraction of infinite positive and negative masses. The condition is mathematically substantive and empirically demanding; it cannot be presumed merely because every finite study produces finite numbers.

Exposure gauge freedom introduces another distinction. Different factorizations into density and exposure can represent the same signed measure. The terminal measure and its Jordan decomposition may remain invariant while duration, intensity, and normalized diagnostics change. A protocol must record the admissible gauge family rather than let terminal fit choose it.

A scientific implementation should therefore maintain a measure packet: domain, sigma-field or generating algebra, ownership convention, exposure measure, density status, atomic or singular components, total-variation condition, and observation bridge. That packet exposes the assumptions on which every later equation depends.

5.2.2 — Positive and Negative Jordan Magnitudes

Every finite signed measure has a Jordan decomposition into mutually singular positive and negative measures.

Their total masses V_i^+ and V_i^- preserve the two directions of phenomenal contribution, while their sum is gross variation and their difference is the terminal signed residual (Folland, 1999).

The decomposition is not a moral partition into deserved and undeserved experience. It is a mathematical separation under a declared sign convention. Positive and negative components

belong to one stream and cannot be transferred between persons, branches, groups, or generations.

$$v_i = v_i^+ - v_i^-, v_i^+ \perp v_i^-, V_i^+ := v_i^+(\Omega_i), V_i^- := v_i^-(\Omega_i)$$

Gross variation is essential because net zero can conceal arbitrarily large experience. A stream with $V_i^+=1$ and $V_i^-=1$ shares the same residual as a stream with $V_i^+=100$ and $V_i^-=100$, yet their total variation differs by two orders of magnitude. Exact closure would therefore never imply equal lives, mild lives, or adequate welfare.

Mutual singularity in the Jordan theorem concerns the measure decomposition, not the impossibility of psychologically mixed episodes. If positive and negative valence can co-occur within the same phenomenal event, the bipolar branch in Section 5.4 preserves overlap explicitly. The additive signed measure and the bipolar component representation are related but not automatically equivalent.

Estimating only the signed residual is insufficient. Measurement error can make two large uncertain components look like a precise small difference. Separate component estimates, covariance, calibration, and identified sets are needed before a near-zero residual can be interpreted as compatible with equal Jordan magnitudes (Cacioppo & Berntson, 1994; Manski, 2003; Imbens & Manski, 2004).

Finiteness must be assessed componentwise. The expression $V_i^+=V_i^-$ is not meaningful on the primary branch if both are infinite. A finite observation window cannot establish complete-domain finiteness, so the claim remains conditional on the domain and bridge assumptions that make the full masses well defined.

A useful simulation contrasts three worlds with the same observed terminal residual: genuinely small component masses, very large cancelling masses, and a miscentered instrument that forces cancellation. A model that reports all three as the same result has not recovered the target object.

Jordan magnitudes thus provide the minimum anatomy of additive PTVC. They protect the theory from the false idea that zero means nothing happened, and they protect readers from the equally false idea that a terminal equality could excuse intense suffering, unequal conditions, or failures of care.

5.2.3 — Experienced Exposure and Temporal Rate

A signed measure becomes a temporal rate only after the program chooses an experienced-exposure measure and establishes absolute continuity on the relevant branch. The realized value density is a Radon-Nikodym derivative relative to exposure; multiplying it by the declared exposure density produces a physical-time contribution rate. Neither object is a mood level with time appended (Folland, 1999; Billingsley, 1999).

Physical time is one possible chart, but phenomenal exposure may depend on subjective duration, unity, or another declared clock. The science does not gain freedom to choose whichever chart closes best. The chart, exposure anchor, admissible gauge family, and transformation rule must be frozen before decisive terminal analysis.

$$[v_i^{\text{real}}] = V \cdot E^{-1}, [g_{\theta,i} q_i^{\text{exp}}] = E \cdot T^{-1}, [r_i] = V \cdot T^{-1}, [L_i^{\text{phen}}] = V$$

Apply the nonduplication rule in §5.1.2: ownership or unity enters the exposure architecture once. Any additional weighting must

represent a distinct scientific quantity rather than re-encode the same allocation.

The dimensional audit separates phenomenal value V , exposure E , and chart time T . The realized density carries V per E ; the exposure density carries E per T ; their product r_i carries V per T ; integration returns V . Checking those relationships helps identify the conversions a proposed measurement bridge requires.

Irregular observation cadence is not the same as irregular phenomenal exposure. Experience can continue between prompts, while a device can sample densely during quiet periods and sparsely during crises. Interval contribution estimators must therefore separate the latent exposure process from the marked observation process (Stone et al., 2007; Shiffman et al., 2008).

Subjective time adds a further identification problem. Retrospective duration, prospective time judgment, memory density, and momentary temporal experience can diverge. A study may compare these channels, but it cannot silently choose one as the complete clock without a validation and transport argument.

Gauge changes can preserve the signed measure while changing density and exposure separately. That invariance is useful: it shows which conclusions depend on the measure and which depend on a particular factorization into intensity and time. Reserve- or horizon-normalized diagnostics require their own anchors because they are not automatically gauge invariant.

The practical result is an exposure register beside every ledger estimate. It records the clock, unit, unity convention, ownership branch, cadence, interpolation rule, unobserved exposure, admissible gauge family, and uncertainty. Without that register,

an accumulated number may be dimensionally neat yet scientifically uninterpretable.

5.2.4 — Dimensions, Units, and Reparameterization

Time reparameterization is where notation can quietly manufacture invariance. Suppose a new clock u is used and physical time is written as $t=\tau(u)$, with τ increasing and differentiable. The ledger does not keep the same contribution rate by magic. The time element changes, and the rate must carry the Jacobian (Folland, 1999; Kallenberg, 2002).

The correct change of variables is:

$$L_i^{\text{phen}}(\tau(u_2)) - L_i^{\text{phen}}(\tau(u_1)) = \int_{u_1}^{u_2} r_i(\tau(u))\tau'(u)du$$

If one wants a rate expressed in u -time, the transformed rate must satisfy:

$$r_{i,u}(u) = r_{i,t}(\tau(u))\tau'(u)$$

Endpoint-normalized time is useful precisely because it can align terminal windows, but that convenience creates a leakage risk. Mapping every history to a unit interval uses endpoint information to define the chart. The transformation, information timing, and Jacobian must therefore be declared before confirmatory analysis; otherwise a clean terminal pattern may be partly manufactured by the clock.

Time normalization can be legitimate. It may be required for comparing terminal windows of different lengths, estimating reserve-space behavior, or displaying model recovery. The rule is that the transformation must be declared before the confirmatory analysis, the rate must carry the Jacobian, and any endpoint

information used to define the clock must be separated from claims of prospective prediction.

Comparability also has a human consequence. A participant's final week should not be compressed into another participant's final hour merely to obtain visual symmetry. Any changed clock must state where the transformation enters the rate, uncertainty, interpretation, and claim status.

More generally, a noninjective time map can preserve the net signed residual while reducing gross variation inside time fibers. Equality of gross variation requires an injective chart, sign-pure fibers, or another proved no-cancellation condition. Protocols should register temporal-resolution sensitivity and retain the event-space branch when cancellation cannot be bounded (Folland, 1999).

Transport remains a separate claim. A time representation validated in one species, developmental stage, clinical state, language, or endpoint class may fail in another. Each transport claim requires its own invariance tests, rival comparison, and possibility of reference-class narrowing.

5.2.5 — Finiteness and Complete Domain

An ordinary pathwise integral of a sufficiently regular contribution rate has finite variation on finite intervals. That fact matters because the reserve-coupled realization later uses stochastic dynamics. A finite-variation process and a diffusion-bearing semimartingale can be related under a declared bridge, but they are not automatically the same process (Folland, 1999; Protter, 2005).

The clean comparison is:

$$[L_i^{\text{phen}}]_t = 0$$

Here $[L_i^{\text{phen}}]_t$ denotes quadratic variation. The statement is a path-class implication of the ordinary integral chart under regularity conditions, not a new empirical result. If the root ledger is interpreted as an ordinary pathwise integral, diffusion-like quadratic variation requires additional structure rather than a change of typography.

This creates a bridge obligation rather than a disaster. One route is to treat the product realization as a reduced-form consequence model for terminal dynamics, not as a pointwise identity with the phenomenological integral. Another route is to enrich the formal ledger with stochastic integration. A third is to define an approximation relationship between the objects. Each route requires visible change control.

Relating $L(t)=U(t)Y(t)$ to the pathwise integral requires a clear account of their process classes. If the product contains a diffusion term, specify whether it models the same object, a projection, an estimator, or an auxiliary consequence. That classification determines the mathematical bridge to establish.

5.2.6 — Temporal Additivity as a Component Claim

Temporal additivity states that the signed phenomenal measure assigned to a disjoint union equals the sum of its restrictions to the disjoint parts. In the primary branch, this is not merely notation. It is a representation claim about how experienced contributions compose across the complete strict-pre-endpoint domain, and it can fail even when a convenient numerical

summary remains available (Stone et al., 2007; Shiffman et al., 2008).

A valid cut-point analysis must prospectively partition the same truth domain into prefix and suffix sets, assign any cut-time atom exactly once, and preserve the same representation, neutral origin, exposure clock, unit, ownership rule, routing, and endpoint convention on both sides. Changing any of those objects across the cut turns an additivity test into a comparison of different ledgers.

On the absolutely continuous chart, the received additive branch yields the increment identity displayed below; the general measure branch uses the corresponding signed-measure increment, including any atoms or singular component. For a fixed terminal residual, prefix and suffix contributions sum to that residual whether or not it is zero.

$$L_i^{\text{phen}}(t_2) = L_i^{\text{phen}}(t_1) + \int_{t_1}^{t_2} r_i(s) ds$$

Across varying cuts, a suffix-versus-prefix slope of minus one is an additivity diagnostic shared by any conserved residual, including a nonzero residual. It supplies no independent vote for PTVC. The PTVC-bearing estimand is the independently adjudicated terminal residual and its fixed zero target, not the generic fact that prefix and suffix restrictions sum to a constant.

Observation-level non-tautology is essential. The measured suffix must come from post-cut observations or from a separately validated terminal-remainder bridge. It may not be defined by subtracting the measured prefix from the zero target under test.

That subtraction would manufacture complementarity and erase the empirical burden.

A bounded laboratory study can test local refinement and complementarity. Complete-stream inference additionally requires justified prefix and suffix information, domain coverage, and an independently adjudicated endpoint. The report identifies which of these objects the design addresses. This separation prevents a successful local additivity test from inheriting whole-stream authority it was never designed to establish.

Sampling design must respect the temporal object. Irregular cadence, state-dependent prompting, missing intervals, high-arousal oversampling, and endpoint-related observation loss can distort both sides of the partition. Duration and exposure weighting must be explicit, and uncertainty from unobserved intervals must travel into the residual rather than disappear through equal-weight scoring. Partition sensitivity can be checked by recomputing the same realized history under alternative admissible sampling grids rather than assuming cadence is innocuous.

Path dependence supplies possible rivals, but history-dependent rates can still be additive along a fixed realized stream. Anticipation, relief, memory, adaptation, saturation, and context may alter those rates; they demonstrate nonadditivity only when the declared disjoint-union rule fails. Stable failure should prompt review of the additive representation and, where justified, a declared nonadditive, generalized, or no-estimate branch rather than a more flexible scalar chosen after the outcome. Testing additivity should therefore vary the partition while holding the

represented path fixed, separating failure of the accumulation rule from ordinary history dependence. An atom at a partition boundary must be assigned once under a convention fixed before either side is scored.

The additivity restriction also needs an identification route. Correlated measurement error, common smoothing, origin drift, or shared-method bias can manufacture a slope near minus one. External calibration, method-diverse replicate channels, valid instruments, sealed recovery studies, or truth-containing error bounds must be declared before the restriction is treated as evidence about the latent measure (Manski, 2003; Borsboom, 2005). Method-diverse replication is most informative when its errors are plausibly independent, because agreement produced by shared preprocessing offers weaker protection against artifact. Where channels share calibration data, report the covariance this creates between the two partition estimates.

A complete report shows the partition rule, atom treatment, observation source for each side, error structure, estimated additivity restriction, terminal-residual region, and admissible alternatives. Separate decisions for additivity and terminal zero identify the representation supported and the next question to investigate. A study can then remain reusable after a terminal-zero failure if its partition and additivity evidence continue to satisfy their own gates. Reporting the two decisions separately also identifies whether a successor needs a different accumulation rule or better endpoint evidence.

5.3 — Additive PTVC and Unequal Gross Variation

This section states the additive branch formally and develops the consequences of its exact intrastream terminal relation. The bearer, measure, origin, domain, and endpoint requirements already defined above remain binding.

The formal simplicity is purchased by exact commitments. The bearer must be separately routed, the measure finite, the origin and sign fixed, the strict-pre-endpoint domain complete, and the branch genuinely additive. When any of those conditions fails, the correct response is not to keep the equation and soften its meaning. The branch must narrow, become unidentified, or yield to another representation.

The equation below states the received additive target. The surrounding discussion explains the equality, the differences among experiences that it preserves, and the assumptions needed to interpret it.

$$Z_i^* := \nu_i(\Omega_i) = V_i^+ - V_i^- = L_i^{\text{phen}}(T_i^* -)$$
$$PTVC_i \Leftrightarrow V_i^+ = V_i^- < \infty \Leftrightarrow Z_i^* = 0$$

The display identifies three equivalent forms within the declared additive branch: equality of Jordan magnitudes, zero total signed mass, and zero latent terminal residual. None of those forms supplies the representation, origin, bearer, domain, or endpoint needed to interpret it.

Table 5.2. Additive PTVC constraints and dimensions that may remain unequal.

Object	Constrained by additive PTVC?	May remain unequal?
Terminal signed residual	Yes, exactly zero on the declared latent branch	No, within the target statement
Positive and negative Jordan magnitudes	Yes, finite and equal	Their common magnitude may differ across streams
Gross variation, duration, order, peaks	No	Yes, potentially radically
Rights, welfare, opportunity, biography	No	Yes; these require independent analysis

5.3.1 — The Exact Additive Statement

The additive statement assigns one finite signed phenomenal measure to one qualifying stream over its complete strict-pre-endpoint domain. Its terminal residual is the measure of that whole domain, not a score at the last observed moment and not a retrospective judgment about whether the life was good. A decisive falsification would be a qualifying stream for which representation, routing, domain, endpoint, and measured-to-latent gates pass while the identified terminal residual excludes zero (Folland, 1999; Cacioppo & Berntson, 1994).

Jordan decomposition writes the measure as a positive part and a negative part whose supports are mutually singular in the measure-theoretic sense. PTVC requires their total magnitudes to be finite and equal, which is stronger than a zero sample mean and weaker than equality at every time.

Empirical work cannot observe the equality directly. It must declare a representation, observation kernel, missingness process, estimand, estimator, endpoint rule, and measured-to-latent bridge before a finite-band result can bear on the latent exact statement.

Consider two streams with the same terminal signed residual but entirely different temporal structures. One may contain long mild burdens and long mild relief; another may contain rare extremes. The additive target treats their net terminal relation alike while preserving their gross variation as radically different.

A critic may object that the target is too coarse because it discards order, agency, meaning, and distribution across time. That objection identifies a real limitation of the additive branch rather than a refutation of its internal statement. Those dimensions remain scientifically and ethically indispensable.

Exact additivity is best treated as a branch-specific invariant. Its scientific value lies in making a strong claim testable without pretending that one scalar relation exhausts a life.

Failure of the additive target would not erase order, agency, meaning, or the distribution of experience across time. It would show that this scalar invariant is false, too coarse, or inapplicable to the declared reference class. A well-documented counterexample would redirect research toward richer representations rather than be absorbed as unexplained noise.

5.3.2 — Jordan Magnitudes and Gross Variation

Equality of positive and negative Jordan magnitudes does not imply small total exposure. Their sum is gross phenomenal variation, and it can be slight or immense while the signed

residual remains zero. Reporting both residual and gross variation preserves the difference between a quiet history and one containing large opposing magnitudes; the equality is a measure-theoretic relation, not a psychological description (Folland, 1999).

The two summaries should be reported together, because gross variation and terminal residual answer different questions.

$$G_i := V_i^+ + V_i^-, Z_i^* := V_i^+ - V_i^-$$

A measurement program must estimate the two sides rather than infer them from a quiet endpoint. Large opposing quantities can produce a small residual, so uncertainty in either component may dominate uncertainty in the difference.

A terminal estimate near zero could arise from two well-measured moderate totals, two poorly measured enormous totals, or a baseline choice that forced cancellation. Those cases have different scientific meanings even when a single plotted residual looks identical.

Ordinary adaptation, opponent processes, and measurement centering can also generate balanced-looking summaries without establishing complete-stream Jordan equality. Equal scoring requires those rivals to receive the same information and flexibility.

Gross variation keeps the formal claim from being mistaken for equal lives. A theory that predicts one terminal invariant can coexist with urgent differences in suffering, rights, care, opportunity, and justice.

The covariance of the two Jordan-magnitude estimates is scientifically consequential. Strong positive error correlation can make their difference appear stable even when each magnitude is poorly determined, so the joint uncertainty region should accompany any terminal residual.

5.3.3 — Intrastream Nontransferability

The additive equality belongs inside one separately routed stream. No positive magnitude from one person, animal, generation, population, institution, or archive may be used to cancel negative magnitude in another (Manski, 2003; Imbens & Manski, 2004).

Formally, each stream receives its own measure space and terminal residual. A sum across streams is a different object requiring an independently justified aggregation rule, and it cannot retroactively satisfy PTVC for any constituent stream.

Routing errors are therefore upstream failures. If observations from distinct streams are pooled before ownership is resolved, later estimation can be precise and still answer the wrong question.

A population average near zero illustrates the danger. Half a cohort could have large positive residual estimates and half large negative estimates, yielding a neutral mean while no individual stream is compatible with closure.

Aggregation across people can be legitimate in welfare science, public health, or institutional planning, but it answers a different question. A cohort mean, family narrative, or social welfare functional cannot substitute for the residual of one routed stream. If stream-specific ownership is unresolved, adjudication requires

a branch-matched conclusion that holds across every admissible ownership map; otherwise intrastream PTVC remains unadjudicated.

Nontransferability is both a formal boundary and an ethical firewall. It prevents the mathematics from becoming a ledger of human worth or a permission structure for cross-person balancing.

When routing remains uncertain, the protocol should preserve an admissible set of ownership maps rather than force a single partition. Each map induces its own stream-specific residual. The set of residuals allowed by alternative admissible ownership maps is their branch-indexed union. Intersections require constraints justified to hold jointly, with any required simultaneous-coverage guarantee; prespecification alone does not justify intersecting residual sets from alternative maps. Pooling becomes permissible only after routing uncertainty has been resolved at the level the claim requires.

Nontransferability fixes the unit of the claim and blocks moral accounting across bearers. One stream's positive measure cannot cancel another's negative measure, and a later event cannot alter the value already assigned to an earlier interval. This boundary prevents the formal ledger from becoming a ranking of lives or a justification for imposed harm.

5.3.4 — Origin, Sign, and Positive Rescaling

Exact zero has content only after the neutral origin and sign orientation are identified. Positive rescaling changes units but

preserves zero; additive translation generally changes whether a path closes (Folland, 1999; Cacioppo & Berntson, 1994).

Origin validity therefore requires independent calibration rather than terminal fitting. Candidate anchors may come from psychophysical indifference, symmetric tradeoff tasks, adaptation models, or cross-channel constraints, but each must survive its own falsification tests.

A questionnaire midpoint called neutral can make every participant appear closer to closure if the midpoint is culturally or clinically mislocated. Better precision around that midpoint does not repair the origin error.

Some theories deny that valence has an instrument-independent zero or interval scale. In that case exact additive PTVC may be unidentified, and a vector, ordinal, or generalized branch must be considered without pretending equivalence.

The scientific gain is not that the origin problem disappears. The gain is that it becomes an explicit gate whose failure can narrow the claim before an attractive terminal graph is overread.

Origin evidence should be challenged with anchors that were not used to fit the terminal model. Agreement among held-out indifference, tradeoff, and cross-channel tests is more informative than a zero chosen because it improves closure.

Under $F'(t)=a+bF(t)$, with $b>0$, positive rescaling preserves a zero residual when the neutral origin is transported consistently. An additive shift contributes an exposure-weighted term proportional to $aA_i(T)$ whenever total experienced exposure is nonzero. Scale invariance therefore does not solve origin identification; the

neutral origin must be independently declared and validated before accumulation.

5.3.5 — Past-Fixity and Non-Equivalent Readings

Past-fixity means that an experienced contribution, once it belongs to the declared history, does not change because later evidence, memory, relief, or interpretation changes. What can change is the estimate of that contribution. The distinction is ontic versus epistemic: the event is fixed as past, while knowledge about it may improve or deteriorate (Billingsley, 1999).

Filtering and smoothing make the distinction concrete. A filter estimates a latent state from information available up to a time; a smoother may revise that estimate after later observations arrive. The smoother can alter the posterior history without rewriting the experienced history itself. Every report should identify which information set produced each estimate.

Later interventions can change future experience, future reporting, and future memory. They cannot retroactively make earlier suffering smaller, morally deserved, or justified. Under exact PTVC, the fixed past constrains the signed remainder regardless of the chosen mechanism. Changing a genuine accumulated balance changes that remainder requirement, but does not by itself determine both future gross totals or identify particular compensating events.

Endpoint-revision rules are also specified prospectively. New evidence may show that the stream continued longer than first believed or that the observation endpoint was not the truth endpoint. The newly included interval belongs to the completed

domain, but the revision does not alter contributions already assigned under the same representation. A changed representation requires a separate migration record.

When a model version changes, old and new analyses should coexist. The record should distinguish changed evidence, changed representation, changed reference class, changed endpoint, and changed scientific claim. Without that matrix, a new scalarization or endpoint can inherit the apparent success of the object it replaced.

Remembered utility and narrative appraisal are scientifically important but non-equivalent targets. A person may remember an episode differently, reinterpret its meaning, or report less distress after recovery while the earlier phenomenal contribution remains uncertain. These processes are rivals or additional objects, not automatic corrections to the ledger.

A terminal residual must be reported with its cancellation geometry. Positive and negative Jordan magnitudes, gross variation, covariance, origin sensitivity, and the residual belong in the same display. Two histories can have similar residuals while differing radically in exposure, intensity, and uncertainty; a single terminal number would hide that structure.

Routing uncertainty should remain explicit as a family of admissible ownership maps when the evidence does not settle one map. Past-fixity then applies within each admissible history, and the terminal result becomes an identified set over those histories. Choosing the route that produces the most favorable residual would be outcome-dependent reconstruction. Set-valued routing

can still yield a decisive result when every admissible map gives the same sign conclusion, while disagreement across maps should widen the verdict rather than disappear.

The public language follows the same discipline. Later evidence may change what researchers believe about an earlier interval, but it does not erase what was lived. Exact closure, if supported, would be a terminal relation within one stream, not a moral story in which later events compensate for earlier harm or justify withholding present care. Public explanations should therefore avoid converting fixed-past arithmetic into counterfactual claims about whether a different life would have been better or worse.

Past-fixity gives tests a stable historical object. Later corrections to the representation, endpoint, or weighting receive explicit successor labels and their own evaluation, preserving the evidence associated with the earlier version (Lakatos, 1978; Mayo, 2018). The version record should specify whether a revision changes only estimation of the fixed past or redefines the target itself, because those changes have different evidentiary consequences.

5.4 — Bipolar Mixed-Valence Branch and Overlap

Mixed valence is not a minor complication added after the scalar case. A conscious episode can contain attraction and aversion, relief and grief, awe and fear, or bodily pain and interpersonal warmth at the same time. A single signed number may compress those components before the science has earned the right to combine them (Cacioppo & Berntson, 1994; Russell & Carroll, 1999).

The bipolar branch therefore begins with primitive positive and negative component measures β_i^+ and β_i^- . Their shared overlap ζ_i is preserved explicitly, while the net signed measure v_i equals their difference. The branch does not assume that every theory of mixed experience is literally two-dimensional; it prevents subtraction from erasing coactivation before it has been studied.

The following displays define the bipolar component decomposition and its primitive gross magnitude. They are not additive PTV in alternate notation. A bridge may connect the branches only under stated component, overlap, origin, unit, and exposure assumptions.

$$v_i = \beta_i^+ - \beta_i^-, \beta_i^+ = v_i^+ + \zeta_i, \beta_i^- = v_i^- + \zeta_i, \zeta_i \geq 0$$

$$G_i^{\text{bip}} = \beta_i^+(\Omega_i) + \beta_i^-(\Omega_i) = V_i^+ + V_i^- + 2\zeta_i(\Omega_i)$$

The net Jordan magnitudes V_i^+ and V_i^- describe the nonoverlapping positive and negative parts of v_i . The overlap measure ζ_i records component mass that cancels in the net signed measure but remains part of primitive gross experience. Net residual, component totals, and overlap therefore answer different questions.

5.4.1 — Why a Net Residual Can Hide Structure

A net signed residual can be identical for experiences with no overlap, complete overlap, or rapidly alternating signs. The compression is mathematically legitimate only if the discarded structure is irrelevant to the target being tested. A scalar residual is therefore sufficient only on a branch that declares overlap and order irrelevant; failure of that sufficiency sends the analysis to bipolar or path-sensitive alternatives (Cacioppo & Berntson, 1994; Russell, 1980).

The mapping from a bipolar state to a scalar residual is many-to-one. Once components are subtracted, the original pair cannot generally be recovered without additional assumptions or observations.

Measurement should therefore preserve component channels long enough to test whether scalarization is stable across people, contexts, intensities, and temporal scales. Early subtraction can manufacture apparent simplicity.

Grief at a wedding and relief during painful treatment illustrate coactivation. A zero net judgment at one instant would not reveal the presence, intensity, or duration of either component.

Preserving component structure makes later failure informative. The data may support scalar additivity, stable bipolarity, partial identification, or no adequate representation, and each outcome teaches something different.

A unidimensional rival can explain mixed reports as rapid alternation, appraisal, or report-generation structure. The bipolar branch therefore earns support only if independent positive and

negative components recover and transport better than those alternatives. If it does not, the additive branch or another declared representation remains the appropriate object.

5.4.2 — Independent Positive and Negative Components

The bipolar branch treats positive and negative phenomenal contributions as separately represented components rather than automatic negatives of one another. This permits coactivation, asymmetric response functions, and tests of whether one component can change while the other remains stable (Cacioppo & Berntson, 1994; Russell & Carroll, 1999; Larsen et al., 2001).

Each component needs its own origin, unit, exposure rule, and observation bridge. For finite components on the same domain and a common scale, $v_i(\Omega_i) = 0$ is equivalent to $\beta_i^+(\Omega_i) = \beta_i^-(\Omega_i)$; it does not identify their common magnitude, overlap, or temporal order.

Protocols should test component reliability, monotonicity, and cross-context transport before combining them. Separate elicitation can reveal ceiling effects, asymmetric noise, and differential missingness that a net scale conceals.

In chronic pain, a person may report persistent nociceptive burden alongside meaningful connection, mastery, or relief. Treating one component as the arithmetic negation of the other may misrepresent both.

Component independence can also be overstated. Shared arousal, attention, language, and response style may induce correlation,

and the representation must not interpret statistical separability as ontological independence.

The scientific payoff is a branch that can be wrong in specific ways. It can fail because components are not distinct, because their units are not comparable, or because no stable terminal relation survives.

Residual dependence after modeling shared arousal, response style, and context can reveal whether the two components carry distinct information. Failure to recover that distinction favors a simpler representation rather than a nominally bipolar scale.

Branch comparison should therefore be explicit. A dataset supports the bipolar branch only when separately identified component channels, coactivation, and asymmetric responses improve recovery and transport beyond a one-axis or rapid-alternation rival under the same observations. Without that advantage, branch identity remains Model-ambiguous rather than being settled by richer vocabulary.

5.4.3 — Overlap, Coactivation, and Gross Exposure

Overlap records the simultaneous presence of positive and negative components. It matters because a stream with high coactivation can have the same component totals as a stream in which the components occur in separate eras (Manski, 2003; Imbens & Manski, 2004).

An overlap functional depends on temporal resolution and representation. Coarse windows may make alternating states look simultaneous, while very fine windows may fragment states whose phenomenology is integrated over longer intervals.

A study should protocol-fix the windowing rule before outcome inspection and examine resolution sensitivity. Stability across plausible resolutions is evidence for a robust overlap construct; instability is a result, not a nuisance to hide.

A difficult rehabilitation session may combine pain, fear, achievement, and hope within the same minute. Summing daily positive and negative totals cannot show whether those elements were integrated, alternating, or separately remembered.

Delayed opponent dynamics and multilayer appraisal can produce apparent coactivation without a primitive bipolar phenomenal state. The branch should therefore be compared against alternation, lagged-response, and report-generation models using common observations. Unresolved equivalence warrants Model-ambiguous, not preference for the richer language.

Overlap therefore belongs in the discovery architecture, not as a decorative complexity term. It tells the science what scalar closure would have to ignore and what a richer branch might preserve.

A resolution study should compare at least two prospectively specified windows and two explicit alternatives: genuine coactivation within the same window, and rapid alternation whose average only appears mixed. The branch is strengthened when the same component structure survives this aliasing test; otherwise the result belongs to the resolution at which it was identified.

Overlap is not a decorative correction to a scalar model. It identifies information that a net residual discards and therefore determines when a richer branch is needed. Past observations

remain fixed; later component activity can change the terminal sum without rewriting what was experienced before.

5.4.4 — Temporal Order and Component Histories

Terminal component totals do not determine temporal order. Positive experience followed by burden, burden followed by relief, and repeated oscillation can end with the same totals while producing different adaptation, memory, action, and clinical consequences (Cacioppo & Berntson, 1994; Russell, 1980).

Observation schedules must be dense enough for the order-sensitive quantity they claim to estimate. Retrospective summaries cannot recover every transition, and missingness may be informative when people disengage during the most intense states.

Two end-of-life trajectories can carry similar component totals but differ in whether relief arrived early enough to preserve communication, agency, or family connection. The formal terminal relation does not erase that difference.

Peak-end, recency, and memory-consolidation accounts are powerful rivals for reported order effects. They may explain later judgments even when the underlying cumulative exposure is unchanged.

The branch remains disciplined by distinguishing the terminal target from scientifically important path structure. A theory can propose one invariant while the book still treats order as essential to explanation and care.

Order sensitivity should be estimated separately for contemporaneous reports, delayed recall, and retrospective evaluation. A pattern that appears only after memory consolidation belongs to the observation or memory model unless a bridge to phenomenal order is independently supported.

Temporal-order extensions may use kernels, path signatures, transition counts, or state-space dynamics, but adopting one creates a new branch with its own invariances, estimands, observation requirements, and counterexamples. The additive terminal residual should not be described as if it already contained sequence information.

5.4.5 — Branch Tests, Failure, and Non-Substitution

The additive and bipolar branches describe different features of experience. A zero net residual can coexist with large positive and negative magnitudes, extensive coactivation, or asymmetric histories. Separate branch labels identify which features a study evaluates and the bridge needed to connect its findings (Cacioppo & Berntson, 1994).

Branch selection must be prospective. The protocol should declare whether positive and negative components are primitive, whether overlap is allowed, how coactivation is measured, and which bridge would connect the bipolar object to an additive signed measure. Selecting the branch after seeing which one closes would make the result outcome-dependent.

Resolution matters because rapid alternation can resemble coactivation when observations are coarse, while genuine coactivation can be forced into alternating labels by a single-sign

instrument. Multiscale analysis should therefore compare component occupancy, overlap, order, and gross exposure across prospectively specified temporal resolutions.

A bridge theorem must state sufficient conditions, not merely visual resemblance. If the bipolar components integrate to the positive and negative Jordan magnitudes of an additive measure under a common origin, exposure rule, and domain, the relationship is testable. When those conditions fail, the branches remain distinct even if their terminal summaries happen to agree.

Failure should be typed. Unstable sign indicates a representation problem; unresolved coactivation indicates an observation problem; nontransportable overlap suggests a reference-class boundary; incompatible component totals pressure the bipolar target; and a nonzero additive residual pressures the additive target. A generic mixed label would discard these distinctions.

The empirical design should give each branch equal opportunity. Instruments that force a single scalar naturally favor the additive formulation, while separate positive and negative channels can favor a bipolar model. Equal-budget comparison uses the same observations, cadence, endpoint rule, calibration opportunity, and held-out scoring criteria.

Non-substitution is also an ethical safeguard. A richer branch cannot explain away an adverse result unless declared and measured. Nor may component magnitudes become scores of personal worth, emotional purity, or eligibility. The branches model a proposed intrastream target; they do not classify people.

A branch-concordance report should name what survived. An additive failure may still preserve sign calibration, component measurement, endpoint work, and useful rival models. A bipolar failure may leave an additive approximation viable in a bounded context. The report should preserve these gains without presenting them as support for the branch that failed.

The resulting architecture allows genuine narrowing. The program can move from a universal additive claim to a bounded bipolar or generalized claim only through visible status change and new risky predictions. It cannot rotate among branches until one fits. That rule turns branch pluralism into scientific strength rather than a rescue device (Mayo, 2018; National Academies of Sciences, Engineering, and Medicine, 2019).

5.5 — Generalized Terminal Neutrality and Bridge Theorems

Generalized Terminal Neutrality is the program's broadest typed terminal language, and for that reason it requires the strictest discipline. It allows a terminal target on a marked carrier and declared value space without privileging one scalar signed measure. The generalization is formal, not evidentiary (Manski, 2003).

Generality is useful when the science has not earned a unique scalarization or when mixed, vector, relational, or distributional structures remain live. It is dangerous when the general functional is chosen after the data so that every terminal pattern can be called neutral.

The display below states a separate GTN target: a frozen terminal functional H_{GTN} evaluates a declared marked carrier (Γ, s) and returns the distinguished neutral element 0_{GTN} . Equivalence to additive PTVC requires a bridge theorem that preserves bearer, domain, origin, sign, exposure, and endpoint commitments.

$$H_{GTN}(\Gamma, s) = 0_{GTN}, (\Gamma, s) \in M_{GTN}, H_{GTN}: M_{GTN} \rightarrow V_{GTN}$$

Here $\mathfrak{M}_{GTN}$ is the declared class of marked carriers, $\mathcal{V}_{GTN}$ is the target value space, and 0_{GTN} is a prospectively identified neutral element. The equation is meaningful only when the carrier, codomain, admissible transformations, and zero set are fixed independently of the observed endpoint.

5.5.1 — A Separate General Terminal Target

GTN names terminal constraints that need not reduce experience to one additive scalar. It can accommodate vector states, distributions, path functionals, or other structures when the scientific reason and typed map are declared in advance. GTN remains testable only when the functional and admissible representation family are frozen before outcomes; a post hoc map that always returns its neutral element is not a terminal law (Manski, 2003).

The formal object is a functional on a represented complete stream, not a license to call any desirable terminal state neutral. Its domain, codomain, invariances, topology, and zero set must be stated before evaluation.

Empirical work must say which features of the representation are observed and which remain latent. A generalized target may be less point-identified than additive PTVC, so set-valued or inequality conclusions may be the most honest outputs.

A vector-valued representation of simultaneous affective components may support a terminal region rather than a single point. That region can be scientifically useful without being mislabeled as proof of exact additive equality.

The principal rival is unrestricted flexibility. If every failed scalar model is rescued by choosing a new terminal functional after inspection, GTN becomes a language of accommodation rather than a hypothesis.

Treating GTN separately gives richer structures their own definitions, predictions, and empirical bridges. The program can

compare their contributions with additive PTV C while preserving the meaning of each target.

5.5.2 — Representation Families and Invariance

A generalized target is intelligible only relative to a family of admissible representations and transformations. The science must identify which changes are coordinate recodings, which preserve the experiment's information, and which change the claim (Krantz et al., 1971; Blackwell, 1953).

An admissible invariance group must be stated explicitly. Positive rescaling, component permutation, monotone transformation, and measure-preserving reparameterization preserve different structures and cannot be treated as one operation.

Measurement invariance should be examined across instruments, cultures, developmental stages, care settings, and temporal resolutions. Apparent invariance in fit statistics is not enough if the substantive zero set changes.

Two laboratories may use different component bases for the same latent vector. A bridge is possible only if the terminal functional transforms consistently across those bases and does not depend on one laboratory's arbitrary coding.

Overly broad invariance can empty the target by making all states equivalent; overly narrow invariance can turn harmless unit changes into different hypotheses. Both errors must be tested through counterexamples.

The payoff is a clear distinction between robustness and vagueness. Robustness survives declared transformations; vagueness avoids saying which transformations matter.

The proposed transformation class should also be closed under composition and inversion where those operations are claimed to preserve meaning. Without that algebraic coherence, two individually permitted recodings can combine into a recoding that changes the target.

5.5.3 — Bridge Theorems to Additive PTVC

A bridge theorem states sufficient and, where possible, necessary conditions under which a generalized terminal functional is equivalent to the additive signed-measure target. It is a theorem burden, not a rhetorical resemblance (Popper, 1959; Mayo, 2018).

A valid bridge must map bearer, complete domain, positive and negative structure, origin, scale, and endpoint across representations. It must show that zero under one branch entails the appropriate zero or equality under the other without hidden outcome selection.

The empirical program must also test whether the theorem's premises are plausible in the declared reference class. A mathematically correct implication can be scientifically irrelevant when its assumptions are unmeasured or systematically violated.

For example, a norm of a vector terminal residual equals zero only when every component is zero. That fact can bridge to componentwise neutrality, but it does not by itself imply equality of integrated positive and negative Jordan masses unless the representation connects them.

A bridge theorem should state which assumptions do the work and, where possible, illustrate their necessity with separating counterexamples outside those assumptions. Such examples may show a generalized functional vanishing while the additive residual remains nonzero, or an additive zero failing the generalized target. Within the theorem's full premises, the proved implication or equivalence must hold.

Bridge theorems allow the program to expand without blurring identities. Until a bridge is established, results remain branch-specific and cannot be pooled into one evidential vote.

Premise testing should be operational rather than ceremonial. If the theorem requires a common origin, additive exposure, exhaustive routing, or endpoint regularity, each premise receives an observable diagnostic, a measurement-error model, and a failure threshold. When a premise is unidentified, the bridge is unlicensed even if both endpoint quantities happen to be near zero (Borsboom, 2005; Mayo, 2018).

Bridge theorems specify the conditions connecting additive, bipolar, and generalized results. Their assumptions identify which theoretical and empirical findings can be used together.

5.5.4 — Counterexamples and Non-Tautology

A generalized terminal target is especially vulnerable to tautology because its functional can be designed around terminal data. Non-tautology requires the carrier, neutral set, representation family, and endpoint rule to be fixed independently, with admissible data capable of producing failure (Mayo, 2018).

The formal test is counterfactual: could an admissible dataset have failed the target under the same prespecified functional? If the answer is no, the construction has no discriminating content.

Simulation should include adversarial generators that place terminal states just inside and just outside the declared neutral set. The analysis must recover those differences under realistic observation error and missingness.

A learned embedding that defines neutrality as the center of its own terminal training sample will almost inevitably report centrality. That result may describe the embedding but cannot adjudicate a pre-existing terminal law.

Flexible representation learning, regularization, and latent-space rotation can all hide post hoc rescue. The strongest safeguard is to freeze the training objective, evaluation set, and failure thresholds before terminal outcomes are inspected.

A generalized theory becomes stronger, not weaker, when it can name the constructions it refuses. The neutral set must be a risky target rather than the place where the method is guaranteed to arrive.

A useful red-team benchmark gives the pipeline data generated from a world with no terminal constraint and asks whether model selection still manufactures one. A method that frequently discovers neutrality in those counterfactual worlds has failed before it reaches human data.

5.5.5 — Empirical Consequences and Status Discipline

Generalized Terminal Neutrality is a separate hypothesis family, not a semantic shelter for additive PTV. Its terminal functional, representation class, invariances, and endpoint domain must be declared before data are inspected. A generalized target becomes scientifically useful only when it generates consequences that can fail under the same source and change-control discipline.

Bridge theorems determine when a generalized result bears on the additive branch. The theorem must name the representation family, origin, sign structure, scalarization, domain, endpoint, and regularity conditions that make the two targets equivalent or one imply the other. Without that bridge, similarity of terminal language is not equivalence.

Empirical consequences should be derived at the level of observables and identified sets. A generalized terminal condition may imply invariance across admissible representations, a bounded compatibility region, componentwise restrictions, or transported order relations. Each implication must state the observation and measured-to-latent bridges it requires.

The strongest protection is to preregister the representation family. Adding a new functional only after the additive residual fails would make the target indefinitely elastic. A successor may still merit study, but it requires a new identifier, reference class, and held-out tests not used to invent it.

Counterexamples are valuable for exposing bridge failures. Two representations may agree on ordinary episodes and diverge under mixed valence, extreme duration, singular contributions, or

endpoint-inclusive events. Those cases should remain a test suite unless their removal from the reference class is explained.

Partial identification is often proper. If several admissible representations yield different terminal values, the output is a set of compatible values or verdicts. Exact neutrality is licensed only when every admissible member satisfies the declared target or when additional evidence narrows the set by a justified bridge. Set width is itself informative, because it reveals whether ambiguity is a narrow numerical tolerance or a disagreement among qualitatively different representations.

Status language identifies the outcome precisely: generalized-compatible, additive-compatible, bridge-supported, bridge-failed, representation-ambiguous, or No adequate estimate. Each label describes the scientific analysis and the next work it supports. A status transition should name the bridge that changed so neighboring branches do not gain or lose standing by association.

Simulation and theorem work make the formal program testable. Simulations assess whether the pipeline recovers the correct branch and distinguishes competing bridges. Derivations establish consistency and consequences; empirical studies evaluate those consequences through their specified measurement, endpoint, observation, and model-comparison procedures. Recovery benchmarks should include data generated from neighboring branches, so a generalized method is tested for false attribution as well as successful detection.

Version control links generalized successors to the objects they replace or extend. Each change record should state which earlier

results remain comparable, which require reanalysis, and which become historical. This prevents a generalized branch from inheriting evidence earned under a different terminal functional. A successor functional that changes the zero set or invariance class should be treated as a new target even if its notation resembles the earlier one.

The durable contribution is a disciplined ladder of claims. If the additive branch fails, the program may still learn that a vector, ordered, bipolar, or generalized object better represents the data. That is progress only when the new object is more constrained and more testable, not merely more accommodating (Lakatos, 1978; Mayo, 2018). Greater generality earns value only when it creates additional exclusions or stable bridges that empirical work can actually challenge.

5.6 — Reference Classes, Modal Scope, and Past-Fixity

A formal equation does not determine how widely it is claimed to hold. Reference class and modal scope are separate scientific objects. A theory may concern one species, one class of maximal qualifying conscious streams, one endpoint type, one observation regime, or a far broader domain, and those possibilities cannot be collapsed into the word universal (Billingsley, 1999; Kallenberg, 2002).

The same separation applies to probability. Probability-one closure under a declared branch law, support containment under a declared topology, high finite-cohort frequency, closure under every policy, and closure under every intervention are different propositions. Evidence for one does not automatically raise the status of the others.

The displays below keep three modal statements apart. The first is the probability-one target under branch law Q^b . The second shows that probability one does not by itself guarantee support containment unless the topology and closedness conditions are supplied. The third reminds the reader that support containment still does not entail all-policy or all-intervention closure.

$$Q^b(FPTVC^b) = 1 \not\Rightarrow \text{supp}(Q^b) \subseteq FPTVC^b$$

$$\text{supp}(Q^b) \subseteq FPTVC^b \not\Rightarrow \forall \pi, a: Z_i^*(\pi, a) = 0$$

These are schematic non-implications, not claims that no stronger theorem is possible. In regular topological settings, probability-one membership in a closed target set may imply support containment. All-policy and all-intervention assertions still

require their own counterfactual domains and assumptions; vocabulary cannot supply them.

Table 5.3. Modal claim forms and non-implications.

Claim form	What it asserts	What it does not establish
Reference-class closure	Target within a declared class	Transport beyond that class
Probability-one closure	Almost-sure under a declared law	Every possible path or intervention
Support containment	All supported residuals satisfy the target	Correct observation or representation
All-policy or all-intervention closure	Counterfactual invariance under specified actions	Ethical permission or universal mechanism

5.6.1 — Reference Classes Before Universality

Every empirical and formal statement needs a declared reference class specifying bearers, stream criteria, endpoint types, settings, and exclusions. A universal statement is defeated by one eligible counterexample, whereas a class-restricted result speaks only to its declared inclusion and exclusion rules (Billingsley, 1999; Kallenberg, 2002).

A reference class can be defined by species, developmental status, clinical condition, stream architecture, endpoint hazard, or measurement feasibility. The defining variables must not be chosen after observing favorable terminal behavior.

Transport beyond the original class requires new evidence about representation, origin, routing, endpoint, observation, and

mechanism stability. Similarity in one observable feature is not enough.

A result in slowly progressive terminal illness cannot simply be extended to sudden death, anesthesia, infancy, nonhuman animals, or artificial systems. The causal and observational structures differ at precisely the points the hypothesis depends on.

A narrow reference class can produce real knowledge, but it can also hide selection. Reports must identify exclusions, their scientific rationale, and whether they remove the trajectories most capable of testing the claim.

Reference-class discipline converts universality from rhetoric into a sequence of transport problems. A narrowed result may be scientifically important even when the grandest claim remains open.

External validity is a separate question. A failure outside the declared class does not refute the class-specific result, but it blocks universal language and identifies the next transport problem. The record should state which representation, origin, endpoint, and observation assumptions would have to survive before extension.

5.6.2 — Probability-One, Support, and Almost-Sure Claims

Probability-one closure is relative to a declared probability law and may tolerate exceptional trajectories; support containment additionally depends on topology, closedness, and regularity; set-universal closure quantifies over every eligible history in the declared class. These propositions are distinct, and none may be inferred from finite-cohort frequency or a confidence interval

around an average (Pearl, 2009; Hernán & Robins, 2020; Frangakis & Rubin, 2002).

Inference must identify the probability law, sampling scheme, dependence structure, censoring, and observation process. A confidence interval around a cohort mean cannot establish an almost-sure latent law.

A continuous model may assign probability zero to each exact path while its support contains many paths incompatible with closure. Saying that each path is individually improbable does not rescue the target.

Rivals can agree on high-probability terminal concentration while disagreeing on support, mechanism, and counterfactual behavior. Proper scoring and held-out prediction should be used to separate them.

Naming the modal claim protects the reader from false certainty. The science can report probability-one under a model, finite-band compatibility in data, or support failure without treating those phrases as interchangeable.

Reports should identify the exceptional set allowed by an almost-sure claim and the topology used to define support. Concealing either choice makes a probabilistic statement sound stronger than the model actually warrants.

5.6.3 — All-Policy and All-Intervention Distinctions

A claim that closure holds under the realized policy differs from a claim that it holds under every possible policy. An all-intervention statement can be stronger when its declared

intervention family includes the policy family and additional interventions that may alter stream unity, routing, endpoint, or representation (Lakatos, 1978; Mayo, 2018).

Counterfactual scope requires a structural model that defines how actions change trajectories and whether the same bearer and endpoint remain meaningful. Without that model, universal intervention language is undefined.

Experiments can test selected interventions, but they cannot license every-policy closure by induction. Each intervention also carries ethical constraints independent of scientific value.

Analgesia, sedation, psychotherapy, stimulation, or environmental change may alter experience, observation, memory, and endpoint hazard simultaneously. A favorable terminal estimate under one treatment does not show policy invariance.

Control-theoretic and time-symmetric routes may imply invariance across policies or interventions that ordinary adaptation models do not. Those stronger quantifiers require direct prospective contrasts. Evidence under one policy cannot be promoted to all-policy or all-intervention scope.

These stronger quantifiers do not create permission to manipulate suffering. The design must state policy and intervention scope prospectively, while care, consent, and legal permissibility remain independent gates that no terminal result can override.

5.6.4 — Compositional Scope and Stream Boundaries

Compositional closure asks whether closure properties of parts imply closure of a whole or vice versa. For conscious streams, composition is inseparable from the rules for split, fusion, pause, branching, and ownership (Billingsley, 1999; Kallenberg, 2002).

A parent stream ending at a split and child streams beginning thereafter is not mathematically equivalent to one ledger continuing through all descendants. The chosen routing rule changes the domain of every terminal statement.

Data systems must preserve those boundaries instead of merging records because one body, account, family, or device persists. Biological continuity and informational continuity do not settle phenomenal ownership.

A hypothetical fusion case shows the difficulty. Two pre-fusion streams may each have histories, while a post-fusion stream may inherit memories from both. Cross-history information does not automatically create cross-stream ledger transfer.

Integrated-information, global-workspace, recurrent-processing, and higher-order theories may propose different unity criteria. PTVC cannot use terminal fit to choose among them without an independent mind-source bridge.

Composition remains an open scientific frontier rather than a loophole. Explicit routing protects nontransferability and makes hard cases available for genuine defeat.

Routing uncertainty can be represented as a family of admissible partitions rather than settled by one preferred consciousness

theory. Closure that survives every admissible routing is stronger than closure under one convenient partition, while disagreement across admissible partitions can leave the result Model-ambiguous.

5.6.5 — Past-Fixity Across Updating and Narrowing

Past-fixity applies to classes as well as histories. Once cohort, branch, endpoint, and representation are prospectively specified, unfavorable cases cannot be removed and reported as though they were never targeted. Updating may change the claim, but never the test already run (Lakatos, 1978; Mayo, 2018).

Each reference class is versioned as an inclusion graph recording bearer, routing, domain, endpoint, representation, observation requirements, exclusions, and failure modes. Parent-child links state what changed and why.

The record specifies modality: probability one under a law, support containment, all-policy, all-intervention, compositional, or set-universal closure. Each proposition has its own assumptions and inference criteria.

Narrowing is legitimate only when it exposes a boundary and creates new risk. The successor class preserves the observations and counterexamples that forced the change and names a transport study capable of challenging it. Removing every difficult case creates a moving target.

Transportability is a separate identification question governed by overlap and stability in representation, routing, endpoint support, observation, and route structure. Similar diagnoses, ages, or

species labels do not establish transport when those deeper structures differ (Pearl, 2009; Hernán & Robins, 2020).

A counterexample archive retains adverse cases with their data-quality, endpoint, measurement, and routing status. It prevents later summaries from remembering only the accepted class and shows whether the challenge reached the target, bridge, route, or estimability.

Representation updates receive a migration matrix. Earlier experiences remain fixed, while estimates may change under a new origin, scalarization, or observation model; the matrix separates changed knowledge from a changed object and marks which verdicts still compare.

The public claim always names its current class and modality. Narrowing can be important, but cannot retain the predecessor's universality. Visible scope change preserves learning, failure memory, and the possibility of reversal.

5.7 — Endpoint Domain and Change Control

The formal hypothesis depends on where the stream begins, where its strict-pre-endpoint domain ends, and how changes to those boundaries are governed. Endpoint language is therefore not a poetic ending. It is part of the mathematical object and part of the protocol's vulnerability (Andersen et al., 1993; Aalen et al., 2008).

This section also gathers the chapter's non-equivalent simplifications. A last observation is not automatically the truth endpoint. A first zero crossing is not automatically termination. A centered residual is not automatically neutral. A product with a vanishing factor is not automatically the phenomenological ledger.

The rule is simple: when the science needs a different object, it should change the object openly. Silent semantic migration is not refinement; it is loss of falsifiability.

$$L_i^{\text{phen}}(T_i^* -) = L_i^{\text{phen}}(t_0 -) + v_i([t_0, T_i^*))$$

The decomposition keeps delayed observation and truth-domain closure separate. The estimated or protocol endpoint may help study the truth endpoint, but it does not become that endpoint through notation.

5.7.1 — Strict-Pre-Endpoint and Endpoint-Inclusive Domains

The primary branch uses the complete strict-pre-endpoint domain and excludes any value assigned at the endpoint itself unless a distinct endpoint-inclusive branch is declared. The two domains

can produce different terminal residuals, so any endpoint atom must be assigned prospectively rather than moved across the boundary after inspection (Andersen et al., 1993; Aalen et al., 2008).

The choice matters when the process may jump, terminate with a final experiential atom, or continue through a boundary that the protocol treats as terminal. Left limits and endpoint atoms are not interchangeable.

Protocols must specify how the last interval is handled, whether terminal uncertainty creates censoring, and whether observations after the protocol endpoint can reveal continued experience.

A final burst of pain, relief, dreamlike experience, or awareness near physiological death could alter an endpoint-inclusive quantity while leaving a strict-pre-endpoint approximation incomplete.

Domain discipline makes terminal evidence honest. The study must say which boundary it observes and which boundary the formal claim requires.

Observation shutdown can manufacture a clean-looking left limit. Devices may be removed, speech may end, sedation may deepen, or sampling may stop precisely when endpoint classification becomes hardest. If the terminal contribution cannot be bounded across that gap, the correct verdict for the strict-pre-endpoint target is No adequate estimate; a narrower observation-window or endpoint-inclusive result remains available only if it is separately defined and supported.

5.7.2 — Truth Endpoint, Protocol Endpoint, and Estimated Endpoint

The truth endpoint is the end of the qualifying stream under the declared bearer and unity rule. The protocol endpoint is the event at which a study stops or classifies. The estimated endpoint is a statistical object inferred from available data (Billingsley, 1999; Kallenberg, 2002; Greer et al., 2020).

The Law formulation used in this series also includes a biological-death admissibility condition. Scientifically, treat it as a separate boundary restriction in the Law formulation rather than by redefining biological death as the truth endpoint. Biological death may not occur before the declared closure condition has been satisfied for the relevant stream. The condition does not require biological death to occur when closure is reached. A qualifying conscious stream may permanently end after satisfying closure while biological processes continue without consciousness, including under artificial life support; such continued nonconscious biological persistence does not extend the completed stream. If the truth-level endpoint coincides with biological death, or if an endpoint-inclusive contribution is declared, any death-associated phenomenal contribution must be assigned prospectively to the appropriate branch. This biological-death admissibility condition is logically additional to the primary terminal-equality statement and therefore requires its own scope, bridge assumptions, and empirical tests.

These endpoint objects require distinct notation and adjudication rules. Conflating them can make a protocol-defined stopping time appear to certify a truth-level boundary.

Endpoint models should use channels not algebraically identical to the ledger estimator. Otherwise closure can become true by defining the endpoint as the time at which the estimated residual reaches zero.

A clinical protocol may stop at loss of responsiveness, while later evidence suggests residual awareness or a new stream state. The protocol was not fraudulent, but its endpoint was not the truth endpoint the formal claim needs.

Rivals include endpoint-conditioned selection, censoring, first-hitting termination, continued stream hypotheses, and misclassified unity. Each can produce different terminal patterns from the same observed window.

Typed endpoint separation lets the science learn without retrospective rescue. A revised endpoint changes the analysis and its status; it does not disappear into the same symbol.

Endpoint adjudication should report a confusion matrix or posterior over endpoint classes when evidence is imperfect. Propagating that uncertainty into the terminal residual is more honest than assigning one boundary and treating its classification as known.

5.7.3 — Initial Conditions and Delayed Observation

A complete-stream law begins at stream onset, while almost every empirical study enters later. The observed window therefore contains an increment plus an unknown pre-entry state (Popper, 1959; Lakatos, 1978).

Setting the running estimate to zero at enrollment is a bookkeeping convenience, not a claim that the latent cumulative history reset. Whole-stream closure cannot be inferred from the window alone without bounds or a bridge for the missing prefix.

Designs should collect historical proxies, repeated informant reports, medical records, and prior self-reports where appropriate, while preserving uncertainty about what those sources cannot recover.

A two-week terminal cohort can provide precise information about its observed interval. Analysis of the preceding history separately records the information available, the admissible bounds, and the uncertainty they introduce.

Delayed enrollment is usually selective. Diagnosis, communication capacity, care setting, social support, referral pathways, and survival to enrollment jointly shape who becomes observable. Sensitivity analysis should vary both the missing prefix and the entry mechanism, and the reported reference class should follow the prospectively specified selection model or bounds rather than the broad population label.

Delayed entry limits what can be estimated rather than resetting the stream. A study may identify local transitions, observed-window increments, or route signatures while leaving the unseen prefix unresolved; without a validated prefix bridge, whole-stream terminal closure remains unadjudicated.

5.7.4 — Non-Equivalent Simplifications and Counterexamples

Several attractive simplifications recur because they make terminal neutrality easy to display. Conservative state functions, adapting baselines, derivative transformations, endpoint centering, and vanishing-factor products can all create zero-like outcomes by construction (Andersen et al., 1993; Aalen et al., 2008).

Model recovery can expose these failures by generating data under known nonclosing processes and checking whether the analysis manufactures support for closure. A pipeline that exceeds its predeclared false-positive tolerance on those controls requires redesign or retirement; valid compatibility under limited resolution remains inconclusive.

A Brownian bridge conditioned to end at zero and an unconditioned process with a genuine preterminal controller may look similar near the endpoint. Without prospective endpoint separation, the simplified interpretation is not identified.

The correct use of simplifications is as explicit models, approximations, or rivals. Their elegance may help derive predictions, but it does not entitle them to inherit the Formal Law's status.

Counterexamples keep the program creative without making it immune. Every shortcut remains available for study and unavailable as an invisible rescue.

A simplification is scientifically useful when it carries an error bound, an approximation regime, and a counterexample outside

that regime. Without those limits, a convenient reduced model can silently replace the object it was meant only to approximate.

5.7.5 — Formal Change Control and Withdrawal

Formal change control lets the program improve without presenting every successor as though it had always been the target. Any change to bearer, ownership, domain, endpoint, origin, representation, quantifier, or terminal functional receives a new version state, a reason, and a dependency record (Billingsley, 1999; Kallenberg, 2002).

The change packet should compare old and new objects line by line. It identifies affected theorems, formulas, simulations, estimands, protocols, reference classes, figures, summaries, and public artifacts. Each dependent item is marked unchanged, reinterpreted, requiring reanalysis, or withdrawn.

Retrospective repair must create new risk. A successor that explains one failed cohort but predicts nothing beyond it is degenerating. A progressive change is frozen before new data and earns its status through held-out predictions, tighter exclusions, or a bridge that can fail independently (Lakatos, 1978; Mayo, 2018).

Supersession is not erasure. Retired objects remain in the archive with their tests, failures, code, and reasons for replacement. Stable identifiers are preserved or tombstoned rather than recycled, so later researchers can determine which version an analysis actually evaluated. A tombstone should point to the successor and reason for retirement, preventing dead identifiers from becoming ambiguous references in later code or prose.

Withdrawal can be granular. A theorem may be corrected while a branch remains; a candidate route may retire while the mechanism-neutral target stays open; a reference class may narrow; or a set-universal claim may fail. The record should withdraw the smallest object justified by the evidence and preserve everything that survives. Granular withdrawal also protects unaffected findings from being discarded simply because a more ambitious claim failed. A narrower successor may retain prior evidence only to the extent that the assumptions and inferential bridge supporting that evidence still apply to the narrowed object.

Correction must propagate beyond the technical chapter. A changed endpoint rule or retired equation requires review of protocols, tables, diagrams, summaries, presentations, websites, and derivative excerpts. A correction that remains trapped in the formal text leaves the public artifact scientifically stale. Dependency tagging can make that propagation selective, updating only artifacts whose claims actually relied on the altered endpoint object. The propagation record should also identify artifacts reviewed and found unaffected, so a deliberate nonchange can be distinguished from a dependency that was simply missed.

Human review closes the change only after formal, measurement, source, and artifact consequences agree. The record names reviewers, dissent, unresolved limitations, completed repairs, and triggers for reopening the decision. This makes scientific version control an accountability mechanism rather than clerical decoration (National Academies of Sciences, Engineering, and

Medicine, 2019; Nosek et al., 2018). Dissent should remain attached to the version when it concerns an unresolved assumption that could materially change interpretation. For consequential revisions, a reviewer who did not design the repair should test whether it resolves the named defect without quietly changing an assumption, target, or evidentiary threshold.

The strongest claim is not the one that never changes. It is the one whose changes remain visible enough that reality can keep answering. Formal change control preserves ambition by making revision, narrowing, retirement, and withdrawal honest outcomes rather than hidden forms of rescue. A visible history of revision also lets later evidence distinguish improvement in the model from movement of the target. Evidence gathered under non-equivalent target versions should remain separated unless an explicit bridge shows that the estimand and inferential meaning are preserved across the change.

Chapter 6 — Representation and Measurement Interfaces

The latent object can be investigated through representations, tasks, reports, behaviors, physiology, neural data, historical records, context, and models, each with a distinct relation to what the science ultimately wants to know.

This chapter builds the interface between the formal target and empirical work. It begins by separating the latent phenomenal object from route state, observation, estimand, estimator, decision rule, intervention, and verdict. Those layers can interact, but none may silently inherit another's authority.

Representation comes first because operations depend on structure. A scalar signed rate supports integration only if origin, sign, units, and cross-sign comparison are identified. A bipolar or vector representation can preserve more information while creating different terminal targets.

The neutral origin is the chapter's sharpest identification problem. More precise sensors cannot determine an arbitrary zero. Positive rescaling preserves zero, while translation generally does not. Origin anchors must therefore be independent of the terminal residual they are later used to evaluate.

Sign and scalarity are separate burdens. A state may be positive in one component, negative in another, and incomparable under a single weight vector. The correct output may be an identified set rather than one ledger, and the book must treat that as scientific information rather than failure of ambition.

Observation then enters through a kernel. Reports, behavior, autonomic signals, neural features, clinician judgment, and informant evidence have different access paths and different error

structures. Fusion should preserve conflict long enough to learn from it.

The protocol measurement map extends beyond one estimator. It includes cadence, missingness, gain, calibration, context of use, versioning, abstention, privacy, and the rule that turns an estimate into a scientific verdict. Clear abstention rules make its conclusions more dependable.

Most studies observe a suffix of a stream. Their analysis combines the measured window with an explicitly unknown prefix, using justified bounds or historical information where available.

Bounds and identified sets offer a rigorous response. Historical records may narrow uncertainty; local dynamics may be testable; whole-stream claims may remain unavailable. The science becomes more valuable when it can distinguish these outcomes without forcing a verdict.

Empirical neutrality also requires a hierarchy. Mean equivalence, distributional concentration, individual compatibility, latent exactness, and structural universality are not one claim. Finite observations can support carefully defined compatibility without proving exact zero.

The chapter will repeatedly ask whether an analysis choice made neutrality easier. Centering, baseline subtraction, derivative transforms, outcome-selected channels, endpoint fitting, and selective exclusion can all manufacture closure. Their exclusion rules belong before estimation.

Sections 9.7 and 28.8 govern non-deployment and computational authority. Here the measurement-interface consequence is

narrower: a representation, observation channel, estimator, or model output retains only the scientific role assigned in the typed pipeline and cannot inherit authority from another layer.

A serious reader should finish with a typed pipeline from representation to verdict and a clear location for every uncertainty. The aim is to identify exactly what a measurement must accomplish to bear on PTVc and which achievable steps can strengthen that connection.

Disciplined approximation gives measurement a practical path forward. Measurement becomes more humane and more scientific when it can preserve uncertainty without abandoning the effort to learn.

A simple hypothetical record shows why the interface must be typed. A participant reports intense distress, a wearable records low movement, a neural channel is unavailable, and the final survey is missing because care takes priority. None of those facts is the latent ledger. Together they define an observation problem with channel-specific error, informative missingness, and a decision about what can still be estimated.

Identification comes before precision. Ten thousand measurements cannot identify a neutral origin that every instrument defines by its own sample mean, and a narrow confidence interval cannot repair a scalarization that erased a relevant dimension. The governing questions are which transformations preserve the target, which anchors are independent, and which conclusions survive the full admissible representation set.

The measurement pipeline is also a provenance graph. Every value that enters an estimator has a source instrument, version, timestamp, preprocessing rule, calibration file, missingness status, and access history. That graph is not administrative decoration. It is how a skeptical reviewer can reconstruct whether the apparent terminal pattern came from the participant, the instrument, the preprocessing code, or a later analytic choice.

The chapter remains valuable under every scientific outcome. A failure to identify origin can improve affect measurement; a vector result can reveal structure a scalar score concealed; a no-estimate verdict can identify the measurement work still needed; and a well-governed observation system can protect participants throughout the research. Together these developments contribute a durable science of inference from lived experience.

6.1 — Latent Objects, Routes, and Estimands

Measurement connects a defined target to the observations used to estimate it. Part II begins with a map of the latent phenomenal object, route state, observation process, estimand, estimator, intervention, decision rule, and public verdict. Each connection specifies the work needed to interpret the resulting estimate (Borsboom, 2005; Cronbach & Meehl, 1955).

$L(t)$ denotes the latent cumulative object specified by the formal branch. $\hat{L}(t)$ denotes a data-derived estimate produced under a declared observation and analysis model. A momentary estimator, interval contribution estimate, operational proxy, posterior path, and public verdict are further objects, each with its own units, uncertainty, and claim ceiling.

The measurement chain is constructive, not merely restrictive. It identifies what must be learned at each arrow: construct validity from latent contribution to channel; calibration from channel to momentary estimate; rate and unit validity from momentary estimate to interval contribution; dependence and missingness propagation from interval contributions to a running estimate; and decision discipline from the running estimate to a verdict.

An observable channel may respond to arousal, pain, attention, medication, sleep, temperature, autonomic state, or device artifact. A prospectively specified and empirically evaluated bridge establishes how that channel informs the declared construct in its intended context.

Table 6.1. Latent, route, estimand, and estimator layer map.

Object	Status	What it can license	What it must not become
$L(t)$	Latent construct received from the formal statement	Formal target and claim object under assumptions about bearer, rate, gate, and endpoint	Sensor output, clinical score, human worth, public identity, or observed truth
$\hat{L}(t)$	Measured or estimated path under an observation model	Qualified empirical statements about a reference class, instrument version, and window	Direct access to $L(t)$ or a rank of persons
Candidate momentary estimator	Momentary physiological contribution estimator or rate proxy	Local evidence about a declared contribution rate under context of use	Universal feeling meter or portable public score
Candidate interval contribution estimate	Interval contribution convention	Additive measured increments when rate, units, and cadence are justified	Moral credit, debt, or exchangeable human value
Posterior path	Model-conditioned distribution over possible measured paths	Uncertainty-aware component claims and sensitivity analyses	Recovered inner life or final verdict

Calibration then turns channel data into an estimator. Preprocessing, artifact rules, transforms, channel weights, lags, signs, calibration samples, and diagnostics belong to the estimator's identity. Transparent composites and hierarchical

latent-state models can both be legitimate; the relevant question is whether their assumptions, failure modes, and uncertainty are recoverable.

Integration adds a separate burden. A momentary value must be a rate, or a validated proportional rate proxy, before it can support additive interval contributions. An index may classify or forecast without carrying the units needed for a cumulative phenomenal measure. Establishing that unit is a substantive scientific result.

Accumulation is more than arithmetic. Serial dependence, interpolation, missingness, model uncertainty, calibration drift, and version changes shape the running measured estimate. A cumulative path assembled from changing instruments is a stitched object whose seams must remain visible.

The final arrow is inferential. A measured path may support a finite-band result, a local dynamics result, a route comparison, or an abstention decision. Exact latent equality requires the additional representation, endpoint, observation, recovery, and measured-to-latent conditions specified for that branch.

Provenance is part of the object, not clerical metadata. Instrument version, code identity, feature map, transform, calibration population, analysis date, and feature-availability time determine which estimator generated each interval. Similar numerical output from different versions does not make those versions interchangeable.

This architecture also prevents uncertainty from being shifted onto participants. The mapping from person to estimate is many-to-one, context-limited, and model-dependent. Similar data can

arise from different inner histories, and similar inner histories can generate different observations. A research estimate cannot rank a person or replace human judgment.

Strong measurement is a chain of testable propositions. A failed link narrows the licensed claim and points to the next technical problem; a strengthened link opens a more demanding test. The program gains credibility by making both movements visible.

The subsections now define each layer and its interfaces. Later curves, bands, and endpoint summaries should be read through this map: every display concerns a named object under a declared model, never an unmediated view of a life.

6.1.1 — The Typed Layer Map

$L(t)$ is the latent cumulative process named by the formal architecture. It is not a sensor output, not a survey total, not a clinical impression, and not the visible shape of a chart. It is the theoretical cumulative object that the science program tries to approach under explicit assumptions about valence, unity, time, and endpoint (Borsboom, 2005; Cronbach & Meehl, 1955).

$\hat{L}(t)$ is different in kind. It is a data-derived estimate of a ledger-like path, produced by a measurement system and an analysis model. Its value depends on channels, transforms, sign conventions, filters, priors, calibration decisions, missingness assumptions, endpoint rules, and the reference class being studied. The hat marks the estimate's dependence on its measurement and analysis model.

$$L_i^{\text{phen}}(t) = L_i^{\text{phen}}(S_i^\theta -) + \int [S_i^\theta, t] r_i(s) ds$$

A clean measurement statement therefore has a grammar. It says: under instrument version v , transform ψ , cadence c , population P , endpoint rule E , and model family M , the data support an estimated distribution of measured cumulative contributions over the observed window. It does not say that the latent life itself has been read.

The temptation to collapse $L(t)$ and $\hat{L}(t)$ is strongest when the estimate behaves as expected. If a terminal estimate sits near zero, the eye wants to say the Law has appeared. If a measured trajectory narrows, the prose wants to say the life converged. This chapter forbids that shortcut because the same visible pattern can arise from measurement attenuation, selection, smoothing, endpoint conditioning, or an omitted initial state.

The distinction also protects negative evidence. If $\hat{L}(t)$ fails, the program must ask what failed: the latent claim, the observation bridge, the instrument version, the scalarization, the endpoint adjudication, the missingness model, or the rival comparison. Treating the estimate as the latent object would make every failure both too large and too small at once.

The public sentence that survives is narrow and powerful. A measured cumulative estimate may support, narrow, suspend, or defeat a component claim under declared conditions. It may never become the ledger itself by confidence, beauty, repetition, or public need.

6.1.2 — Momentary and Interval Estimators

Candidate momentary and interval estimators are often the first terms readers want to use because they sound like instruments. In

this book they are not consumer devices or public scores. A candidate momentary estimator is the momentary contribution estimator: an attempt to estimate a physiological or physiological-plus-model signal that bears on the latent valence rate. A candidate interval contribution estimate is the interval contribution convention that lets those momentary estimates enter a running measured cumulative estimate (Carroll et al., 2006; Hernán & Robins, 2020; Pearl, 2009).

To construct an interval contribution, express the momentary estimate as a validated rate or proportional rate proxy and integrate it over the specified duration. The conversion defines the units of the accumulated quantity.

$$\Delta \hat{L}_{ij} := \int_{t_j}^{t_{j+1}} \hat{r}_i(s) ds$$

A candidate interval contribution estimate therefore has a narrower role than a general pleasure or pain unit. It is a research contribution over a specified interval, under a specified estimator and transform. It exists only inside a context of use. It is not a portable coin of experience, not a unit of spiritual status, not a clinical entitlement, and not a way to compare the worth of lives.

A useful way to read the stack is moment, interval, path, and verdict. A momentary estimator belongs to the first layer. An interval contribution estimate belongs to the second. $\hat{L}_i(t)$ belongs to the running measured path. Public claim language belongs to the verdict layer. The stack becomes unsafe when any layer speaks with the authority of another.

This stack also disciplines uncertainty. Uncertainty in a candidate momentary estimator is local and channel-specific. Uncertainty in a candidate interval contribution estimate includes duration, interpolation, and covariance across time. Running-ledger uncertainty includes serial dependence, parameter uncertainty, model choice, and version migration. A public verdict inherits all of them.

Later chapters will deepen the measurement stack. The governing relation is already clear: a candidate momentary estimator targets momentary contribution; a candidate interval estimate integrates that contribution over a justified interval; and the measured cumulative estimate aggregates intervals only after units, signs, cadence, missingness, and uncertainty have been declared.

6.1.3 — Operational Proxies and Context

Not every useful signal is a ledger estimate. Unity markers, reserve proxies, sedation status, device tolerance, clinician notes, family reports, movement, sleep stage, medication, and context can all matter profoundly without becoming a candidate momentary estimator or a candidate interval contribution estimate. They are operational proxies that help interpret, bound, challenge, or qualify the measurement bridge (Campbell & Fiske, 1959; Manski, 2003).

The distinction is practical. A unity measure may indicate whether the gate is plausibly open; a reserve proxy, whether a terminal model is in the relevant regime; and a motion artifact, why a physiological channel lost reliability. None alone estimates cumulative felt burden.

Operational proxies prevent false precision. A participant's wearable signal may become cleaner near the endpoint because movement stops and artifact decreases. A naive model might mistake this for affective convergence. A disciplined model treats observation quality as a proxy for channel reliability, not direct evidence about neutrality.

Contextual proxies carry similar discipline. A family visit, a medication change, an infection, a delirium episode, or a sleep disruption can shift observed signals and missingness. These facts may explain a measured pattern, identify confounding, or trigger exclusion from a specific estimand. They do not give the model permission to revise the latent cumulative process after the fact.

A proxy can reduce burden when it prevents overinterpretation, and increase burden when it expands surveillance. Treat proxies as governed research metadata: minimal, purpose-bound, versioned, and incapable of ranking persons.

A neutrality claim requires a clear distinction between proxy and estimator. The first names context; the second estimates contribution. Keeping their roles explicit allows ambient evidence to inform the appropriate part of the PTVC analysis.

6.1.4 — Posterior Paths and Information Sets

A posterior path is a distribution over possible trajectories conditional on data and assumptions, not a recovered autobiography of consciousness. Narrowness need not reflect access to the latent path: it may arise from strong priors, smoothing, shared parameters, endpoint conditioning, or an

overconfident observation model (Borsboom, 2005; Cronbach & Meehl, 1955).

Given model M , instrument version v , data D , and specified priors or estimation rules, a posterior may favor some ledger-like paths. Another observation model may yield a wider distribution, shifted path, or no usable estimate from those data.

The estimated path is shaped by scalarization, unity gating, interval integration, missingness, and endpoint timing. A defensible posterior path carries each of those uncertainties into its reported conclusions.

The filter-smoother firewall starts here. Filtered or forecast paths use information available at estimation; smoothed retrospective paths may use future observations. Smoothing can aid sensitivity analysis and visualization but cannot count as prospective prediction of the terminal approach.

Posterior paths are maps with legends, not windows without glass. The legend must state whether a path is filtered, forecast, cross-fitted, smoothed, endpoint-aligned, retrospectively adjudicated, or simulated. A missing label is a scientific defect.

A posterior-path result identifies the component studied and the measurement and analysis conditions supporting it. This makes the finding usable in subsequent comparisons and replication.

6.1.5 — Versioning and Provenance

Every measured object has a history. Instruments change, firmware changes, sampling rates change, channel availability changes, questionnaires change, code changes, preprocessing

changes, and calibration models change. A measured cumulative estimate that does not carry version and provenance cannot be compared responsibly across time, sites, or studies (Carroll et al., 2006; Hernán & Robins, 2020; Pearl, 2009).

Versioning identifies the measurement and analysis procedure. If one estimator version uses heart-rate variability, sleep architecture, and endocrine timing, while another adds skin conductance and removes a motion-sensitive channel, the intended estimand may remain the same even though the estimator changes. A migration study must establish whether the versions estimate that target comparably; a changed target requires a separately stated estimand.

Provenance must travel from raw data to public summary. It should identify source channels, device identifiers, timestamps, preprocessing, artifact rejection, imputation, transformations, scalarization weights, model version, code hash, analyst role, and release status. Without it, neutrality language cannot be audited.

Versioned objects also matter for participant dignity. A person should not be haunted by a stale estimate after a model changes. Research governance must define when a derived result is retained for reproducibility, when it is superseded, and when downstream model training requires separate permission.

Version comparison needs a declared migration protocol. It may use overlapping calibration samples, synthetic fixtures, bridge studies, or consent-permitted reanalysis of archived raw data, or find versions incomparable for a given verdict.

A measured cumulative estimate becomes scientifically usable when its version is visible enough to be challenged. Hidden version drift is a quiet way to manufacture agreement.

6.1.6 — Intervention and Scientific Verdict

Intervention stays on its own layer because an action may alter the latent process, route state, observation process, endpoint distribution, or several at once. The causal estimand names the manipulated object and its identification assumptions; otherwise reporting, medication, or observation changes can masquerade as ledger change (Pearl, 2009; Hernán & Robins, 2020).

The decision rule is distinct from the estimator. One interval can yield different decisions under different loss functions, equivalence regions, or abstention costs, so the rule must state how false support, false defeat, and forced estimation are treated.

A verdict packet names the target component, branch, class, estimand, estimator, uncertainty set, recovery result, rival comparison, sensitivity analysis, and licensed language. The packet distinguishes route preference, model ambiguity, and estimation availability, giving each result its own interpretation.

Synthetic recovery tests verify that the system does not confuse representation failure with route failure, visibility collapse with neutrality, or rival equality with preferred-route support. A numerically accurate estimator can still yield a wrong verdict.

The result remains a research object, never a personal label. It cannot locate consciousness, summarize a life, rank character, determine eligibility, or certify balance, completion, safety, holiness, or worth (Campbell & Fiske, 1959; Manski, 2003).

Human governance completes the map. Algorithms may estimate, simulate, and reproduce analyses, but named reviewers must own status updates, dissent, correction, and withdrawal, and leave a record another qualified reviewer can reconstruct.

Typed lineage records each variable's layer, transformation, assumptions, and prohibited verdicts. No sensor-to-latent-state, state-to-estimand, or estimate-to-verdict arrow is automatic.

This architecture supports strong science without building a hidden ledger of persons. It permits route tests, principled abstention, and component-wise learning while care, dignity, privacy, and human authority remain independent.

6.2 — Representation and the Neutral Origin

Measurement begins by defining the representation that a signal is intended to inform. For an accumulated signed quantity, the representation specifies its origin, scale, and temporal composition before sensor calibration begins (Luce & Tukey, 1964; Krantz et al., 1971; Borsboom, 2005).

The origin problem is not solved by more participants, denser sampling, or a more accurate device. Those improvements can reduce uncertainty around a coordinate system whose zero is still arbitrary. Identification requires an independent rule that distinguishes neutrality from a convenient reference point.

Representation and origin therefore precede estimation. The aim is not to impose one psychophysical theory, but to specify what any adequate theory must identify, preserve under transformation, and expose to failure.

$$\tilde{v}_i(t) = a_i + b_i v_i(t), b_i > 0, L_i(T) = a_i A_i(T) + b_i L_i(T)$$

Positive rescaling preserves terminal zero when the origin term vanishes. Translation generally does not. The cumulative active exposure $A_i(T)$ makes the origin error grow with the domain over which experience is accumulated.

6.2.1 — Representation Before Measurement

A representation determines which phenomenal distinctions the model treats as scientifically meaningful. It may be scalar, bipolar, vector-valued, ordinal, distributional, or partially ordered, and each choice supports different operations (Krantz et al., 1971; Borsboom, 2005).

Integration is licensed only after sign, interval-comparable units, exposure, and clock are identified. A vector representation additionally requires either a declared scalarization whose weights are identified or a genuinely non-scalar target with explicit adjudication rules.

Instrument design should follow the representation rather than define it accidentally. Questions, anchors, tradeoffs, physiology, behavior, and neural measures are observations whose relationship to the representation must be modeled.

A device that predicts self-reported intensity may be useful while remaining agnostic about whether positive and negative valence share one axis. Predictive success on one channel does not settle the representation.

Competing theories may treat valence as constructed, multidimensional, action-oriented, or inseparable from arousal and meaning. The program must compare those views rather than encode one into the scoring pipeline.

Beginning with representation keeps the book scientifically generous. PTVC may be narrowed or defeated, while the work on phenomenal measurement remains valuable.

Representation choice can be compared through out-of-sample measurement invariance, predictive calibration, and recovery under known generative structures. The winning representation is the one that survives those tests, not the one that yields the most appealing terminal graph.

6.2.2 — Neutral Origin as Identification Problem

The neutral origin is the point separating positive from negative phenomenal contribution under the declared representation. It cannot be assumed to coincide with a verbal midpoint, sample mean, adaptation level, or absence of overt distress (Cacioppo & Berntson, 1994; Russell, 1980; Cronbach & Meehl, 1955).

Because translation changes an accumulated residual, the origin is a structural parameter rather than a cosmetic convention. Exact closure is unidentified when multiple origins fit the same observations and imply different terminal signs.

Candidate origin anchors should be triangulated through indifference, symmetric tradeoffs, within-person reversals, psychophysical thresholds, and invariance tests. None should be accepted solely because it produces terminal balance.

A person may use the word neutral for emotional numbness, calm, boredom, low arousal, or inability to report. Those states need not occupy the same phenomenal origin.

Moving-reference models are not nuisances around a fixed zero; they are competing explanations of apparent neutrality. Adaptation level, expectation, and homeostatic prediction may all shift reports toward a local baseline. An invariant origin is supported only if independent anchors outperform those dynamics.

Treating origin as identification creates a clear failure route. The program can report that valence was measured but exact-zero adjudication was not identified.

Triangulation is informative only when disagreement is preserved. If indifference judgments, psychophysical thresholds, and within-person reversals identify different neutral regions, the protocol should carry that discordance into an identified set or No adequate estimate rather than average the anchors until the terminal residual closes.

Adaptation-level and active-inference models predict moving references, so the prospectively specified contrast must include outcomes that favor those rivals. Neutrality that tracks expectation shifts, physiological set points, or context-specific prediction errors would count against a fixed phenomenal origin even if terminal estimates appear centered.

6.2.3 — Affine Freedom and Positive Rescaling

Many psychometric representations are identified only up to an affine transformation. For PTVC, a stream-constant positive change of units preserves sign and terminal zero, while translation changes the neutral origin and adds an exposure-weighted term to the accumulated ledger. The usual interval-scale freedom must therefore be narrowed by independent origin evidence (Mokkink et al., 2024; Gagnier et al., 2025).

Apply §5.3.4’s affine result here. The empirical task is to identify the origin independently enough that translation freedom cannot manufacture or erase terminal neutrality, then propagate that origin uncertainty into every absolute-level inference.

The zero-preserving transformation criterion fixes the admissible change of units. A fixed positive measurable pointwise multiplier chosen independently of the ledger preserves zero total for every

zero-total finite signed measure for which the weighted total exists exactly when it is constant on the event space. To see why, place equal positive and negative unit masses at any two events. Their original total is zero; the weighted total is zero only when the two multipliers agree. Because the events are arbitrary, the multiplier is constant. Conversely, a constant multiplier factors out of every total and preserves zero. Event-, state-, or time-dependent reweighting therefore defines a new representation whose invariance must be established on its declared branch (Folland, 1999).

That distinction matters for attention weights, subjective-time weights, unity weights, and adaptive rescaling. A strictly positive reweighting preserves pointwise sign but may preserve the final net residual in one dataset while changing atomic or singular masses, gross variation, covariance, or route diagnostics elsewhere. Weights that can vanish may additionally remove contributions from sign regions. Protocols should register its integrability domain and effects before terminal fitting.

Common-factor models constrain factor means or intercepts to identify their statistical coordinates. Terminal analyses should propagate admissible location uncertainty and evaluate the resulting estimates against independently established origin anchors.

Two laboratories can therefore report almost perfectly correlated trajectories and still disagree about the terminal residual because one scale is shifted by a constant. Agreement in rank or covariance cannot repair a displaced origin.

Cross-instrument calibration should estimate whether linking transformations are origin-preserving in the declared population and context. When the admissible transformation family changes the terminal conclusion, the result belongs to an identified set, sensitivity envelope, or No adequate estimate rather than to exact-zero adjudication.

Before terminal fitting, the protocol should freeze the admissible origin family, its complexity, calibration sample, and leverage limits. Blocked cross-fitting can estimate that family without allowing terminal outcomes to select the zero, and the report should show terminal-origin leverage and sensitivity across every admissible anchor. If a saturated or outcome-adaptive origin class can manufacture closure, or if the verdict changes across admissible origins, the correct result is Origin-sensitive or No adequate estimate rather than selection of the favorable parameterization (Manski, 2003).

6.2.4 — Independent Origin Anchors

An origin anchor is independent when it is chosen through information not algebraically equivalent to the terminal residual under evaluation. Independence prevents neutrality from being fitted into existence (Krantz et al., 1971; Borsboom, 2005).

Possible anchors include within-person indifference points, bidirectional tradeoff tasks, opponent-process symmetry, physiological transitions with convergent self-report, or experimentally manipulated reference conditions. Each anchor needs a context of use.

Validation should examine stability across time, language, culture, clinical state, and response mode. A universal anchor should not be inferred from one instrument in one population.

In a repeated-choice task, the point at which a participant is indifferent between a brief positive and negative perturbation may provide one origin constraint. It remains an experimental construct rather than a direct reading of the latent zero.

Demand characteristics, framing, loss aversion, memory, and strategic responding can shift apparent indifference. Multi-method convergence is therefore more informative than any single task. If the anchors still admit several origins, the result is an identified set or No adequate estimate, not a favored neutrality convention.

Independent anchors let the study evaluate the origin before terminal analysis begins.

Any diagram of origin identification should show the independent anchor, the moving-baseline rival, and the abstention route. A zero mark without those dependencies falsely presents a calibration choice as an observed fact.

Independent sign anchors can place a concrete interval around a common origin. Suppose a candidate channel has the local relation $Y = aV + b + e$, with $a > 0$, and independently qualified negative and positive anchors have $V \leq 0$ and $V \geq 0$ respectively. If each anchor error satisfies $|e_k| \leq \delta_k$, every admitted origin b lies in

$$[\max_{i \in \mathcal{N}}(Y_i - \delta_i), \min_{j \in \mathcal{P}}(Y_j + \delta_j)].$$

Here $\mathcal{N}$ and $\mathcal{P}$ denote the negative and positive anchor sets, each nonempty. An empty interval challenges the common-origin, sign or error assumptions; a nonempty interval preserves the remaining origin uncertainty. Anchor signs must be justified as experienced valence, not inferred solely from preference, avoidance or the channel being calibrated. With probabilistic error bounds, coverage must hold jointly across the anchors. Holding out a context or anchor family then tests whether the same origin interval transports without using terminal outcomes to select it.

6.2.5 — Adaptation, Moving Baselines, and Abstention

Reports can adapt to context, expectation, illness, deprivation, repeated exposure, and local norms. A moving comparison level can make severe states sound ordinary without making them phenomenally neutral. The scientific task is to separate change in represented experience, change in adaptation state, and change in reporting rule (Cacioppo & Berntson, 1994; Russell, 1980; Borsboom, 2005).

A dynamic-origin model specifies how its reference point changes and how that changing reference relates to the target origin. Recentring on a recent mean removes variation that an analysis of drift may need to preserve.

Neutral-anchor tasks, indifference choices, bidirectional perturbations, and diverse channels can constrain the origin; disagreements must remain visible. A questionnaire midpoint, population average, or phrase such as normal for me reflects response and adaptation, not an automatic zero of lived valence.

Digital measurement already offers an encouraging, testable starting point. In the thirty-day study by Cloos et al. (2025), 3,761 Norwegian adults registered for ecological momentary assessment and 2,718 completed the post-study survey. That survey showed high tactile precision and generally consistent ratings of affective scenarios. Among its respondents, 82.19% placed neutrality within five points of the unipolar midpoint of 50, and 88.89% within five points of the bipolar midpoint of zero. Some participants instead located neutrality near their own typical affect. These findings support the feasibility of precise reporting and identify a concrete calibration task: distinguish familiar feeling, scale interpretation, and phenomenal neutrality.

Negative controls should distinguish genuine origin movement from response-style change. A valid origin should remain stable under manipulations that alter expression without altering the represented neutral point, and it should move coherently when independent anchors indicate a real change.

Transport offers another test. Freeze an origin model estimated in one context and test it under different language, burden, affective range, and observation conditions. Failure may indicate construct drift, response shift, or a reference-class boundary; it cannot justify silent recalibration until terminal zero returns (International Test Commission, 2018; Mokkink et al., 2024).

Origin uncertainty must propagate into every residual and equivalence test. A narrow terminal band under a fixed baseline may widen sharply when anchor disagreement or dynamic-origin uncertainty is included. Exact zero is demanding precisely because location uncertainty cannot be ignored. Origin sensitivity

should therefore be reported beside the point estimate rather than hidden in a secondary robustness appendix.

Abstention is therefore a positive scientific output. When available anchors cannot distinguish neutrality from adaptation or scale-use change, apply §6.2.4's identified-set/No adequate estimate rule and target the missing origin, invariance, or transport information rather than enlarging the same ambiguous sample.

The abstention rule should be protocol-fixed in the units of the identification problem before outcome inspection. It can depend on anchor disagreement, posterior width, invariance failure, transport loss, or sensitivity to admissible baseline models. Once the threshold is crossed, terminal-neutrality language stops for that context. The trigger should be tested on simulated and negative-control cases so its abstention behavior is known before it encounters the substantive endpoint data.

The archive should preserve competing origin models, accepted anchors, overlap regions, residual sensitivity, and reopening conditions. This record makes moving baselines tractable and prevents a preferred origin from becoming invisible through repeated recalibration (Manski, 2003; Gagnier et al., 2025). Archived origin alternatives also make future reanalysis possible without pretending that the originally chosen baseline was uniquely identified.

6.3 — Sign, Cross-Sign Units, and Scalarity

Sign is not merely a plus or minus printed before a number. It is a claim that experiences on opposite sides of an origin are oriented within a common structure and that their magnitudes may be compared or accumulated under declared units. Such arithmetic requires empirical representation conditions, not just labels (Luce & Tukey, 1964; Krantz et al., 1971; Cacioppo & Berntson, 1994).

Cross-sign comparison is one of the least studied obligations in any exact cumulative theory. Many instruments are good at ordering severity within pain or pleasure while offering little evidence that one unit on one side is commensurate with one unit on the other.

This section separates sign identification, unit construction, scalarity, and non-scalar alternatives. The purpose is to prevent arithmetic from outrunning phenomenology.

$$x_i(t) \in R^d, F_{i,w}(t) = w^T x_i(t)$$

$$I_i(T) := \{ \int w^T x_i(t) dt : w \in W \}$$

When weights are not identified, the scientifically honest object may be the identified set $I_i(T)$ rather than one scalar ledger. Exact zero is then a property of all, some, or none of the admissible scalarizations, and those cases must be distinguished.

6.3.1 — Sign Identification

Sign identification determines which phenomenal changes count as positive, negative, or neutral under the target representation. Verbal labels alone are insufficient because language, appraisal,

and response strategy can reverse or blur them (Krantz et al., 1971; Cacioppo & Berntson, 1994).

A sign rule should be anchored in directional preference, controlled tradeoffs, approach and avoidance under controls, and convergent channels while permitting mixed and uncertain states. The rule constrains sign without pretending direct access or forcing near-origin observations into binary labels.

Measurement models should propagate sign uncertainty rather than force every observation into a binary classification. Near-origin states may require intervals or posterior probabilities over sign.

A state described as painful but meaningful may be negative in one component, positive in another, and ambiguous under a scalar summary. The sign cannot be settled by choosing the adjective the analyst prefers.

Motivational salience, arousal, and action tendency are imperfect proxies. Fear can motivate approach, pleasure can coexist with avoidance, and social display can oppose felt valence.

Sign identification gives the terminal claim a chance to fail for the right reason. Without it, zero can be produced by misclassified contributions rather than genuine balance.

6.3.2 — Cross-Sign Comparability

Cross-sign comparability asks whether positive and negative magnitudes share units that support subtraction. Ordering states on each side separately does not answer that question (Russell, 1980; Borsboom, 2005; Manski, 2003). For a mixed-sign record

with positive total $P > 0$ and negative magnitude $N > 0$, rescaling the two signs by separate positive factors a and b preserves every ordering and the neutral point, yet changes the total to $aP - bN$. Choosing a/b above, below or equal to N/P gives a positive, negative or zero result from the same ordinal observations. Independent cross-sign calibration is therefore what makes a zero total informative.

Commensurability may be investigated through bidirectional tradeoffs, duration exchange, intensity matching, or structural models that predict choices across signs. Each method introduces assumptions about memory, risk, and decision context.

Protocols should report whether comparability is global, local, person-specific, or only partially identified. A single conversion factor is not justified by convenience.

A participant may judge ten minutes of severe pain as outweighing an hour of mild pleasure, while another makes the opposite tradeoff. The difference may reflect true scaling, framing, or unstable decision processes.

Choice asymmetries do not automatically reveal phenomenal cross-sign units. Prospect-theoretic weighting, loss aversion, and decision noise can produce similar behavior. Choice data can inform the bridge only through a model that separates valuation, action, and experienced exposure.

The program gains credibility by allowing comparability to fail. A non-scalar branch may preserve scientifically meaningful structure when subtraction is not earned.

Cross-sign comparability should be tested as a family of local bridge functions, not presumed to be one universal multiplier. A protocol can ask whether the positive-to-negative exchange rate is stable across intensity, duration, context, and person. Heterogeneity that survives calibration belongs in the identified set and limits any scalar terminal claim.

Local exchange maps also need loop consistency. If a sequence of positive-to-negative and negative-to-positive calibrations returns to a different unit when the comparison loop closes, the scalarization is path-dependent rather than globally coherent. A global scalar claim therefore requires identity holonomy, or a prospectively declared tolerance, across the relevant comparison graph; persistent loop discrepancy points to context dependence, an omitted state variable, or the need for local charts and an identified set (Krantz et al., 1971).

6.3.3 — Units, Rates, and Exposure

A momentary value becomes an accumulated contribution only through units and exposure. Rate, duration, sampling cadence, and time parameterization must fit together dimensionally (International Test Commission, 2018; Mokkink et al., 2024).

If F has units of phenomenal magnitude per experienced-time unit, integration produces phenomenal magnitude. Changing the clock requires a corresponding Jacobian so that the represented exposure does not change merely because the timeline was reparameterized.

Instruments should distinguish state level from rate contribution. Repeated samples may approximate an integral, but irregular

spacing and missing intervals require explicit quadrature or state-space estimation.

Two studies can report the same average intensity while observing different durations. Treating the averages as equal accumulated burden would discard the very exposure PTVC concerns.

Retrospective duration neglect and peak-end effects are important rivals because reported totals may not scale with elapsed time. They challenge the observation bridge, not the need to specify units.

Dimensional discipline connects every formula to a clearly defined quantity. Every formula should make clear what accumulates, under which clock, and in which units.

A reproducible dimensional audit should let a reader who never saw the fitting code identify every state, rate, increment, exposure clock, integration step, and unit conversion that turns observations into a cumulative quantity. Repeating the audit after each transformation often exposes a hidden change of estimand before statistical fitting begins.

6.3.4 — Scalarity and Non-Scalar Alternatives

A scalar representation can support a total order; arithmetic accumulation additionally requires justified units and additivity. Experience may resist these requirements because states can differ along dimensions that are not reducible without value-laden weights (Krantz et al., 1971; Cacioppo & Berntson, 1994).

Non-scalar alternatives include vectors, cones, partial orders, signed measures on feature spaces, and distributional

representations. Each supports different terminal constraints and different empirical tests.

Model comparison should ask whether scalarization improves held-out prediction and transport without erasing systematic residual structure. A scalar model that fits only after flexible weights may be less informative than a bounded identified set.

A nominated scalar measurement model can face an explicit test before accumulation. In one fixed context, suppose four channels satisfy $Y_j = \alpha_j + \beta_j V + e_j$, with finite second moments, fixed loadings, conditionally zero-mean errors and errors uncorrelated across channels conditional on V . Their off-diagonal covariances obey $\sigma_{ij} = \beta_i \beta_j \text{Var}(V)$, so four distinct indices must satisfy

$$\sigma_{ij}\sigma_{k\ell} - \sigma_{ik}\sigma_{j\ell} = 0.$$

Freeze the channels and error structure before testing this restriction on held-out records. Correlated method effects, nonlinear loadings or additional dimensions can break it. Failure challenges this particular linear observation model; a scalar phenomenal quantity may still admit a different observation relation. Success earns further sign, origin, cross-sign and additivity tests. Repeated channels are informative only when their error assumptions survive independent checks.

Pain intensity, emotional valence, agency, and meaning may move in different directions. A scalar summary can be useful for one decision while remaining inadequate as a universal phenomenal currency.

One objection is that no science can proceed without simplification. The answer is not to reject scalars, but to label their context of use and test the consequences of alternative simplifications. For scalarity and non-scalar alternatives, prediction and recovery are evaluated together so one branch cannot benefit from asymmetric validation.

The title's scientific mission is served when scalarity becomes a hypothesis with competitors. Exact additive PTVC then stands or falls on a declared representation rather than on arithmetic habit.

Technical and public artifacts should label whether they display a scalar, a vector, a partial order, or an identified set. A single number is not a harmless simplification when the representation question remains open.

When scalarity fails, the analysis need not collapse into silence. It can retain a vector-valued path, a partial order over states, or a set of scalarizations that preserves all admissible weights. Those outputs answer weaker but still exact questions and reveal precisely which additional comparison axiom a scalar ledger would require.

6.3.5 — Cross-Stream Noncomparability and Surviving Claims

PTVC is intrastream. Even when each stream admits a useful signed representation, the theory does not supply a common interpersonal cardinal scale on which one person's magnitude can be subtracted from another's. Positive rescaling within a stream can preserve its zero without fixing a shared unit across streams (Krantz et al., 1971).

This blocks cross-stream balancing and ranking. A larger estimated residual, component magnitude, or gross variation in one stream does not show greater moral worth, blame, need, holiness, civic fitness, or entitlement than a value from another stream. The measurement architecture does not by itself establish an interpersonal scale that the formal target does not supply; even a separately justified common scale would not permit cross-stream cancellation.

Population science remains possible. Researchers can estimate the prevalence of branch compatibility, distributions of within-stream parameters, instrument performance, endpoint classes, or route-specific effects. Those summaries concern patterns across streams, not a pooled phenomenal ledger.

Hierarchical models can borrow statistical strength while preserving semantic separation. Partial pooling may improve estimation of within-stream objects, but shrinkage toward a population distribution does not make the latent units interpersonally commensurable. The model should report which parameters are shared and which remain stream-specific.

Group-level averages require an explicit measured-scale interpretation. They may summarize reports, behaviors, physiological variables, or decision outcomes under a validated common instrument. They do not become averages of total lived value unless an additional interpersonal representation theorem is supplied, and no such theorem is assumed here.

Transport across streams is a separate problem. Similar observation patterns can arise from different origins, response

functions, routing, or exposure clocks. A transported estimator must state the invariances and overlap conditions it uses rather than treating demographic or diagnostic similarity as sufficient.

Several strong claims survive noncomparability. Within-stream sign, temporal order, exact or approximate residual compatibility, component structure, local dynamics, endpoint support, and route restrictions can remain scientifically meaningful. The absence of an interpersonal scale narrows what can be compared; it does not erase every within-stream question.

Governance must reflect this limit. No dashboard, ranking, eligibility rule, resource-allocation score, or social dossier may be built from estimated ledgers. Care and rights are governed by ordinary ethical, clinical, legal, and public reasons, not by a cross-stream comparison the science cannot identify.

The result is a disciplined population science of nontransferable objects. It can compare methods, frequencies, mechanisms, and uncertainty without pretending to compare the value of lives. That boundary is both mathematically honest and essential to the humane use of the research (Manski, 2003; Nissenbaum, 2010).

6.4 — Mixed Valence and Identified Sets

The primary additive branch uses the signed valence-rate representation specified in Sections 4.2 and 5.2. That gives the Law its mathematical force. It also creates a measurement burden: the science book must test whether a scalar, signed, additive path is adequate for the domains in which it speaks. A single path is not a premise that measurement may inherit without scrutiny (Cacioppo & Berntson, 1994; Russell, 1980).

Human experience is often mixed, layered, and temporally structured. Pain can coexist with meaning. Grief can contain love. Fear can carry agency or helplessness. Numbness can be relief, dissociation, medication effect, exhaustion, or shutdown. A measurement system that compresses all of this too early may create a ledger that is smooth because it has discarded the dimensions that mattered.

The program can use scalar paths where their predictive performance, discrimination, and sensitivity checks support that representation. Vector, ordinal, partially ordered, kernel-weighted, and nonadditive alternatives provide comparison models when additional structure is useful.

The scientific question is whether a neat scalar has shifted uncertainty into dimensions it cannot express. Scalarization is admissible only when the weighting rule is identified well enough for the intended conclusion and when sensitivity across the admissible weight family remains visible.

Table 6.2. Representation options, strengthening evidence, and narrowing triggers.

Representation	Scientific question	What would strengthen it	What would force narrowing
Single signed scalar	Can one additive path represent contribution?	Stable held-out prediction, sign validity, residual adequacy	Vector or ordinal rivals dominate
Vector state $z(t)$	Do multiple dimensions carry irreducible information?	Distinct dimensions predict auxiliary evidence and dynamics	Projection loses key burden patterns
Weight family W	Do conclusions survive plausible scalarizations?	Same qualitative result across W	Sign or verdict changes across W
Temporal kernel K	Does simple duration-weighting hold?	Additive path beats recency and memory rivals	Kernel models explain outcomes better

A scalarization sensitivity module should be treated as a standard output, not a special appendix. The study declares a family W of admissible weights and computes the full range of measured cumulative estimates over W , or a certified outer bound on that range. A representative grid alone yields a sampled sensitivity analysis, not the full identified set, unless a justified interpolation or extremum bound covers the unsampled weights.

Consider a terminal-window dataset with three dimensions: bodily distress, fearful arousal, and peaceful social safety. One weight vector may produce a near-zero measured terminal value

because distress and safety cancel. Another may produce a negative value because bodily distress is weighted more heavily. A third may produce an indeterminate result because peaceful safety and fear cannot be ordered on one axis. The scalar conclusion is then representation-sensitive.

Temporal alternatives create a parallel sensitivity. Simple duration weighting may produce one path. A recency kernel may privilege the last day. A memory-consolidation kernel may make sleep intervals matter disproportionately. A peak-end model may predict reports better than an additive path. The measured object changes with the temporal rule.

These examples show how evidence can distinguish among competing representations. Predictive accuracy, calibration, and held-out performance guide the choice of model under its stated assumptions.

Representation can be qualified separately in different settings. A palliative terminal cohort might require a vector measured object while ambulatory longitudinal cohorts permit a stable scalar proxy. Reporting those reference classes identifies which representation is supported in each setting.

The same framework guards against overengineering. A vector model with many dimensions can overfit. A kernel family can be too flexible. A rival can be designed to explain every outcome. The answer is a prospectively specified model space, held-out prediction, and model recovery, not simpler prose.

The fair burden here is the burden of representation. If the book asks lived experience to become a number, the book must show

what the number sacrificed and what evidence justifies the sacrifice.

The scalar ledger becomes credible only after it has survived the possibility that experience required more than one axis.

Table 6.3. Scalarization-sensitivity scenarios and verdict consequences.

Scenario	Scalar weight family result	Temporal rule result	Verdict consequence
Stable scalar	All plausible weights preserve sign and near-band conclusion	Additive model predicts held-out data best	Measured scalar path may proceed for this context
Weight-sensitive	Some weights support near-neutrality and others do not	Temporal rule unchanged	Report identified set; no single neutrality sentence
Kernel-sensitive	Weights stable, but recency model beats additive path	Recency or peak-end rival dominates reports	Narrow additive claim or separate remembered-experience target
Vector-required	No scalar projection preserves residual adequacy	Multiple dimensions needed	Suspend scalar candidate interval contribution estimate for that reference class

Scalarization is where the Law's elegance meets the complexity of experience. A single signed axis is powerful because it lets accumulation, neutrality bands, and dynamic signatures be stated clearly. It is dangerous because real experience may contain dimensions that resist collapse: pain with dignity, fear with

meaning, grief with love, numbness with relief, exhaustion with gratitude, or attachment with dread.

A projection from a vector representation can be evaluated through stability across held-out contexts, preservation of relevant temporal dynamics, prediction of auxiliary observations, and residual structure. When admissible projections lead to different signs or decisions, report the corresponding set of results.

Identified sets over weight families are the disciplined middle. The study declares a plausible set of weights before outcome analysis and reports the range of cumulative results across that set. If the entire set supports the same local conclusion, the conclusion gains robustness. If the set crosses neutrality, support, defeat, and abstention, the result is representation-sensitive rather than quietly positive.

Temporal kernels introduce a parallel issue. The received ledger treats duration additively, but remembered experience, decision value, trauma consolidation, habituation, anticipatory dread, and relief can follow different temporal rules. A rival may weight peaks, endings, recency, duration, repetition, or state transitions differently. The program must show when simple accumulation is empirically adequate and when a kernel-weighted path is the better object.

Testing representation can reveal the structure the object requires. If experience is ordinal, multidimensional, thresholded, hysteretic, or path-functional in ways that prevent a single

additive representation, the analysis should adopt the appropriate representation and identify the revised branch being tested.

6.4.1 — Vector and Multidimensional States

A vector experience state represents the possibility that lived experience contains multiple dimensions relevant to burden and relief. Instead of assuming one latent rate $F(t)$, the model may begin with $z(t)$, a vector of affective, interoceptive, motivational, and contextual dimensions that might or might not collapse responsibly onto one signed axis (Cacioppo & Berntson, 1994; Russell, 1980).

The vector is not a rejection of the Law. It is a representation test. If a scalar projection of $z(t)$ can reproduce held-out dynamics, preserve sign, predict auxiliary witnesses, and remain stable across contexts, the scalar path gains credibility. If no projection can do this without hiding systematic residuals, the scalar ledger narrows.

Dimensions must be chosen carefully. They should not be a grab bag of every measurable feature. Candidate dimensions may include valence, arousal, bodily distress, agency, social safety, cognitive load, temporal orientation, or meaning-related affect, but only where each has a measurement route and a reason to bear on the latent target.

Vector states also make mixed affect visible. A participant may have high physical pain and high peace, low arousal and high dread, or numbness and relief at once. A single score can hide these patterns unless the scalarization rule explains how they combine.

The vector approach protects against false neutrality. Opposing dimensions can cancel numerically while remaining phenomenologically distinct. A zero scalar projection may mean balanced contributions, inadequate representation, or loss of information. The model must distinguish those possibilities.

Vector experience states are the measurement chapter's way of saying: one axis must be earned, not assumed.

A multidimensional representation also changes what counts as empirical agreement. Two models may predict the same signed projection while disagreeing sharply about the geometry of the underlying state, the covariance among dimensions, and the transformations that preserve meaning. Accordingly, validation cannot stop at aggregate fit. It should test whether the proposed dimensions are recoverable across tasks, whether their relations survive held-out contexts, and whether rival dimensional systems explain the same observations with fewer unsupported commitments. A vector model earns scientific value by preserving distinctions that improve prediction or adjudication, not by multiplying coordinates. When additional dimensions do not change any observable consequence or decision rule, they remain descriptive possibilities rather than identified structure.

6.4.2 — Scalarization Weight Families

Scalarization weights define how a vector state becomes a signed rate. A weight vector w maps $z(t)$ into $w^T z(t)$. That operation is not just arithmetic. It is a claim about which dimensions count, in what direction, with what relative force, and under which

population and context (Krantz et al., 1971; Manski, 2003; Imbens & Manski, 2004).

Weights can come from theory, within-person calibration, expert prior, measurement model, predictive performance, or declared sensitivity analysis. They cannot be chosen because they make terminal results look favorable. Outcome-selected weights manufacture evidence by changing the object after seeing the answer.

$$F_w(t) = w^T z(t)$$

$$L(T; W) := \{ \int_0^T g_\theta(t) w^T z(t) dt : w \in W \}$$

A transparent scalarization report should state the candidate dimensions, raw units, transformations, signs, weights, constraints on admissible weights, and why the family W was chosen before terminal analysis. It should also report which conclusions survive across W and which depend on a narrow region of the weight space.

Within-person weights may differ from between-person weights. A channel that predicts distress within one stream may not compare across streams without invariance, and a population-average scalarization can erase individual structure. Scalarization is therefore context-bound and reference-class-bound.

Weights should be testable. Held-out prediction, residual structure, response shift, auxiliary witness conflict, and rival model comparison all place pressure on the chosen projection. A scientifically useful scalarization states in advance which observations would support it, require revision, or rule it out.

The safest scalar path is the one whose weights were declared before it knew where the path would end.

Weight families should therefore be treated as scientific objects rather than silent tuning parameters. A defensible program states how weights are learned, which transformations leave conclusions invariant, how uncertainty in weights propagates to the terminal claim, and which populations or contexts fall outside the calibration domain. Hierarchical or partially pooled weights may improve transport, but they also introduce assumptions about exchangeability and group structure that must be tested. The strongest analysis reports not only a preferred weighting rule, but the region of weight space over which the substantive conclusion survives. If a narrow, outcome-selected corner alone produces compatibility, the correct result is fragility, not confirmation.

6.4.3 — Identified Sets and Partial Orders

When weights are uncertain, the study can report every ledger conclusion generated across a declared weight family, together with the evidence and assumptions that define that family. Use the term identified set when these are values of one fixed target compatible with the available evidence and declared model. When changing the weights changes the target itself, report a scalarization-sensitivity set and distinguish that sensitivity from uncertainty about a fixed target (Manski, 2003; Imbens & Manski, 2004; Mokkink et al., 2024).

Suppose plausible weights produce terminal measured values ranging from strongly negative to near neutral. A single chosen weight might tell a compelling story, but the identified set tells

the scientific truth: the result depends on scalarization. The public claim must narrow until the representation problem is solved.

Identified sets can also strengthen a result. If every admissible weight family produces the same qualitative local signature, such as variance compression or rival defeat within the observed window, the component result becomes less representation-sensitive.

The set must be declared before outcome inspection. A weight family expanded only to include favorable weights, or narrowed only to remove inconvenient weights, is another form of neutrality by fiat. The family W is part of the prospectively specified bridge.

Identified sets show which values remain compatible with the evidence and declared assumptions. Reporting that range gives readers a clear account of what is established and which further observations could sharpen the result.

6.4.4 — Sensitivity to Weight and Kernel Choice

The received ledger integrates contributions over time without an additional memory kernel. Measurement must still test whether relevant empirical targets behave that way. A recency kernel, memory-consolidation kernel, or state-dependent temporal weighting can produce different path functionals from the same momentary estimates (Cacioppo & Berntson, 1994; Russell, 1980).

This matters because lived experience and remembered experience are not identical. A participant's later report, clinical expression, or decision behavior may depend more on recent,

peak, unresolved, or narratively organized states than on simple duration-weighted accumulation. If the study's observed outcome is a report or behavior, the temporal rule matters.

$$L_{w,K}(T) = \int_0^T K(T,s) g_{\theta}(s) w^T z(s) ds$$

A kernel-weighted model can explain how a reporting channel depends on temporal history. Comparison with the proposed accumulation model identifies which observable summaries the channel supports and which additional measurement relation is needed.

Temporal kernels must be specified before analysis. $K(T,s)$ may depend on recency, sleep consolidation, arousal, memory salience, or state transition, but each dependence changes the measured object. Endpoint-normalized kernels chosen after seeing terminal data can manufacture convergence.

A strong study should compare simple integration with kernel alternatives using held-out prediction and rival discrimination. It should ask whether the additive path predicts future physiological and auxiliary patterns better than recency or memory-weighted rivals.

The time rule is part of the construct. A ledger is not additive merely because the analyst prefers integrals.

Sensitivity analysis should also distinguish epistemic uncertainty from genuine heterogeneity. A conclusion that changes because the analyst lacks information about the correct kernel is different from one that changes because different people or contexts require different kernels. The first calls for better identification,

richer measurements, or wider uncertainty sets. The second may require a reference-class restriction or a formally heterogeneous model. Collapsing these cases can make a program look more stable than it is, or more unstable than it is. A serious report therefore attributes each change in verdict to the assumption, population, observation regime, or transport step that produced it and preserves those dependencies in the public summary.

6.4.5 — Memory, Recency, and Duration Rivals

Peak-end and duration rivals deserve special attention because they can make a path look cumulatively meaningful without being a cumulative ledger. Remembered evaluation can overweight the most intense moment and the ending, while neglecting duration or the distribution of experience across the interval. A life-course or terminal report may therefore reflect salient moments rather than additive accumulation (Kahneman et al., 1993; Redelmeier & Kahneman, 1996).

The Law of Fairness claim is about felt experience as it occurs within the qualifying conscious stream, not merely retrospective satisfaction. Still, if the data used to estimate the ledger are dominated by memory, report, or decision, the rival must be modeled. Otherwise the study may confuse remembered burden with experienced burden.

Duration also matters. Equal peak pain for ten seconds and ten hours cannot be treated identically in an additive ledger. Yet some reports compress duration, especially under memory distortion, trauma, sedation, or narrative reconstruction. The measurement system must identify whether the channel is duration-sensitive.

A useful analysis can compare additive duration-weighted models, peak-end models, recency models, and hybrid models. The winner should depend on held-out prediction and calibration, not on which model produces prettier neutrality language.

If peak-end rivals explain reports better, the study may still use physiological rate channels to estimate additive contributions. But it must not use those reports as if they validated the additive path without resolving the mismatch.

The chapter's rule is simple: remembered shape can inform the bridge, but it cannot replace the path unless the claim changes.

6.4.6 — Representation Failure as a Result

Representation failure means the evidence does not support a requirement of the declared branch, such as sign, neutral origin, scalarity, additivity, component structure, or invariance. These are typed failures: each invalidates a different descendant and points toward a different successor (Borsboom, 2005; Cronbach & Meehl, 1955).

Failure may be local. A scalar can work for ordinary unimodal episodes yet fail under mixed valence, trauma, altered consciousness, or extreme duration; one instrument may fail while another remains usable. The least committal supported object then replaces the failed one: vector for scalar, identified set for point, partial for total order, generalized functional for additive branch, or No adequate estimate when the family remains unresolved.

Representation includes resolution. Coactivation at one scale can appear as alternation at another, and smoothing can erase short

excursions. Weights, kernels, summaries, and resolutions must therefore be justified independently, evaluated out of sample, and varied within prospectively named families rather than selected for a desired residual.

Sealed-world recovery should distinguish scalar, vector, set-valued, origin-failed, and observation-failed generators. A pipeline that always returns one scalar cannot recognize when that object is unwarranted. Its failure register must identify the smallest invalidated descendant, preserving ordinal, componentwise, or formal work that still survives.

Public language names the scientific limit without pathologizing the participant. Representation not identified in this context is more accurate than declaring the person incoherent or the entire inquiry unmeasurable. Recovery-qualified abstention removes hidden flexibility and identifies the next discriminating study (Manski, 2003; Mayo, 2018).

6.5 — Observation Kernel and Protocol Measurement Map

The observation kernel is the probabilistic and procedural map from latent phenomenal states to the data a protocol records. It includes instruments, response processes, context, missingness, timing, calibration, and the transformations that turn raw signals into analysis variables (Bollen, 1989; Carroll et al., 2006).

A protocol measurement map is broader still. It says which latent object is targeted, which estimand is defined, which estimator is used, and which decision rule produces a verdict. Without that map, a measured ledger can quietly replace the latent ledger in the reader’s mind.

The section defines each estimator by its target, observation model, and context of use.

$$Y_{ijk} = \mathcal{H}_{\eta,j}(X_i(t_k), C_{ijk}, R_{ijk}) + \varepsilon_{ijk}, \quad \hat{\theta}_i = \mathcal{A}(Y_i, M_i; \eta)$$

The observation kernel $\mathcal{H}_{\eta}$ maps latent state, context, and response conditions into observations. The analysis operator $\mathcal{A}$ then produces an estimator under an explicit missingness model M_i . Here i indexes person or stream, j indexes channel, k indexes occasion, and Y_i denotes the collection $\{Y_{ijk}\}_{j,k}$. Neither object is the latent experience itself.

6.5.1 — Momentary Contribution Estimators

A momentary contribution estimator targets the signed phenomenal rate or a declared local functional at one interval. It is not a direct meter of consciousness and not a permanent score attached to a person (Bollen, 1989; Carroll et al., 2006).

The estimator may combine channels only through a declared model that preserves their distinct error structures. A composite gains no authority merely because it predicts one report channel well.

Calibration should use held-out tasks, repeated measures, and within-person anchors. The estimator's context of use must state populations, settings, time scales, and conditions under which abstention is required.

A phone prompt, bedside report, and neural recording may disagree during the same interval. The disagreement is data about the observation process rather than permission to average blindly.

Proxy dominance is a central risk. A high-performing behavioral or neural model may predict reports while missing unreported experience, response suppression, or culture-specific expression.

The scientific role is modest but essential: estimate a local contribution with uncertainty, then allow later models to test whether those estimates can support cumulative claims.

Local estimators should be recalibrated across contexts and versions, with drift monitored through anchor tasks and replicate measurements. A stable model coefficient is not evidence of stable measurement when the response process has changed.

The received candidate momentary estimator uses qualified physiological channels. Self-report, pairwise comparison, behavior, and contextual variables remain distinct auxiliary witnesses for calibration, challenge, and the modeling of observation conditions. A broader multimodal estimator may combine these sources with autonomic signals and neural features

under a separately declared model, but it must not silently replace the received physiological candidate. Each channel retains its own error structure.

6.5.2 — Auxiliary Witnesses Remain Distinct

Self-report, behavior, physiology, neural data, clinician observation, and informant evidence are witnesses with different access paths. None is the privileged voice of the latent object in every context (Campbell & Fiske, 1959; Mokkink et al., 2024; Gagnier et al., 2025).

A multi-channel model should preserve channel identity before fusion. Conditional dependence, shared artifacts, and common causes must be represented rather than treated as independent confirmations.

Protocols can compare channel-specific likelihoods, posterior predictive checks, and conflict patterns. Persistent conflict may narrow the estimand or trigger no-estimate rather than being hidden in a composite.

Sedation can reduce speech and movement while leaving uncertain residual experience. A bedside observer and a device may both report quiet, yet quiet is not a validated neutral origin.

Keeping witnesses distinct respects both persons and data. It prevents an algorithmic consensus from being mistaken for access to inner truth.

Conflict analysis should ask which channel fails under which conditions. A channel may lag, saturate, react to observation, or lose validity near an endpoint while another remains informative.

Modeling those patterns explicitly can identify the failing measurement interface, whereas an omnibus composite can conceal it behind an apparently stable average.

Common-method bias can make questionnaires converge, while shared device placement can make sensors share one artifact. The adversarial plan should treat agreement that disappears when methods, hardware, or timing are diversified as support for a shared-method rival rather than counting the number of channels as independent evidence.

6.5.3 — Latent-to-Observed Channel Map

The channel map specifies how latent states generate observable responses under context, memory, attention, communication, and device conditions. It is the causal heart of measurement rather than a technical appendix (Shiffman et al., 2008; Stone et al., 2007; International Test Commission, 2018).

A channel model may be parametric, nonparametric, state-space, or simulation-based, but it must expose identifiability assumptions. Different latent trajectories can produce the same observations when gain, noise, or missingness changes.

Negative controls and perturbation studies can test parts of the map. Instrument changes, repeated prompts, known stimulus manipulations, and cross-device calibration reveal whether the estimated channel behaves as expected.

A decline in facial expression near an endpoint may reflect reduced experience, motor weakness, medication, fatigue, or observation-gain collapse. The channel map must carry those alternatives.

A flexible neural decoder can fit observed labels while remaining untransportable across scanners, populations, or states of consciousness. Prediction within one dataset is not channel validity.

A credible map makes later terminal evidence possible by showing how observed data could have been different under different latent states.

Channel validity should be evaluated through held-out devices, sites, states, and perturbations, with calibration as well as discrimination reported. A decoder that preserves rank but not scale cannot support the same cumulative estimand without an additional bridge.

Channel validity becomes scientifically useful when it yields counterfactual separation: the same latent change should alter the channel in a predicted direction, while a channel-specific artifact should not masquerade as a change in the latent object.

6.5.4 — Interval Contribution and Cadence

Cumulative estimation requires interval contributions, not isolated snapshots. Cadence determines what transitions, bursts, and durations can be recovered from discrete observations (Bollen, 1989; Carroll et al., 2006).

An interval contribution estimator may integrate a filtered latent path, use quadrature between observations, or model continuous-time dynamics. Its uncertainty must include interpolation and unobserved intervals.

Sampling design should be tied to the fastest scientifically relevant dynamics and participant burden. Dense measurement is not automatically better when it changes experience, exhausts participants, or increases dropout.

A daily rating can miss short severe episodes; a minute-by-minute protocol can create intrusion and reactivity. The appropriate cadence depends on the estimand and ethical context.

Irregular sampling, informative prompting, and event-triggered recording can distort apparent duration and transition rates. The design mechanism belongs in the likelihood or sensitivity analysis. When those designs remain observationally equivalent, cadence cannot be used to favor a route; the ambiguity belongs in the verdict.

Plots and tables must encode actual observation intervals, not just row order. Cadence, gaps, and interval length determine what cumulative contribution is represented; a smooth trajectory drawn through irregular samples can conceal the exposure uncertainty under study.

Cadence is therefore an identification parameter. Sampling that is too sparse aliases bursts into trends and alternation into coactivation; sampling that is too dense can increase reactivity and participant burden. A defensible design studies this tradeoff prospectively and reports which interval functionals remain recoverable at each cadence.

6.5.5 — Context of Use and Versioning

Every estimator needs a context of use stating what decision it supports, for whom, under which conditions, and with what

consequences of error. A research estimator is not automatically a clinical, legal, or public instrument. A version is qualified only for its declared population, setting, cadence, and decision; material changes require new validation rather than silent inheritance (Campbell & Fiske, 1959; Mokkink et al., 2024; Gagnier et al., 2025).

Versioning should lock features, calibration data, preprocessing, model weights, uncertainty rules, and abstention thresholds. A changed estimator is a new measurement object even if its public name remains the same.

Performance should be reported by relevant setting and subgroup, with transport tested rather than assumed. Retired versions, changed items, preprocessing revisions, and recalibration reasons belong in the production record so every result can be traced to the exact instrument that generated it.

An estimator trained on verbal adults in laboratory tasks may fail in pediatrics, dementia, intensive care, nonverbal disability, or another language. Those failures are not edge cases when the theory claims broad conscious scope.

Continuous software updates can create silent measurement drift. Apparent longitudinal change may reflect the instrument's evolution rather than the person's experience.

Context and versioning make measurement answerable. They allow the book to say exactly which object a result concerns and which object it does not.

6.5.6 — Abstention, Privacy, and No-Score Governance

Abstention rules must be protocol-fixed before outcome inspection for excessive uncertainty, out-of-distribution inputs, unresolved channel conflict, missingness, calibration failure, endpoint ambiguity, or privacy limits. Human review may add context, but it cannot convert an unidentified object into an estimate or waive a formal stop (Manski, 2003; Mokkink et al., 2024).

An abstaining system should name the failed gate: origin not identified, observation insufficient, endpoint unresolved, model recovery failed, or privacy-limited audit. Typed outcomes preserve information that a generic inconclusive label would erase.

Data minimization is part of validity. Collect only channels needed for the declared estimand, retain them for a stated period, and separate research identifiers from ordinary identity records. Secure enclaves, federated analysis, disclosure limits, and protected access may reduce exposure, but protocols must state their effects on reproducibility, calibration, subgroup analysis, and independent audit. More data or more privacy does not automatically improve or verify a measured-to-latent bridge (Nissenbaum, 2010).

No cumulative estimate may become a personal score or determine care, employment, insurance, education, legal standing, access, spiritual status, trustworthiness, or public worth. The rule applies to positive- and negative-looking outputs, including those marketed as wellness, balance, or resilience.

Participants retain refusal, pause, withdrawal, correction, and care rights; review bodies, not automated systems, own deployment limits, adverse-event response, suspension, and correction propagation.

Public communication must describe the research object rather than the person. It may report that a protocol-fixed pipeline returned a specified evidential status under declared assumptions; it may not call anyone fair, balanced, complete, unfinished, or on a required trajectory. Governance requires versioning, access logs, secondary-use limits, audit rights, incident response, and a retirement path. Changed models or contexts invalidate automatic carry-forward; affected outputs must be revalidated, narrowed, or withdrawn.

Abstention, privacy, and no-score rules are part of validity, not warnings added afterward. They determine collectable data, adjudicable estimands, and communicable conclusions without converting uncertainty into hidden human judgment.

6.6 — Missing History and Running-State Uncertainty

A complete-stream hypothesis collides with an ordinary empirical fact: researchers almost never observe a stream from its onset. They enter through a clinic, cohort, device, survey, or historical record after an unknown amount of phenomenal history has already passed (Little & Rubin, 2019; Rubin, 1976).

The unknown prefix is not a nuisance constant that can be set to zero. It is part of the latent state at enrollment, and different compatible prefixes can imply different whole-stream terminal residuals even when the observed window is identical.

This section develops decomposition, bounds, historical evidence, and the limited claims that survive delayed entry. It also clarifies why a running measured estimate is uncertainty over histories rather than a fresh ledger created by the study.

$$\begin{aligned} L_i^{\text{phen}}(T_i^* -) &= L_i^{\text{phen}}(t_0 -) + \Delta L_i(t_0, T_i^*) \\ L_i^{\text{phen}}(t_0 -) &\in B_i(t_0) \end{aligned}$$

The observable window can inform the increment. The missing prefix belongs to a bounded or modeled set $B_i(t_0)$ unless independently recovered. Whole-stream adjudication depends on how much that set can be narrowed.

6.6.1 — Observable-Window Decomposition

The decomposition separates the pre-entry cumulative state from the observed-window increment. It prevents a study from treating enrollment as stream onset (Little & Rubin, 2019; Rubin, 1976).

The identity is bookkeeping rather than evidence. Its scientific content depends on how the missing prefix and observed increment are represented, measured, and linked.

Analyses should report window-specific estimands even when whole-stream claims remain unavailable. Local drift, variance, response to intervention, and endpoint timing can still be studied.

A hospice cohort may provide high-frequency data for the final month. That data can test terminal route signatures while remaining silent about the complete lifetime residual.

Retrospective reconstruction can create an illusion of coverage when later reports are used as if they were continuous observations. Recall and narrative are channels with their own models.

The decomposition preserves scientific value without overclaim. It lets the final window answer the questions it can actually answer.

The prefix identified set should be displayed separately from the observed-window increment so readers can see which part of the conclusion comes from data and which part comes from assumptions. A narrow total produced by a narrow prior is not equivalent to direct historical coverage.

The decomposition becomes scientifically useful only when each term is assigned a distinct source of information and uncertainty. The observed-window increment can be estimated from sampled data; the missing prefix requires a historical model or bounds; and their dependence must be propagated rather than suppressed by treating the prefix as a fixed offset.

6.6.2 — Multiple Compatible Prefix Histories

The same observed late trajectory may be compatible with many earlier cumulative histories. This is a structural source of nonidentification, not merely a shortage of sample size (Tsiatis, 2006; Manski, 2003; Aalen et al., 2008).

Compatibility sets can be defined by bounded rates, known events, historical observations, or mechanistic assumptions. The wider the set, the weaker the whole-stream conclusion.

Sensitivity analysis should vary prefix assumptions and display which terminal verdicts change. A result that depends on one narrow prior should be reported as such.

Two people with identical final-week observations may have had very different prior burdens and relief. The late window cannot erase that difference.

Identified-set reporting is often more honest than one posterior mean. It shows what the data and assumptions jointly permit.

The sensitivity analysis should vary more than the prior mean. It should alter admissible path roughness, exposure rates, origin uncertainty, and dependence between the missing prefix and observed window. A conclusion that survives only one narrow historical model is a property of that model, not of the complete-stream target.

Population priors can narrow prefix uncertainty by importing social stereotypes, health inequities, or diagnosis-based assumptions. Apparent historical reconstruction that collapses under subgroup transport, prior sensitivity, or record-free

validation should favor that rival explanation rather than a recovered individual history.

6.6.3 — Bounds and Sensitivity Sets

Bounds translate incomplete history into explicit limits on possible terminal residuals. They can be wide and still scientifically useful because they reveal which conclusions do not depend on unverifiable reconstruction (Rizopoulos, 2012; Imbens & Manski, 2004).

Rate bounds, duration bounds, event records, and monotonicity assumptions can narrow the prefix set. Each assumption should be named and stress-tested.

Protocols can report best-case, worst-case, and assumption-indexed residual ranges. Equivalence with zero is meaningful only if the relevant range lies within a declared empirical band under all required gates.

A documented period of prolonged severe pain may support a lower bound on the magnitude of a negative historical contribution under a justified observation bridge, even when finer details are missing. That bound is different from a complete reconstruction.

Overly tight bounds can be manufactured by excluding unrecorded states or assuming stable reporting. Conservative uncertainty is not a defect when the history is genuinely unavailable.

Bounds make the limits of identification visible and show which additional evidence or assumptions would support a sharper conclusion.

Each bound should be accompanied by an assumption-deletion analysis showing how it widens when one restriction is removed. This reveals which premise supplies apparent precision and prevents several weak assumptions from hiding behind one narrow interval.

6.6.4 — Historical Records and Their Limits

Medical records, diaries, ecological momentary assessments, wearable data, family testimony, and institutional records can constrain missing history. None is a transparent archive of phenomenal experience (Little & Rubin, 2019; Rubin, 1976).

Each source has selection, coding, purpose, and missingness mechanisms. Records created for billing or treatment may omit duration, meaning, or unreported experience.

Source triangulation should preserve provenance and disagreement. Historical evidence can update a prefix model without being merged into one falsely homogeneous stream of data.

A medication chart may document dosage accurately while offering little information about relief, side effects, fear, or interpersonal context. A family narrative may preserve meaning while misremembering timing.

Historical records constrain specified features of a prefix; they do not establish a complete conscious history. Their contribution

must be evaluated through the coverage and source-specific checks below.

Historical evidence should narrow uncertainty proportionately to what it actually records. The record's dignity lies in being used carefully, not in being treated as complete.

Historical records should be displayed with coverage windows, source type, provenance, and known omissions. A chart that fills unrecorded years with a continuous line converts absence of evidence into invented history.

Historical evidence is strongest when it constrains a specific feature rather than pretending to reconstruct an inner archive. Medication records may bound exposure, diaries may locate episodes, and wearable traces may constrain timing; none by itself identifies phenomenal sign or magnitude. The protocol should record which latent dimensions each source can and cannot narrow.

6.6.5 — Local Dynamics Versus Whole-History Claims

Delayed-entry studies can investigate local dynamics, route predictions, transitions, and bounded terminal implications. A justified prefix model extends those results to questions involving earlier history (Tsiatis, 2006; Manski, 2003; Aalen et al., 2008).

A local model can estimate drift, innovation, response kernels, or observation gain in the observed window. Those estimates require no claim that the prefix is known.

Every result should identify its object: local state dynamics, an observed-window increment, a prefix bound, or the complete

terminal residual. The label determines which missing-history assumptions and transport claims are required.

A study of naturally occurring changes, or an independently justified beneficial intervention, can test short-window opponent dynamics without measuring a lifetime ledger. The design must satisfy Chapter 3's prohibition on inducing suffering for Law-specific evidence.

The temptation is to let a strong local signature stand in for the whole law. Rivals can share local dynamics while differing at the boundary.

Layered claims preserve value under defeat. Local affective science, measurement, and dynamics remain useful even if complete-stream closure is not identified.

6.6.6 — No Reset at Enrollment

Enrollment begins the observed window. A complete-history analysis combines its measured increments with an independently identified or bounded prefix (Manski, 2003).

The correct decomposition keeps the prefix explicit. Multiple compatible histories can produce the same observed state at enrollment while implying different component totals, residuals, route states, and future completion sets. Replacing that family with zero is an assumption, not a neutral starting point.

A useful analysis carries a distribution, interval, mixture, particle cloud, or compatible-prefix set suited to the problem. A mean and variance may fail when the family is multimodal or sign uncertainty changes reachability in opposite directions.

Historical records can constrain the prefix, but each channel needs validation. Diaries, medical notes, informant reports, prior devices, treatment histories, and recalled episodes capture different objects and fail for different reasons. Agreement may reflect shared documentation, not access to phenomenal value.

Overlapping cohorts can test local-dynamics transport. Different entry times provide common windows for comparing transition structure and measurement behavior, while historical coverage is documented separately.

A reset-artifact negative control should be part of model recovery. Synthetic worlds can share identical post-entry dynamics while differing in prefixes chosen to imply different whole-history verdicts under the benchmark assumptions. A method that returns the same whole-history verdict despite sufficient information to distinguish those cases should fail recovery; the audit should test whether it has reset the ledger implicitly. Including reset artifacts in recovery makes delayed-entry bias an explicit failure mode instead of a theoretical warning.

Prefix and endpoint uncertainty must be varied jointly. Modest uncertainty on each side can combine into a wide terminal set, especially when continued-experience, false-ending, or routing branches remain plausible. The report should identify whether history, endpoint, representation, observation, or their interaction is the limiting gate. Factorial sensitivity analysis can show whether uncertainty is dominated by one bridge or by interactions that become important only when several weak links coincide.

The output should distinguish post-entry change, a full-history bound, and a complete-stream verdict. The first may be estimable when the others are not. This distinction permits useful longitudinal science without overstating enrollment data. That separation also prevents a precise within-window effect from lending unwarranted precision to the unobserved prefix.

No reset at enrollment is a technical and ethical rule. It prevents convenience from erasing hidden prior burden or presenting a study-relative baseline as the beginning of a person's lived history. When the prefix cannot be identified or validly bounded, No adequate estimate is the honest whole-stream result. A bounded prefix may still support useful partial conclusions; an unbounded one should block only the whole-stream inference that depends on it.

6.7 — Equivalence, Adjudicability, and No-Neutrality-by-Fiat

Exact closure, finite-resolution compatibility, an atom at zero, probability-one closure, and set-universal closure are different targets. Section 6.7 prevents a favorable measurement result from moving among them. The central question is not whether an estimate looks close to zero, but which object, resolution, bridge, and quantifier the study can actually adjudicate (Manski, 2003; Mayo, 2018).

The exact-branch decision rule used in this section is stated formally in §6.7.1. The key distinction is that empirical uncertainty containing zero is not the same object as a truth-containing singleton $\{0\}$; the former may support compatibility at a declared resolution without establishing exact latent closure.

A finite-band target asks a different question. It can test whether the truth-containing residual set lies inside a prospectively declared acceptance region at the study's resolution. Passing that test can be valuable evidence for the declared band while leaving exact equality open.

Scientific acceptance geometry must also remain separate from epistemic uncertainty. The equivalence band describes the target region the protocol is prepared to treat as scientifically indistinguishable for a named use. The confidence, posterior, or identified set describes what the data and model allow researchers to know about the estimand.

Table 6.4. Neutrality-manufacturing routes and required controls.

Manufacturing route	How it can fake neutrality	Required control
Centering	Forces means or windows toward zero	Pre-outcome origin rationale and sensitivity
Baseline subtraction	Makes residuals appear balanced by reference choice	Independent baseline and status label
Derivative transforms	Telescopes cumulative claims into boundary terms	Label the observed change and its historical coverage
Outcome-selected weights	Finds channels or signs that cancel	Frozen weights or exploratory label
Endpoint fitting	Moves window to the favorable ending	Endpoint firewall and sensitivity
Exclusions	Removes inconvenient trajectories	Symmetric rules and independent audit

An atom at zero is different again. A distribution can place increasing mass in narrow neighborhoods of zero without assigning positive probability to zero itself. Claims about an exact pile-up therefore require a validated inverse bridge, deconvolution, partial-identification argument, or another structure that distinguishes an atom from a narrow continuous law.

Adjudicability precedes estimation. A large sample cannot rescue a design whose bearer, ownership map, origin, sign, endpoint, observation process, or measured-to-latent bridge leaves the target unidentified. The correct result may be a bounded statement, an identified set, or No adequate estimate.

No-neutrality-by-fiat protects this hierarchy from analytic choices that make favorable outcomes easier. Centering, baseline subtraction, difference transforms, flexible scalarization, endpoint alignment, smoothing, missingness handling, and exclusions can all be legitimate. They become defects when their role or timing is hidden or when they quietly change the target.

The timing vocabulary is exact. Protocol-fixed means written into the study protocol before outcome inspection. Prospectively specified means fixed before outcome inspection without asserting a public registry. Publicly preregistered is reserved for a timestamped external registry with a persistent identifier; this Part makes no such claim without that record.

Before outcome inspection, the protocol fixes the instrument version, channel list, sign rules, scalarization family, temporal kernel family, endpoint rule, missingness model, equivalence region, bias-transfer strategy, exclusion rules, and abstention criteria. Later deviations remain visible and are routed to sensitivity or exploratory status unless an independently governed amendment justifies another label.

Adversarial reanalysis asks whether reasonable alternatives reverse, erase, or weaken the conclusion. Synthetic fixtures ask whether a nonneutral process can be manufactured into apparent neutrality, whether observation attenuation can imitate latent convergence, and whether derivative transforms telescope into boundary differences. These tests let the pipeline fail before participants carry more burden.

Figure status is part of inference. Observed, filtered, smoothed, forecast, endpoint-aligned, retrospectively adjudicated, and simulated trajectories must be labeled as such. A smooth line can communicate a result only when readers can see which transformations and endpoint rules produced it.

This audit identifies results that survive specified alternatives, independent reconstruction, strong rivals, and transparent abstention. Each successful check strengthens the result by showing which analytical choices it can withstand.

Table 6.5. No-neutrality-by-fiat audit.

Audit item	Frozen before outcome?	Independent check	Failure consequence
Origin or baseline	Yes	Sensitivity across declared alternatives	Withdraw exact or measured neutrality language
Channels and signs	Yes	Blind artifact and sign audit	Exploratory-only if changed after outcome
Scalarization weights	Yes	Identified-set report over W	Report representation sensitivity
Endpoint rule	Yes	Endpoint-firewall review	Abstain or rerun under sensitivity
Missingness model	Yes	Severity and device-tolerance checks	Widen uncertainty or no estimate
Code and figures	Versioned	External reanalysis or secure audit	Correct, retract, or retire claim

Human dignity does not depend on the outcome. Participants are not failed subjects when a bridge collapses, a rival wins, or the study cannot estimate the target. The scientific object has encountered a limit; the person remains outside every ledger, score, and verdict.

No-neutrality-by-fiat is therefore an affirmative research standard. It tells collaborators exactly what must be frozen, what may be learned, what remains exploratory, and what would force the claim to narrow. The discipline makes favorable evidence more valuable because the conditions under which it could have failed are visible.

The standard also protects cross-study accumulation. A later meta-analysis can combine results only when target geometry, observation resolution, endpoint class, and bridge status are sufficiently aligned. Pooling incompatible exact, band, atom, or measured-only objects creates apparent precision around no single scientific question.

Every later protocol should carry this section's audit packet forward. A favorable pattern is not complete until the route from target to data, code, figure, and public verdict can be reconstructed and challenged. That requirement is part of the contribution, not a final caution.

The final product is an inference architecture that can say exact-compatible, band-equivalent, exact-adverse, band-adverse, indeterminate, route-failed, rival-favored, or No adequate estimate without collapsing them into one success score. Such

typed outcomes allow the research program to learn without moving the claim it set out to test.

6.7.1 — Exact Latent Zero and Empirical Compatibility

Exact latent closure and empirical compatibility must remain visibly separate. For a nonempty truth-containing residual set R_i , exact compatibility requires $R_i = \{0\}$; exact adversity requires $0 \notin R_i$; and every wider set containing zero is exact-indeterminate. A confidence interval or posterior region containing zero does not by itself satisfy the singleton condition (Manski, 2003; Imbens & Manski, 2004).

Finite data can nevertheless contribute. A study may show that a declared measured estimand is compatible with a narrow region around zero under a specified observation, endpoint, missingness, and recovery model. That result is resolution-bounded evidence for the measured or bridged branch it actually addresses.

Repeated success across prospectively nested bands can strengthen the case only while the representation, bridge family, endpoint class, recovery guarantees, and limiting rule remain fixed. Choosing a narrower band after seeing favorable data tests a new analysis, not a stronger version of the original one.

An exact latent atom requires more than shrinking observed bands. A narrow continuous distribution, rounded measurements, censoring, smoothing, or an instrument floor can all create a visible concentration near zero. Distinguishing an atom requires a bridge that can recover that feature or a partial-identification argument that rules out the continuous rivals.

The report should therefore separate three sentences: what the observations establish directly, what the measured-to-latent bridge adds, and how the conclusion changes when the bridge is weakened. Precision in an estimator cannot substitute for exactness in the target.

Adverse evidence is equally typed. A valid truth-containing set that excludes zero rejects exact closure for the declared stream and branch. A point estimate away from zero without adequate coverage, endpoint, or bridge support does not yet carry that force.

This hierarchy lets the program accumulate real progress without pretending that finite measurement has solved an ontological question. Compatibility can be informative, exact adversity can be decisive for a declared branch, and indeterminacy can identify the next bridge or instrument the science needs (Mayo, 2018; Lakens, 2017).

6.7.2 — Equivalence Bands and Observation Error

An equivalence band is a scientific acceptance region for a named estimand and use; an uncertainty interval is an epistemic statement about what values remain compatible with the data and model. They can overlap, nest, or diverge, but they answer different questions (Lakens, 2017; Schuirmann, 1987; Mayo, 2018).

The band must be justified before outcome inspection through measurement resolution, calibration error, biological or temporal variability, and the consequence of false equivalence. A tolerance

chosen because the observed estimate fits inside it is an outcome-selected target.

Observation error enters through bias as well as variance. A narrow interval around a biased measured estimand can falsely suggest equivalence, while a wide but unbiased interval may remain scientifically honest. The analysis must propagate calibration, origin, endpoint, missingness, and bridge uncertainty rather than attaching them as prose after the decision.

Different uses may require different bands. An exploratory route screen, a measurement-qualification study, and a public claim about terminal concentration need not share one threshold. Each band should name its estimand, scientific purpose, error control, and status ceiling.

When several bands are defensible, the report should show the verdict profile across them rather than select the most favorable. A prospectively specified hierarchy can distinguish a primary band from sensitivity bands without treating all thresholds as interchangeable.

Observation floors, rounding, smoothing, and censoring can compress estimates into the band even when latent dispersion remains. Negative controls and simulated nonneutral data should show whether the pipeline can separate genuine compatibility from instrument-limited concentration.

Band-equivalence assesses the declared estimand against an acceptance region at a specified resolution. Reporting the estimand, band, uncertainty, and decision procedure makes that result precise and reusable.

6.7.3 — Adjudicability Before Estimation

Adjudicability is a property of the whole design, not merely of sample size, estimator precision, or computational sophistication. A study becomes adjudicative only when distinct scientific states can produce distinguishable planned outcomes under the declared measurement and endpoint architecture (Borsboom, 2005; Manski, 2003; Mayo, 2018).

Pre-estimation review traces the dependency chain from bearer and ownership through representation, origin, sign, exposure, endpoint, observation, missingness, estimand, estimator, rival set, and decision rule. A broken prerequisite blocks promotion beyond the last object that remains identified.

Large datasets can remain nonadjudicative. If two endpoint models, scalarizations, or observation kernels generate the same observed law, more observations of that law improve precision without separating the explanations. The design needs a new contrast, perturbation, instrument, or assumption, not merely more participants.

Model recovery provides an early gate. Simulated worlds with known additive closure, band compatibility, atoms, continuous near-zero laws, observation attenuation, and rival dynamics should be analyzed blind. A pipeline that cannot recover those known cases is not ready to interpret human data.

Endpoint ambiguity, unstable sign, incomplete routing, or an unidentified neutral origin can make the primary target unanswerable while leaving narrower science available. The

report should name those surviving estimands instead of treating all measurement failure as one undifferentiated limitation.

A pre-estimation adjudicability table should list each target branch, the contrast that could separate it, the principal rival, the required data, and the abstention condition. The table reveals when a planned analysis is descriptive, route-informative, or capable of adjudicating the declared terminal branch.

When no planned contrast separates the relevant states, the scientifically correct output is Model-ambiguous when adequate rivals remain inseparable, No adequate estimate when the target cannot be identified or validly bounded, or Open-set inadequate when none of the models is adequate, together with the evidence needed to change that status. Estimation should begin only after the design has shown how the result could matter.

6.7.4 — Centering and Baseline Subtraction

Centering and baseline subtraction are useful descriptive tools, but neither identifies the phenomenal neutral origin. A sample mean, adaptation level, site mean, preterminal average, or fitted terminal center can force measured values toward zero while leaving the latent origin unknown (Borsboom, 2005; Lakens, 2017).

A baseline must have a pre-outcome rationale and a declared role. It may support visualization, within-person contrast, calibration, nuisance adjustment, or a state model. Each role licenses different language; none automatically creates the zero used by the terminal hypothesis.

Temporal placement matters. A baseline estimated after adaptation, medication, sleep loss, disease progression, or entry into terminal care may absorb part of the process under study. A baseline fixed too early can instead treat ordinary drift as cumulative valence. The protocol should state the causal and temporal relation between baseline and target interval.

Within-site or within-person centering can also erase scientifically relevant heterogeneity. Culture, illness severity, communication capacity, device gain, and reporting standards may differ across sites or periods. The analysis should show whether conclusions survive defensible centers rather than hiding those differences through normalization.

Derivative and difference transforms create a related hazard. Summed changes can telescope to a final-minus-initial state, converting path burden into boundary contrast. Such transforms may test local dynamics, but they do not become cumulative phenomenal measures without an independently validated bridge.

$$\sum_{j=0}^{m-1} [\varphi(X_{j+1}) - \varphi(X_j)] = \varphi(X_m) - \varphi(X_0)$$

Endpoint alignment can compound the problem. If trajectories are centered or stopped at the point closest to zero, the procedure has placed the finish line near the answer. Truth and protocol endpoints must be fixed by information not algebraically identical to the residual being tested.

A transformation audit should report the original scale, every centering or differencing operation, the reason and timing of the

choice, alternative defensible transformations, and the resulting verdict profile. A centered graph may be useful; it must never conceal that neutrality entered through the preprocessing rule.

6.7.5 — Outcome-Selected Weights, Endpoints, and Exclusions

Outcome-selected flexibility can manufacture neutrality while looking like model improvement. With many signs, channels, lags, weights, filters, windows, endpoints, and exclusions, some combination may approach zero even when no prospectively specified representation does (Mokkink et al., 2024; Gagnier et al., 2025; Simonsohn et al., 2020).

Weights and signs may be learned on development data, but the confirmatory terminal analysis must apply a protocol-fixed rule to protected outcomes. Cross-validation helps only when the endpoint and feature construction do not leak into every fold.

Endpoint fitting includes trimming the final interval, selecting the closest zero crossing, excluding sudden or low-signal endings after inspection, or changing the endpoint class because one definition is favorable. Necessary exclusions require symmetric, documented rules and sensitivity across plausible adjudications.

Channel rejection has the same burden. Artifact removal can protect validity, yet a contradictory channel cannot be dismissed merely because it weakens the preferred story. Blind quality review, negative controls, and predefined failure rules reduce that discretion.

A prospectively specified multiverse can show how the result changes across defensible weights, kernels, endpoints, and

exclusions. The primary confirmatory route remains one declared analysis; the wider multiverse is sensitivity evidence, not a license to choose the branch that wins.

When a favorable representation is discovered after outcome inspection, the correct status is exploratory. Its value lies in generating a new protocol-fixed test on independent data. The science becomes stronger when discovery and confirmation are separated rather than rhetorically blended.

6.7.6 — Audit, Reanalysis, and No Adequate Estimate

A complete audit reconstructs the result from frozen scientific objects, not only the final code. The packet identifies the representation and origin versions, ownership map, endpoint, observation and missingness models, estimand, estimator, exclusions, equivalence rule, recovery evidence, rivals, software environment, random seeds, access controls, and protocol deviations (National Academies of Sciences, Engineering, and Medicine, 2019; Nosek et al., 2018).

The trail must carry each published claim backward to its data provenance and forward to every dependent table, figure, summary, excerpt, and verdict. That chain makes later correction precise rather than reputational.

Reanalysis asks whether the protected data support the same result under the declared pipeline and defensible alternatives. Replication asks whether a prospectively specified design transports to new data. Neither substitutes for the other.

Blinded reconstruction gives an independent analyst the frozen objects and protected data without the original conclusion.

Rebuilding the estimand and decision rule can expose undocumented preprocessing, software defaults, ambiguous definitions, or hidden judgment.

Adverse reanalysis should test bounded alternatives for bias, informative missingness, covariance, origin and weight families, endpoint uncertainty, and serious rivals. Scientific purpose constrains the search, because unbounded flexibility can manufacture defeat as readily as support (Steege et al., 2016; Simonsohn et al., 2020).

Sensitive records require secure audit routes, including controlled environments, disclosure-limited outputs, synthetic fixtures, federated execution, and purpose-limited external review. Privacy limits must be reported as limits on audit scope, never as evidence that an unreviewable claim was independently verified (Nissenbaum, 2010). When audit access is restricted, independent reviewers should still receive enough synthetic or derived material to test the transformations that carry the claim.

Every abstention status must name its reason under §24.2's canonical evidence-state rules. Representation, endpoint, observation, missingness, recovery, computation, privacy-limited audit, and an open rival envelope are distinct failures that call for different next studies. A reason-coded abstention register also lets later work measure which gate most often limits adjudication and prioritize method development accordingly.

Corrections propagate to every dependent estimate, formula, table, summary, diagram, public excerpt, and reference record. A superseded certainty may not survive in a higher-reach artifact.

Propagation should follow dependency links rather than keyword similarity, so unaffected claims remain stable while genuinely dependent artifacts update.

The closing verdict states what the evidence earned under the standing rule in §24.2. Abstention, reanalysis, replication, and correction must be as reproducible as favorable results (Munafò et al., 2017; Mayo, 2018). Replicating an abstention boundary is informative because it tests whether the same inferential limit appears again under the same declared conditions.

Chapter 7 — Mechanism-Neutral Consequences

Once a boundary hypothesis has been stated and its measurement layers separated, the next question is unavoidable: what must follow from exact closure before any mechanism is chosen? That question gives the program consequences that cannot be protected by changing routes.

Mechanism-neutral reasoning begins with prefix feasibility. A nonzero cumulative residual requires an equal and opposite remaining net increment under exact PTVC, and bounded remaining exposure can make that increment unreachable in a declared continuation class. This is conditional mathematics, not an individualized reward forecast or permission to impose suffering.

Endpoint timing then introduces a sharper challenge. If a diffuse endpoint is independent of a nontrivial ledger path, exact zero at the random cut is severely obstructed. The theorem forces the program to distinguish independent timing from state-coupled hazards, first hitting, absorption, endpoint atoms, singular support, continued experience, and routing change.

Directional completion sets generalize one reserve number. Positive and negative capacity can differ, reachable increments can be state-dependent, and action can alter the route space. These sets describe possibility under a model; they do not prescribe action or forecast personal fate.

Endpoint support and compensators add time to reachability. A target may be geometrically reachable and still unlikely to be reached before termination. Counting processes, occupation

measures, hazard models, and boundary accessibility make that distinction testable.

Doob transforms and path constraints provide exact comparison models for terminal drift and concentration. Specifying those alternatives precisely makes any predictive advantage of a candidate interpretable.

The route also faces direct failure. Reserve may be unmeasurable, endpoint synchronization may fail, normalized dynamics may explode, observation gain may collapse, or rivals may predict equally well. Any of those outcomes can narrow or retire the route without rewriting the Formal Law.

The strongest rivals receive equal information and scoring. Ordinary mean reversion, adaptation, homeostasis, frailty, disease severity, medication, endpoint-conditioned bridges, Doob transforms, selection, missingness, and flexible observation models all remain capable opponents.

Open theorems are part of the positive contribution. The integral-to-route bridge, measure-level reserve geometry, random-endpoint branches, boundary support, and transport across representations remain research problems whose resolution could advance science even if PTVC loses.

Reserve, admissibility, and completion sets have defined mathematical roles in the models that follow. Care, consent, and interpretation of personal meaning remain governed by the chapter's independent ethical commitments.

By the end, the reader should see a more sharply testable program with clear opportunities for discovery. The candidate routes turn

the Law's formal target into competing scientific proposals, each with predictions that evidence can support, revise, or reject.

The chapter begins by refusing a common shortcut: no candidate mechanism is allowed to define the consequence it later claims to explain. Exact closure, if imposed on a complete stream, creates feasibility, endpoint, and support constraints before any reserve, bridge, selector, controller, or biological route is chosen. Those mechanism-neutral pressures form a theorem-to-test map. Each consequence must name the formal premises, observable implication, required bridge, strongest counterexample, and result that would count as failure. A route becomes scientifically interesting only when it adds predictions that could distinguish it from other ways of satisfying or imitating the same boundary.

A simple pair of synthetic trajectories shows why this ordering matters. One path is generated by a native state-dependent process whose innovations contract as a real reserve declines. The other is an ordinary diffusion conditioned to arrive near zero at a selected endpoint. Their terminal graphs can be nearly indistinguishable. The difference appears under an unexpected endpoint, a reserve perturbation, a held-out action, or a change in observation shutdown. A beautiful closing curve is therefore the beginning of identification, not the end.

The chapter organizes the pressure in stages. Prefix feasibility asks whether the remaining continuation set can still reach the boundary. The random-endpoint obstruction asks what exact closure would imply under independent diffuse timing. Endpoint support and compensators ask where endings can occur and how the path occupies the relevant times. Bridge and selector

distinctions separate native dynamics from conditioning, admissible-history pruning, intervention, and sampling. The stages form a dependency graph rather than a checklist: a failed representation or endpoint premise can invalidate a later route test, while a failed route prediction need not erase the earlier mechanism-neutral result. Only after those relations are explicit does the reserve route enter.

The reserve route is treated with unusual strictness because its intuition is powerful. A declining nonnegative reserve multiplied by a signed arithmetic reference process can generate steepening drift and shrinking diffusion near the boundary. Yet the product rule, scaling law, shared shocks, jumps, observation noise, denominator instability, and route-state validation must all be derived under the declared filtration. If any of those links fails, the route may be retired even while the target question remains open.

The chapter ends with a common model-comparison scorecard. Brownian bridges, Doob transforms, Ornstein-Uhlenbeck regulation, frailty, endpoint selection, observation floors, and hidden-state models receive the same data, preprocessing, information clock, parameter budget, and evaluation horizon. Component scores show performance on endpoint separation, observation robustness, and transport. The licensed conclusion may be Route-favored, Rival-favored, Model-ambiguous, Open-set inadequate, or No adequate estimate. Transparent comparison makes each outcome informative.

7.1 — Mechanism-Neutral Consequences of Exact Closure

Exact closure has consequences before any mechanism is chosen. If one stream's complete signed phenomenal measure must terminate at zero, then every observed prefix places constraints on what the remaining domain must permit. Those constraints are reachability statements, not promises that nature will supply a particular compensating event (Aubin, 1991; Aubin et al., 2011).

Mechanism-neutral consequences are valuable because they survive the retirement of a favored route. They ask what any realization of the target would have to respect, whether the route is global, local, conditioned, state-coupled, psychophysical, or not yet imagined.

The section begins with remaining capacity, nontransferability, and failure. A necessary future contribution is a mathematical requirement under stated assumptions. Any accounting language refers to that signed net requirement, never to moral debt owed by a person or to a method for selecting future rewards.

$$|L_i^{phen}(t)| \leq \int_t^{T_i^*} m_i(s) ds =: C_i(t)$$

The inequality is a reachability bound. If the current residual exceeds the maximum remaining signed capacity in the needed direction, exact closure is impossible under that bound and route class.

7.1.1 — Constraint Before Mechanism

A terminal constraint specifies an allowed boundary relation without specifying the dynamics that produce it. PTVC can therefore be studied before a controller, reserve, bridge, selector, or physical mechanism is identified (Aubin, 1991; Aubin et al., 2011).

Mechanism-neutral derivations use only the target, domain, regularity, and boundedness assumptions explicitly stated. Any result that invokes a route-specific state belongs to a later layer.

Protocols can test necessary consequences across multiple routes. A consequence that fails under adequate measurement narrows the target or its assumptions regardless of which mechanism was preferred.

If exact closure requires a path to remain within a shrinking feasible region near the endpoint, that geometric implication can be examined without knowing whether selection, control, or boundary conditioning produced it.

Some alleged consequences disappear under an allowed change of coordinates or arise because the endpoint was built into the state definition. A mechanism-neutral result must survive admissible rescaling and an independently specified endpoint. Otherwise it is a representational artifact rather than a consequence of closure.

Constraint-first reasoning makes the research program resilient. It preserves risky predictions while allowing mechanisms to compete rather than protect the target.

Each consequence should be linked to a theorem-to-test table: formal premise, observable implication, required bridge, rival explanations, and failure verdict. That table prevents a route-specific prediction from masquerading as a consequence of closure and lets several candidate mechanisms be challenged by the same declared necessary condition.

7.1.2 — Prefix Feasibility and Remaining Capacity

At any prefix time, the accumulated residual and the maximum possible remaining signed exposure jointly determine whether closure remains feasible under a declared class (Protter, 2005; Kallenberg, 2002; Ames et al., 2019).

The reserve bound compares current magnitude with an integral bound on future contribution. It is necessary under the rate bound, but it is not sufficient when sign, timing, routing, or endpoint accessibility also constrain the future.

Estimating the bound requires uncertainty in the current residual, remaining duration, rate limits, and observation model. Feasibility may therefore be set-valued rather than binary.

A large negative residual near a short, independently defined endpoint may be incompatible with closure if the maximum possible positive contribution is too small. The conclusion concerns the formal model, not the person's worth or care.

Flexible rate bounds can make every path feasible. Bounds chosen after observing the residual are therefore not tests; they are rescue parameters.

Feasibility analysis tells researchers where a strong claim becomes vulnerable. It also identifies the data needed to distinguish genuine remaining capacity from unconstrained speculation.

Rate and exposure bounds should come from independent physiological, psychophysical, or protocol evidence and should be stress-tested before terminal outcomes are inspected. Their scientific value lies in excluding continuations, not in expanding until every path survives.

7.1.3 — Nontransferability as Consequence

Nontransferability is a mechanism-neutral consequence of the received object: a feasible continuation for one stream cannot be substituted for another stream's missing signed contribution.

No aggregation across people can repair an infeasible prefix. A family's positive experience, a community's welfare gain, or a later archive cannot satisfy another stream's terminal residual.

Data linkage should preserve ownership boundaries. Household, institutional, and social variables can be covariates or causes without becoming ledger entries for the wrong bearer.

A caregiver's relief after a patient's death may be ethically and scientifically important. It cannot serve as the patient's compensating positive magnitude.

Collective-consciousness or fusion hypotheses would require new bearer and routing definitions. They cannot be introduced after individual-stream failure merely because social interaction was present. Unless a new ontology and data model distinguish

fusion from interaction, the individual-stream analysis is narrowed rather than rescued.

The consequence is both exact and humane: the formal burden stays with the object that bears it, while care and justice remain independently owed across persons.

Any detachable explanation of nontransferability should keep the unit of analysis visible. Population averages and cross-person comparisons may answer other questions, but they cannot be drawn as if one stream completed another.

This boundary also disciplines intervention design. A social, clinical, or environmental event can change a stream's future completion capacity only through the experience and timing it produces within that stream. Resources, care, and relationships remain causally important, but they are not transferable ledger entries.

7.1.4 — Necessary Compensation Without Moral Payment

For a nonzero prefix to end at zero, the remaining aggregate increment must have the opposite sign and equal magnitude. This gives a direct test of its attainable range under the declared dynamics and remaining domain (Aubin, 1991; Aubin et al., 2011).

The needed increment is defined over phenomenal contribution, not over narrative categories. Many possible trajectories can supply the same signed total, and the formal statement does not rank them by desert.

Relief, adaptation, ordinary positive experience, and other subsequent states can change the signed contribution accumulated after a negative prefix. A separately justified stream boundary defines the domain over which that contribution is evaluated.

Teleological storytelling is a major rival interpretation rather than a scientific route. It can fit any sequence after the fact and therefore generates little discriminating content.

The requirement concerns the future net difference, not a fixed quota of either pleasure or suffering. Additional positive or negative experience changes the required signed remainder by the opposite amount. The resulting gross totals, opportunities, and timing may differ between possible continuations; terminal equality alone does not establish that a chosen manipulation improves a life.

Prospective tests can examine whether remaining aggregate increments have the required sign and attainable magnitude. They should not assign compensatory meaning to individual events after the fact, because the arithmetic entails direction, not purpose.

A joint mathematical fingerprint can make the cumulative claim more informative. Consider a declared probability law for a qualified reference class on the primary additive branch. Partition each stream's complete strict-pre-endpoint domain into m disjoint measurable parts, for the same prospectively fixed finite integer $m \geq 1$, assigning each exposure token and any cut-time atom exactly once under independently justified endpoint rules. Write X_j for the signed phenomenal mass in part j and assume $\mathbb{E}[X_j^2]$ is

finite for every j . Let X collect those masses, let $\Sigma = \text{Cov}(X)$, and let $\mathbf{1}$ denote the m -vector of ones. Then probability-one closure entails

$$\mathbf{1}^\top \mathbb{E}[X] = 0, \quad \Sigma \mathbf{1} = 0.$$

Conversely, these two exact population conditions imply $\sum_{j=1}^m X_j = 0$ with probability one: the sum has both mean zero and variance $\mathbf{1}^\top \Sigma \mathbf{1} = 0$. This is a direct derivation from additivity and elementary covariance identities, under the square-integrability assumption stated here. Each row also gives $\text{Var}(X_j) + \sum_{k \neq j} \text{Cov}(X_j, X_k) = 0$, exposing a whole-history dependency restriction rather than a requirement that every neighboring interval oppose the last.

This supplies a useful multivariate diagnostic when the complete-domain and measurement premises can be met. To distinguish zero from another fixed total, test the mean restriction alongside the covariance restriction using the independently calibrated origin. Fit an unconstrained measurement model, propagate correlated errors, and quantify uncertainty in the joint mean and covariance restrictions when comparing the linked prediction with equally flexible rivals.

7.1.5 — Mechanism-Neutral Limits and Falsifiers

Mechanism-neutral consequences fail when their premises fail, and those failure conditions should be recorded before data. Unbounded rates, incomplete domains, uncertain routing, or endpoint-inclusive jumps can invalidate a simple reserve bound (Protter, 2005; Kallenberg, 2002; Ames et al., 2019).

The target also faces direct falsification when an adequately identified prefix cannot reach the terminal set under any admissible continuation in the declared class. Widening the feasibility set after seeing the residual would erase that risk.

A recovery benchmark should include provably feasible, provably infeasible, and observation-limited histories. The pipeline should classify the first two and abstain on the third; a method that merely widens remaining-capacity bounds until closure becomes possible has no exclusion power.

A protocol-fixed falsifier should state the measurement precision, endpoint class, and admissible-route family under which an empty completion set would be decisive. Changing any of those after failure creates a new test rather than rescuing the old one.

An empirical infeasibility certificate requires more than a point estimate. The prefix, directional capacity bounds, endpoint support, and admissible route class must be identified tightly enough that every compatible continuation misses the target. When that standard is met, the counterexample attaches to the declared branch rather than to a person or an informal narrative.

A mechanism-neutral falsifier must be stated at the level of the target, not at the level of one route. If a qualifying stream, complete domain, valid representation, endpoint, and measured-to-latent bridge are all secured, and the identified terminal residual excludes zero, the exact branch fails for that declared class. By contrast, a failed reserve model, a flat hazard relation, or absent variance compression defeats only the assumptions that made those patterns necessary (Popper, 1959).

The prerequisite order assigns separate tests to origin, ownership, observation, and reachability. A terminal inference uses the components that meet their stated criteria and records any unresolved dependency.

Counterexamples should be built prospectively. Synthetic one-sign streams test whether the model recognizes impossible additive closure. Prefixes outside every completion set test reachability. Independent diffuse endpoints test the non-atomic obstruction. Paths with identical terminal residuals but different gross variation test whether the analysis confuses net and total variation. A recovery pipeline should identify which condition failed rather than returning one omnibus fit score.

Severe testing requires a serious rival. Before inspecting data, the plan should state what would favor ordinary mean reversion, a conditioned bridge, endpoint selection, observation-floor compression, frailty, or a flexible hidden-state model. The target earns credibility only if the same data and scoring budget can produce a rival-favored result (Mayo, 2018; Gelman et al., 2013). Rival plans should specify a protected-data failure signature strong enough to displace the preferred account rather than merely reduce its apparent advantage.

Mechanism-neutral limits make the program durable without protecting it. They preserve useful theorems, bounds, and diagnostics when a candidate route retires, while defining when the central branch must narrow or fail. That combination is appropriate optimism for a strong formal hypothesis: discovery remains possible, and defeat remains real. Preserving route-

independent results also prevents mechanism turnover from erasing formal constraints that later models must still satisfy.

Mechanism-neutral restrictions can be organized as an exclusion geometry. At each prefix, uncertainty in residual, remaining exposure, rate bounds, routing, and endpoint class defines continuations still capable of reaching the terminal target. As observations accumulate, that set may contract, split, or empty. An empty set under prospectively justified bounds directly falsifies the declared branch; a large set means the data are not yet discriminating. This geometry is useful because it reports what the claim requires without inventing a controller to supply it (Ames et al., 2019; Protter, 2005). Tracking the size and shape of this continuation set over time can provide a model-agnostic measure of how strongly observed history restricts possible completion.

7.2 — Random Endpoints and the Non-Atomic Obstruction

Endpoint timing is one of PTVC's sharpest discriminators. If an endpoint can occur independently at a continuously distributed time while a nontrivial pre-endpoint ledger evolves, exact closure at that random cut is extraordinarily restrictive (Kallenberg, 2002; Billingsley, 1999).

Let E_i be the prospectively declared positive-probability event on which the stream, frozen routing and truth domain, finite ledger, and pre-killing extension exist on a deterministic interval I , and write $P_i^0 = P(\cdot | E_i)$. Under this same law, let $\tilde{L}_i(t -)$ be jointly measurable, let $\mathcal{F}_i^L = \sigma\{\tilde{L}_i(s -) : s \in I\}$, and let T_i^{exo} be independent of $\mathcal{F}_i^L$. Assume that T_i^{exo} is I -valued, has a Lebesgue density $f_{T_i^{\text{exo}}}(t)$ positive for Lebesgue-almost every $t \in I$, and $P_i^0\{\tilde{L}_i(T_i^{\text{exo}} -) = 0\} = 1$.

$$0 = P_i^0\{\tilde{L}_i(T_i^{\text{exo}} -) \neq 0\} = \int_I P_i^0\{\tilde{L}_i(t -) \neq 0\} f_{T_i^{\text{exo}}}(t) dt.$$

The integrand is nonnegative. Therefore $\tilde{L}_i(t -) = 0$ for Lebesgue-almost every $t \in I$ on a P_i^0 -probability-one set of eligible paths.

The result does not apply when timing is state-coupled, independence fails, the endpoint contributes phenomenally, routing changes the stream, or the pre-killing extension does not exist. First-hitting or absorbing constructions, endpoint atoms, singular timing laws, continued experience, and endpoint-inclusive value remain separate branches requiring their own

premises rather than proof details that may be changed after a result is seen.

The implication is conditional, not empirical evidence that the assumptions hold. Removing independence, diffuseness, joint measurability, or the positive-density condition changes the branch and the required data. A protocol should test those premises and report which one fails before interpreting the theorem.

Table 7.1. Endpoint classes, ledger relations, and scientific burdens.

Endpoint class	Relation to ledger	Primary scientific burden
Independent diffuse cutpoint	No path dependence under reference law	Non-atomic obstruction
State-coupled hazard	Hazard depends on declared state	Recover coupling beyond frailty and selection
First hitting or absorption	Endpoint generated by boundary event	Avoid tautological endpoint definition
Atomic or singular support	Timing concentrated on restricted set	Specify support and transport limits

7.2.1 — The Random-Cutpoint Question

The random-cutpoint question asks what exact terminal closure would imply if a declared exogenous endpoint probe sampled the pre-killing left-limit ledger at a time not selected by that ledger or by its state. This is a branch-specific discriminator, not a universal premise of PTVC. Its force depends on a prospectively declared timing law, measurable ledger path, positive-risk class, and support conditions (Billingsley, 1999; Kallenberg, 2002).

The universal requirement is anti-tautology. Whatever endpoint branch is used, the truth-level endpoint must be defined and adjudicated independently of the ledger value whose closure is tested. First hitting, absorption, zero-surface, and last-exit routes supply no target evidence when the endpoint is defined by the same zero event and then scored on that event.

On the independent diffuse branch, almost-sure exact closure over a region with positive timing density imposes a severe restriction: the pre-endpoint ledger must be zero almost everywhere on that region for almost every eligible path. The result is conditional. It does not apply automatically to state-coupled, atomic, singular, first-hitting, or continued-experience branches.

Empirical work cannot prove full independence from finite data, but it can compare timing classes. A prospectively specified tournament can include independent diffuse timing, measured state dependence, latent frailty, first hitting, absorption, endpoint atoms, and observation-shutdown models, each with its own likelihood, diagnostics, and failure conditions.

Biological death or an external accident may be relevant timing variables without being the phenomenal endpoint. A cause of bodily death is not automatically a cause or observation of the end of qualifying experience. The endpoint bridge remains a separate object that can fail.

Negative controls should expose leakage. Variables known only after the endpoint, indicators of observation shutdown, and features affected by the ledger but not by the exogenous probe can

reveal a model that appears independent because the timing process or data pipeline was misclassified.

Selection, common causes, and unobserved frailty can manufacture apparent dependence or independence. The joint model must therefore include who enters the risk set, which endpoints remain observable, and how latent state affects both timing and observation. Narrative plausibility cannot replace recovery and held-out performance.

The question is productive under every outcome. Independent diffuse timing may pressure exact closure, a state-coupled model may earn support, or endpoint adjudication may remain inadequate. Each result narrows the space of viable endpoint architectures without allowing the endpoint to be chosen retrospectively to protect the terminal claim.

7.2.2 — Independent Diffuse Endpoints

An independent diffuse endpoint has no atoms and carries positive density over a time interval while remaining independent of the ledger path under the reference law. Such timing can sample any region of that interval (Aalen et al., 2008; Andersen et al., 1993; Revuz & Yor, 1999).

Before the stronger independence theorem, a simpler at-risk screen applies. If the regular conditional law of the pre-endpoint ledger at the endpoint assigns no atom to zero for the declared conditioning history, exact zero has conditional probability zero on that risk set. This result does not call the endpoint exogenous and does not require path-endpoint independence; it only rules out probability-one exact closure for the specified non-atomic

conditional law. Empty or unidentifiable risk sets return No adequate estimate (Kallenberg, 2002).

If the ledger were nonzero on a set of times with positive measure, an independent endpoint with positive density would hit that set with positive probability. Almost-sure terminal zero therefore excludes such nonzero regions.

Studies should distinguish physical event timing from truth-level stream termination. Independence of an accident time does not imply independence of the actual conscious endpoint if experience continues or ends earlier.

A device failure time may be diffuse and independent of experience but is merely an observation endpoint. Treating it as the truth endpoint would produce a false obstruction or false support depending on the analysis.

The empirical task is to estimate how much endpoint-ledger dependence reconciles the observed path occupation with the endpoint distribution under prospectively specified covariates and timing classes.

The approximate conditional-dependence result supplies a graded target. Fix the covariates, off-band threshold, and a pre-killing ledger process on a common time domain prospectively. Work on standard Borel path and covariate spaces with jointly measurable left-limit evaluation and the required regular conditional laws. For each covariate value, compare the actual joint law of endpoint time and ledger path with the product of their conditional marginal laws. Under the product law, the off-band probability is the ledger's off-band occupation weighted by that covariate-

specific endpoint-time distribution. Average this probability over the covariates and subtract the actual off-band endpoint probability. Define the mismatch as the positive part of that difference. The mean conditional total-variation distance is at least this mismatch, and conditional mutual information, measured in nats, is at least twice its square (Cover & Thomas, 2006).

The proof compares the same off-band event under the conditional joint and product laws. By the definition of total-variation distance, their probability difference is bounded by that distance. Averaging gives the mismatch bound. Conditional Pinsker's inequality and Jensen's inequality give the squared information bound. The result quantifies the residual endpoint–ledger dependence that a state-coupled or selection model must explain after the declared covariate adjustment.

A sharper information bound uses the same common pre-killing domain and conditional joint and product laws as above. Given covariates $C = c$, let P_c be the joint law of endpoint and ledger path, Q_c the product of their conditional marginals, and $E_\varepsilon = \{|L_{T-}| \leq \varepsilon\}$. Write $p_c = P_c(E_\varepsilon)$, $q_c = Q_c(E_\varepsilon)$, $p = E[p_c]$ and $q = E[q_c]$. Mapping both laws to this same event and applying joint convexity gives

$$I(T; L \mid C) \geq E[d_{\text{Ber}}(p_c \| q_c)] \geq d_{\text{Ber}}(p \| q).$$

$$d_{\text{Ber}}(p \| q) = p \log \frac{p}{q} + (1 - p) \log \frac{1 - p}{1 - q}.$$

Logarithms are natural, with the usual extended-value conventions. For $p = 0.9$ and $q = 0.1$, the lower bound is 1.758

nats, compared with 1.280 from the squared total-variation bound. If $p = 1$, it becomes $\log(1/q)$; shrinking bands with product-law probability tending to zero require unbounded endpoint-path information in this idealized comparison. Ordinary hitting or state-coupled timing can supply that dependence. The scientific task is to identify which timing mechanism predicts its observable consequences.

An observable companion tests endpoint enrichment against a specified ordinary event model. Fix a finite horizon u . Let N_i count prospectively classified events while observed, stopped at censoring; let Y_i be the predictable at-risk indicator. In one declared observed filtration, let $Y_i \lambda_{0i}$ be the null compensator density and $Z_{i,\varepsilon}$ a bounded predictable band indicator or filtered probability for a separately defined observed-window residual. Then

$$U_\varepsilon(u) = \sum_i \int_0^u Z_{i,\varepsilon}(t) [dN_i(t) - Y_i(t) \lambda_{0i}(t) dt].$$

When the compensator is correct and square integrability holds, $E[U_\varepsilon(u)] = 0$. With continuous compensators and orthogonal stream martingales, the predictable quadratic variation is

$$\langle U_\varepsilon \rangle_u = \sum_i \int_0^u Z_{i,\varepsilon}(t)^2 Y_i(t) \lambda_{0i}(t) dt, \quad \text{Var}[U_\varepsilon(u)] = E[\langle U_\varepsilon \rangle_u].$$

The random bracket is not itself an unconditional variance or an automatic normal-test justification. Estimated intensities require nuisance uncertainty and validated calibration. Freeze models on development records; include frailty, treatment, state-dependent

timing and informative observation loss. Cross-fitting controls some outcome reuse but cannot repair an incorrect hazard. Survivor-conditioned risk sets and shuffled endpoint dates do not reproduce the product-law comparison above. A positive score identifies residual event association relative to the declared model; the event and experiential bridges determine its stronger interpretation.

7.2.3 — The Non-Atomic Obstruction

Under the declared positive-density and measurability assumptions, the non-atomic obstruction says that probability-one exact closure at an independent endpoint requires the ledger to be zero for Lebesgue-almost every time on almost every eligible path. The issue is not merely low probability; it is structural incompatibility under the assumptions (Protter, 2005; Mayo, 2018).

The proof can be expressed by conditioning on the path and integrating the indicator of nonzero ledger values against the endpoint density. A positive-measure nonzero set yields positive failure probability.

The result should be checked under discontinuities, càdlàg paths, equivalence classes, and left limits. Endpoint atoms or singular supports require separate analysis.

A simulated ledger that is nonzero on a set of positive Lebesgue measure in the sampling interval has a probability strictly below one of exact zero at an independent uniformly sampled endpoint. The probability is zero only when its zero set has Lebesgue measure zero. Model recovery should reproduce that distinction.

Numerical rounding can hide the obstruction by turning a finite band into exact zero. The empirical band and the latent theorem must remain separate. For the non-atomic obstruction, non-discrimination supports only the common observable family, not either latent explanation.

The obstruction gives the program a rare hard discriminator. A branch that posits nontrivial ledger motion and independent diffuse timing must either show why the theorem's premises fail or accept the adverse implication; aesthetic appeal cannot carry that burden.

A public rendering of the non-atomic obstruction must show its assumptions, especially independent endpoint timing, positive density on declared support, and strict-pre-endpoint closure. Without those conditions the theorem becomes an overbroad claim that all random endings force an always-zero ledger.

The obstruction is a branch separator, not a universal refutation. If its assumptions fit the reference class, nontrivial exact closure cannot be maintained on that branch; if they fail, the analysis must name the alternative timing, support, routing, or endpoint structure that replaces them and derive its own predictions.

7.2.4 — State-Coupled, Hitting, and Absorbing Alternatives

State-coupled endpoints have hazards that depend on route state or ledger-related variables. Hitting-time endpoints occur when a process reaches a boundary, and absorbing endpoints remain in a terminal state thereafter. Each endpoint class induces a different likelihood, support geometry, and rival set; they cannot be pooled

as interchangeable explanations of closure (Kallenberg, 2002; Billingsley, 1999).

These alternatives evade the independent-cutpoint implication by changing the timing law. They also create new testable relations among state, hazard, approach geometry, and endpoint support.

A first-hitting rule can guarantee terminal zero by definition if the endpoint is set to the first time the ledger reaches zero. That is a tautology unless an independently motivated physical or psychophysical mechanism links termination to that surface.

Absorption can also be confused with observation shutdown. A flat observed series after device removal is not evidence that the latent process entered an absorbing neutral state.

Alternative timing branches are scientifically legitimate when they accept their own burden. They must predict more than the terminal value they were built to enforce.

Protocols should model endpoint hazard prospectively and compare state-coupled, frailty, disease-severity, treatment, and observation-selection accounts under the same information clock. A branch remains viable only if its distinctive state-hazard relation, support implication, or safe-intervention response recovers in simulation and transports beyond the fitted cohort.

7.2.5 — Atomic, Singular, and Protocol Consequences

Endpoint laws may contain diffuse, atomic, mixed, or singular components generated by scheduled procedures, biological thresholds, or classification rules (Aalen et al., 2008; Andersen et al., 1993; Revuz & Yor, 1999).

Atomic timing samples named times, so closure constrains those masses rather than an interval.

Support is decomposed by component and tied to declared timing mechanisms or protocol classes instead of being forced into one smooth hazard.

Anesthesia emergence, scheduled life-support withdrawal, and device-defined stops may concentrate protocol times, but their relation to the truth-level stream endpoint remains empirical.

Mixture class, support, and assignment are fixed or validated on held-out data. The estimand is component-specific mass and support, not a smooth hazard flexible enough to absorb every failure.

A branch matrix states the consequence of each component: diffuse mass can invoke the interval obstruction, atoms constrain named points, and singular mass needs carrier analysis. Mixed laws require mixed conclusions. Recording each component's weight, or the range of weights consistent with the data, makes the scope of each conclusion easier to assess. A mixture weight near zero may make a component practically minor, but it does not disappear from a universal or probability-one statement that quantifies over it.

Protocol timing remains distinct from truth timing. Device removal, withdrawal, discharge, report loss, and censoring may end observation while the stream continues, so terminal promotion requires an independent bridge. At each stop, the study can record the reason, the last usable measurement, and which aspects of the subsequent trajectory remain observable. This

record lets later return or resuscitation evidence reconnect to the same case without retroactively converting the protocol stop into the truth endpoint.

Report timing class, support, uncertainty, endpoint alternatives, and downstream sensitivity. Unrecoverable class membership narrows the result or yields No adequate estimate (Aalen et al., 2008; Revuz & Yor, 1999). A compact comparison across endpoint alternatives can show which findings remain stable and which are driven by the chosen timing rule. Where timing-class uncertainty is substantial, averaging across endpoint models can conceal incompatible assumptions; branch-specific results should remain visible before any synthesis. Reports should separate within-branch sampling uncertainty from between-branch sensitivity to endpoint classification, because precise estimates within individual branches can coexist with substantial uncertainty about which branch applies.

Stress tests vary density support, state dependence, frailty, selection, and competing definitions, recording where assumptions hold, fail, or remain untestable and how departures change off-band occupation (Billingsley, 1999; Kallenberg, 2002; Andersen et al., 1993). Varying assumptions individually and in combination helps distinguish a single influential choice from interacting sources of sensitivity. A useful stress grid reports both verdict changes and changes in off-band occupation, revealing influential assumptions even when the headline classification does not flip. A sensitivity ranking can then prioritize validation by identifying which assumptions move the protocol-fixed result closest to its decision boundary.

Multi-state models separately label clinical transitions, observation shutdown, and theorem-relevant endpoints. Nonresponse and protocol stops may reduce observation while the stream continues. An explicit return-to-observation transition lets resumed monitoring reconnect with the existing longitudinal record. That transition structure also prevents a temporary loss of observability from being mistaken for a truth-level endpoint. Where the declared endpoint bridge supports identification, separate estimates or bounds for observation loss, observation return, and endpoint entry can keep observation dynamics from being silently absorbed into endpoint hazard.

7.3 — Directional Reachability and Completion Sets

Remaining capacity is rarely symmetric. A stream may retain more opportunity for positive than negative contribution, or the reverse, because duration, physiology, environment, action, care, and endpoint hazard constrain directions differently (Aubin, 1991; Aubin et al., 2011).

Directional reachability therefore replaces a single scalar reserve with sets of attainable future signed increments. The result is not a forecast of what will happen. It is a statement about what remains possible under a declared model class.

Completion sets make prefix feasibility testable while preserving mechanism neutrality. They also reveal where an intervention changes the route space without guaranteeing a terminal outcome.

$$C_i(t, x) := \left\{ \Delta \in R : \exists \gamma \in A_i(t, x), \Delta = \int_t^{T_i^*} d v_i^\gamma \right\}$$
$$-L_i(t) \in C_i(t, x)$$

The completion set depends on current state x , admissible histories $\mathcal{A}_i$, endpoint support, and the representation. Closure is feasible only if the required opposite increment lies in that set.

7.3.1 — Directional Remaining Capacity

Directional capacity distinguishes how much positive and negative contribution remains attainable. A symmetric absolute bound can conceal the fact that one direction is practically or biologically unavailable (Aubin, 1991; Aubin et al., 2011).

Upper and lower reachability envelopes can be derived from signed rate bounds, state constraints, and endpoint support. They need not be equal or monotone.

Estimation requires models of future state, action availability, endpoint support, experienced exposure, and route uncertainty. The relevant state variables, admissible action set, and capacity bounds should be fixed before scoring; when those elements are weakly identified, the output should be directional bounds or an identified set rather than a point forecast.

Severe sedation may reduce both positive and negative observable variability while leaving asymmetric possibilities for pain, comfort, or awareness. A single reserve number cannot capture that structure.

Shrinking remaining capacity can arise from frailty, disease progression, treatment, or loss of social support without any fairness route. Those processes must be fit as equal-budget rivals. Reserve-linked evidence begins only where the joint directional pattern exceeds what those ordinary dynamics predict.

Directional capacity turns vague “room to balance” language into a geometry that can exclude routes and guide experiments without becoming a personal prediction.

7.3.2 — Positive and Negative Completion Sets

Positive and negative completion sets collect future increments reachable in each direction under the declared dynamics. Their geometry may be disconnected, state-dependent, sign-asymmetric, or constrained by action and endpoint timing (Ames et al., 2019; Altman, 1999; Kallenberg, 2002).

The sets may be represented through stochastic reachable sets, viability kernels, control bounds, or simulation-based envelopes. Each representation has assumptions about dynamics and intervention.

Protocols should report uncertainty in set boundaries and test calibration through held-out transitions. A set that contains every observed outcome is not automatically informative if it is too wide to exclude anything.

A rehabilitation program may expand positive experiential possibilities by restoring agency while also increasing short-term pain exposure. The two directional sets change differently.

Ordinary decision-making and social support provide comparison processes for changes in reachable experience. Their predictions can be evaluated alongside those of a specified terminal-control model.

Separate completion sets preserve the scientific distinction between what can happen and what the Law predicts must happen.

Sign-specific reachability should be reported as more than two maxima. The analysis should preserve gaps, disconnected regions, action constraints, and the probability or support attached to each attainable increment. A route may permit some positive movement while still excluding the exact opposite-signed increment required for closure.

Directional completion sets also reveal asymmetry that a single reserve number conceals. A path may retain ample capacity in one

sign while having no admissible route to the opposite-signed increment required by the current prefix.

When several active streams share finite resources or opportunities, individual reachability and joint solvency separate. The correct object is a vector of current residuals together with a joint attainable future-contribution set whose coordinates preserve stream ownership and provenance. Simultaneous completion requires the negative residual vector to belong to that joint set; summing coordinates or allowing one stream's surplus to cancel another's deficit would change the hypothesis (Aubin et al., 2011).

Shared constraints can create subset bottlenecks: each stream may have an individually completing continuation while no single feasible allocation completes all of them together. For any fixed direction, every jointly attainable increment has a projection no larger than the supremum over the joint set. If the required increment exceeds that supremum, simultaneous completion is infeasible. Testing directions supported on stream subsets supplies necessary support-function screens for the convexified joint set; exact membership remains the sufficiency target when the attainable set is nonconvex. Each coordinate retains its original stream ownership.

7.3.3 — Prefix Infeasibility and Reachability Bounds

A prefix is infeasible for exact closure under a route class when the required compensating increment lies outside the completion set. This is a direct route-failure condition (Protter, 2005; Mayo, 2018).

Infeasibility may be proved by analytic bounds, comparison theorems, justified dynamic programming, or certified numerical outer bounds. Failure to find a completing path in a finite simulation is not by itself a proof of impossibility. Empirical use must also carry endpoint and observation uncertainty into the bound.

Empirical adjudication should distinguish structural infeasibility from insufficient estimation. When a valid set cannot be narrowed enough for a decision, the verdict is Inconclusive evidence rather than compatibility by default. No adequate estimate applies when the target cannot be identified or validly bounded.

A short remaining support interval with bounded positive rate can make a large negative residual unreachable. The conclusion is conditional on the representation and rate bound, not a forecast about the person's future emotions.

Outcome-dependent enlargement of the completion set is a rescue move. The admissible dynamics and bounds must be fixed before the terminal residual is known. The analysis of prefix infeasibility and reachability bounds must report the unresolved equivalence class when the candidates cannot be distinguished.

Infeasibility is one of the program's clearest ways to lose. It transforms a grand terminal claim into a local, checkable exclusion.

Reachability figures should mark the declared completion set and the current prefix. If the required opposite-signed increment lies outside that set, the route fails locally; expanding the set after seeing the path would erase the falsifier.

A reachability failure should be reported at the narrowest justified level: the declared route cannot complete from the observed prefix under the protocol-fixed bounds. It does not by itself refute every route or the target law, but it removes any explanation that depends on unavailable same-stream capacity.

7.3.4 — Action Support Without Prescribing Action

Action support describes which transitions are structurally available from a reached history. It is not a recommendation, a moral instruction, or a claim that a person should choose experiences for the sake of terminal fit. Physically possible actions, ethically admissible actions, and actions that receive positive behavioral probability are different sets (Aubin, 1991; Aubin et al., 2011).

Under a frozen action-first regime, let each admissible action carry a completion probability after every downstream policy, physical transition, endpoint, routing, selection, and measurement-reactivity component is fixed. The policy-level completion probability is the policy-weighted mixture of those action-specific values.

That mixture equals one only when the policy assigns probability one, almost everywhere under its own action distribution, to actions whose complete frozen continuations close with probability one. A favorable action, nonempty reachable set, positive-probability closure, or topological-support statement is insufficient. The condition characterizes policy mass, not psychological motivation, conscious ledger awareness, moral instruction, or endpoint support.

Finite soft guidance has a ceiling. Reweighting actions by a finite positive power of their completion probabilities removes zero-completion actions but retains any baseline-positive action with an intermediate probability. Any retained intermediate mass prevents exact probability-one completion. Approaching one as guidance strengthens is limit-sure behavior, not finite attainment.

Almost-sure and limit-sure attainability must remain distinct. Almost-sure attainability requires one admissible policy that reaches completion with probability one; limit-sure attainability may only provide a sequence of policies whose probabilities approach one. If the admissible policy class is empty, the route is unavailable rather than almost-sure or limit-sure (Chatterjee et al., 2016; Asadi et al., 2025).

Partial observation creates a robust intersection problem. An observation-adapted policy can guarantee completion across all compatible histories only when their probability-one action sets have a nonempty admissible intersection and a measurable, time-consistent selector exists. If indistinguishable histories require disjoint safe actions, no policy based only on that observation can guarantee both.

Hard exclusion also creates an identification problem. When observed behavior assigns zero probability to putatively unsafe actions, their counterfactual completion probabilities are not identified without positivity, structural restrictions, valid instruments, experiments, or partial-identification bounds. The strongest safety claim can concern precisely the actions least observed.

Ethically bounded evidence may come from ordinary treatment variation, low-risk tasks, natural experiments, exogenous availability changes, or sealed recovery studies. Harmful, illegal, endpoint-manipulating, or lifetime-risk interventions remain prohibited. The route must accept unavailability rather than treating ethical limits as missing opportunities to test the theory.

Action support is useful because it makes a route vulnerable while preserving human authority. It can show that a claimed guarantee lacks the required policy mass, attainment, information, or selector. It can never delay care, rank people, induce burden, or turn a control model into a prescription engine.

7.3.5 — Completion Potentials and Prediction Without Forecasting

A completion potential is a declared state function tied to future reachability, such as a committor, viability value, harmonic function, or bounded reachability functional. Each has its own boundary condition, recursion, and interpretation; a flexible endpoint predictor does not acquire that status by name (Ames et al., 2019; Altman, 1999; Kallenberg, 2002).

Its strongest test is transported prediction under frozen state variables, feature times, endpoint, and action interface. Re-estimating the coordinate system in every cohort tests local predictors, while terminal or post-baseline information may not leak into a representation later praised for forecasting.

Generic prognosis, frailty indices, and latent embeddings are equal-treatment rivals. A completion potential earns distinction only by recovering its defining equation or recursion and adding

held-out sign-specific reachability, action-sensitivity, or boundary-access predictions beyond ordinary prognosis, with calibrated recovery. It remains a research object, never a personal forecast (Gneiting & Raftery, 2007; Vehtari et al., 2017).

Identification requires the defining recursion, calibration over reachable states, safe-intervention response, and recovery in synthetic worlds to distinguish the potential from alternative representations with similar endpoint probabilities (Aubin, 1991; Ames et al., 2019; Kallenberg, 2002).

Calibration uses only information available at prediction time. Cross-fitting limits direct leakage but cannot repair target leakage in features or cohort selection, so provenance records when every variable became available and which transformations were frozen.

Action invariance is stronger than passive discrimination. If safe interventions create the same measured state but different reachability, a potential that treats them alike lacks causal structure; if it changes when only observation changes, it may be tracking measurement. Matched interventions should therefore vary action support while preserving observation quality, making causal reachability harder to confuse with sensor response.

Held-out scoring should cover transition, hitting, and endpoint distributions, then transport a frozen potential against simpler prognosis, flexible machine learning, and path-conditioned rivals. Advantage must appear on restrictions unique to completion geometry, not general outcome prediction (Gneiting & Raftery, 2007; Dawid, 1984). A model that predicts generic prognosis well

but adds no accuracy on completion-specific events should not receive route support merely for overall fit.

Action-specific potentials require intervention data, defensible natural experiments, or explicit causal assumptions. Observational prediction alone cannot show which action changed the completion set (Pearl, 2009; Hernán & Robins, 2020). Where intervention identification is weak, the analysis should separate predictive reachability from causal controllability rather than treating one as evidence for the other.

When several potentials remain compatible, report a reachability set. Robust claims survive across the family; fragile claims depend on unverified geometry. The width and topology of that set can themselves be reported, showing whether uncertainty is a small quantitative margin or a qualitative disagreement about accessible routes.

7.4 — Endpoint Support and Accessibility

Reachability is not enough when the endpoint may arrive before the path reaches the required region. The support of endpoint timing, the intensity of termination events, and the accessibility of the boundary jointly determine whether a completion set is relevant (Andersen et al., 1993; Aalen et al., 2008).

Counting-process and compensator language provides a way to separate observed event occurrence from predictable hazard. It also clarifies how much time the process spends in states that make closure possible or impossible.

This section treats endpoint support as a scientific object in its own right. It keeps protocol stopping, truth-level termination, observation shutdown, and endpoint-inclusive jumps distinct.

$$N_i(t) = M_i(t) + \Lambda_i(t)$$

$$E\left[\int_0^T H_i(t) dN_i(t)\right] = E\left[\int_0^T H_i(t) d\Lambda_i(t)\right]$$

For predictable H_i that is nonnegative, or satisfies $E \int_0^T |H_i(t)| d\Lambda_i(t) < \infty$, the compensator identity relates event-weighted occupation to the predictable endpoint intensity. It does not identify the truth endpoint unless the counting process itself has been validly linked to stream termination.

7.4.1 — Endpoint Support as a Model Object

Endpoint support consists of the time-state points whose every open neighborhood has positive probability under the declared endpoint law. It constrains which prefix states the boundary

hypothesis must handle (Andersen et al., 1993; Aalen et al., 2008).

Support may depend on calendar time, biological state, route state, intervention, or latent hazard. It is distinct from the observed distribution in one selected cohort.

Estimating support is harder than estimating density because rare regions and censoring matter. Conservative support sets and sensitivity analysis may be more honest than smooth extrapolation.

A terminal study that recruits only after hospice enrollment observes a narrow support shaped by clinical referral and service access. That support cannot stand in for all stream endpoints.

A hazard model with arbitrarily thin tails can make every time technically possible and thereby evade a support failure. The analysis should distinguish practically occupied support from numerical tails introduced by smoothing. Sensitivity to tail thresholds and censoring is part of the conclusion.

Making support explicit reveals where the law is being tested and where it remains untouched.

Support uncertainty should be represented by nested lower and upper support sets. The inner set contains regions with well-supported endpoint risk; the outer set contains regions not excluded after censoring and rare-event uncertainty. Boundary-accessibility claims may use only the set appropriate to their error cost, rather than treating a smoothed density tail as established support.

Effective support may guide finite-sample design, but it must remain distinct from mathematical support. A low-probability region cannot be discarded when evaluating a claim that quantifies over that region. Any tail truncation must therefore be stated as a reference-class or approximation choice, with its effect on the conclusion reported.

7.4.2 — Counting Processes and Compensators

A counting process records endpoint-like events or transitions, while its compensator represents the predictable cumulative intensity under the filtration. The martingale residual captures departures from that predictable component (Protter, 2005; Jacod & Shiryaev, 2003; Revuz & Yor, 1999).

Compensator analysis can test whether endpoint events are related to route states beyond ordinary risk factors. It requires careful specification of the event, at-risk process, censoring, and time scale.

Endpoint support supplies a restriction without assuming independence from the ledger. On a declared stopping-time branch, let $T > 0$ be the true endpoint, $N_t = \mathbf{1}_{\{T \leq t\}}$, and Λ its predictable compensator. In that same filtration let L_{t-} be predictable. For finite u and $\delta \geq 0$, compensation of the nonnegative predictable indicator gives

$$\Pr(T \leq u, |L_{T-}| > \delta) = E \int_0^u \mathbf{1}_{\{|L_{t-}| > \delta\}} d\Lambda_t.$$

Exact closure makes this nonnegative integral zero almost surely, so endpoint compensator mass is confined to the pre-endpoint

zero set. If $d\Lambda_t = Y_t \lambda_t dt$ with ordinary finite intensity and that zero set has zero at-risk time occupation, no exact-closing endpoint can occur in the interval with positive probability. A singular or predictable hitting endpoint can have a different structure.

If $\lambda_t \geq \lambda_0 > 0$ throughout the off-band at-risk region and the displayed endpoint-failure probability is at most ε , positivity gives

$$E \int_0^u Y_t \mathbf{1}_{\{|L_{t-}| > \delta\}} dt \leq \varepsilon / \lambda_0.$$

A lower bound established only on a subregion gives only that subregion's occupation bound. The compensator and ledger predictability must use the same filtration: projecting a hidden endpoint to an observed hazard does not permit multiplication by a separately projected band probability. Ordinary hitting and zero-plateau shutdown mechanisms can satisfy the restriction. Their prospectively predicted timing and occupation relations, together with independent event and contribution calibration, determine the comparison.

Protocols should avoid using the same fitted ledger residual to define both the event and the predictor. Separate channels and cross-fitting reduce algebraic dependence.

In a clinical cohort, loss of responsiveness, device removal, physiological death, and adjudicated stream endpoint may be different counting processes. Combining them erases the very distinctions the formal model needs.

Frailty, treatment changes, care setting, and informative dropout can alter intensities. A state-coupled pattern may disappear once those rivals are modeled.

The compensator supplies a disciplined language for timing. It does not turn a medical event into a phenomenal boundary by notation.

Compensator diagnostics should therefore include time-varying covariates, treatment processes, observation intensity, and care transitions in the at-risk specification. Residual state coupling after those adjustments is the relevant signal, not the unadjusted hazard shape.

7.4.3 — Occupation Measures and Remaining Exposure

Occupation measures record how long a trajectory spends in regions of state space before the endpoint. They connect reachability geometry with the temporal opportunity to realize future increments (Kallenberg, 2002; Billingsley, 1999).

A state may be reachable yet have negligible occupation probability before termination. Conversely, long occupation in a region can dominate accumulated exposure even when transitions are rare.

Estimation can use continuous-time state-space models, inverse-intensity weighting, or simulation. Observation cadence and informative missingness must be part of the calculation.

A person may repeatedly enter a state associated with relief but remain there only briefly, while spending long intervals in

burdened states. Counting visits alone would misrepresent exposure.

Ordinary disease progression can alter occupation patterns without any terminal controller. Equal-treatment rivals should predict the same state-time summaries. A route-specific conclusion requires a pattern that those disease and care processes cannot reproduce under the same observation model.

Occupation analysis makes time visible inside boundary accessibility. It prevents the model from confusing possible states with experienced exposure.

Occupation displays should distinguish states that are mathematically reachable from states in which the process spends appreciable time. Coloring an entire state space as available without exposure weights overstates practical opportunity.

Occupation data can reject a reachability story even when the target state is topologically accessible. A path with insufficient occupation of the necessary region before the qualifying stream's endpoint lacks the temporal exposure required by the route. Reaching that region only after observation ends instead limits empirical adjudication unless the observation stop has been independently linked to the stream endpoint. Conversely, long occupation does not establish completion unless the permitted signed increments and endpoint relation are also validated.

7.4.4 — Boundary Accessibility and First-Hitting Geometry

A boundary is accessible when admissible trajectories can reach it before termination under the declared dynamics. First-hitting geometry describes approach, contact, crossing, and absorption.

Inaccessibility under those dynamics is a direct route failure; apparent access created only by numerical smoothing or changed boundary rules is not recovery (Andersen et al., 1993; Aalen et al., 2008).

Accessibility depends on drift, diffusion, jumps, state constraints, and endpoint hazard. A terminal set may be mathematically present yet polar or practically unreachable.

Simulation should estimate hitting probabilities and times under each declared route and rival, then test calibration on held-out transitions. Numerical schemes need dedicated checks near singular, sticky, reflecting, or absorbing boundaries.

A zero surface in a high-dimensional latent state can be crossed frequently, touched rarely, or never reached depending on dynamics. A plotted trajectory cannot establish the general geometry.

Defining the truth endpoint as the first hit makes accessibility tautological. A valid zero-surface termination route needs independent evidence that the phenomenal or physical system actually terminates there.

Boundary geometry gives the program concrete failure modes: inaccessible targets, wrong approach rates, or endpoint hazards that ignore the proposed surface.

Numerical recovery requires convergence diagnostics, discretization sensitivity, and benchmark cases with known solutions or trustworthy bounds. A simulated hitting pattern that changes materially with step size, boundary convention, or

interpolation rule is a numerical result, not evidence about the target route.

7.4.5 — Endpoint-Inclusive Value, Jumps, and Support Failure

A process may carry a jump or terminal atom, so strict-pre-endpoint and endpoint-inclusive closure are distinct branches. An endpoint-inclusive model must prospectively specify the mark distribution, timing law, sign, magnitude, measurability, ownership, latent-representation link, and compensator; an unobserved contribution cannot be added merely because it repairs the residual (Protter, 2005; Jacod & Shiryaev, 2003; Revuz & Yor, 1999).

Observation is often weakest at the jump. Communication loss, emergency intervention, device failure, sedation, or classification uncertainty can hide the final interval. A route that repeatedly needs an unseen contribution of exactly the required sign is fragile, and support failure must be allowed to retire it.

Sensitivity analysis should bound the unobserved contribution and vary mark and hazard laws rather than impute closure. Support must be separated into topological, effective, and observed forms: a state can be reachable yet negligible before the endpoint, or model-supported yet absent from the cohort because of censoring and care transitions (Aalen et al., 2008; Andersen et al., 1993).

Simulation should include inaccessible and rare boundaries, wrong support classes, missed jumps, device shutdown, sedation, and false endpoint labels. Negative-control channels and

administrative timing can reveal whether an apparent terminal atom belongs to the latent process or the measurement system. Simulated false atoms are especially useful because they test whether the pipeline can distinguish structural endpoint mass from censoring or device-induced concentration.

Outcomes remain branch-specific. Strict-pre-endpoint closure may fail while an endpoint-inclusive branch remains open; a first-hitting route may fail while state-coupled hazard survives; observation may be inadequate while truth-level status remains unresolved. Failure should localize the branch rather than create an all-purpose terminal rescue. This branch accounting should remain visible in summaries so a surviving alternative is not mistaken for rescue of the branch that actually failed.

A frozen decision table distinguishes strict-pre-endpoint, endpoint-inclusive, first-hitting, state-coupled, unresolved-endpoint, and No adequate estimate outcomes. None permits a terminal value to be selected solely because it closes the ledger. A predeclared table also makes endpoint changes auditable by showing which classification rule would have produced each verdict before the data were seen.

7.5 — Bridge, Selector, and Admissible-History Distinctions

Several mathematically distinct constructions can produce paths that approach a terminal target. A native dynamical law can drive the process. A bridge can condition ordinary dynamics on a future endpoint. A selector can retain only histories that close. An intervention can alter the path. A protocol can observe only the subset that survives to measurement (Doob, 1957; Föllmer, 1985).

These constructions are not rival notations for the same mechanism. They answer different causal and probabilistic questions, and they generate different counterfactuals away from the conditioned endpoint.

The section develops their distinctions because terminal curves are visually deceptive. Similar paths can arise from incompatible generative stories.

$$L^h f(x, t) = Lf(x, t) + a(x, t) \nabla \log h(x, t) \cdot \nabla f(x, t)$$

$$h(x, t) = Pr_{x, t}[X(T) \in A]$$

For the displayed diffusion case, $\mathcal{L}$ is the baseline spatial generator and $a = \sigma \sigma^T$ is its local covariance matrix. The formula is used where h is positive and sufficiently regular for the generator calculation. A zero-probability point endpoint instead requires a transition-density or other justified regular-conditional bridge construction; its zero event probability cannot be substituted into $\log h$. The Doob h -transform modifies the drift of the baseline process under the declared conditioning. It is a bridge construction whose predictions must be compared with an unconditioned native process and with selection mechanisms.

Table 7.2. Native dynamics, bridges, selectors, and observation rivals.

Construction	What changes	Key discriminator
Native dynamics	Forward generator or state law	Perturbation and off-endpoint behavior
Bridge or h-transform	Path law conditioned on terminal event	Dependence on endpoint information
Admissible-history selector	Support or weight of complete paths	Prospectively fixed path constraint
Policy/intervention	Action or causal transition law	Counterfactual response under controlled change
Observation selection	Which data are recorded	Missingness and gain mechanisms

7.5.1 — Native Dynamics Versus Conditioning

Native dynamics specify how the process evolves before any terminal outcome is imposed. Conditioning reweights those paths by a future event and can create an apparent pull toward the endpoint (Doob, 1957; Föllmer, 1985).

A conditioned bridge often has singular or steepening drift near the terminal time even when the baseline process has none. Observing steepening drift is therefore not uniquely diagnostic of a controller.

Protocols should separate data used to define the terminal condition from data used to test preterminal predictions. Prospective endpoint rules and held-out windows are essential.

A Brownian bridge and a feedback-controlled diffusion can both approach zero continuously. Their responses to perturbation, endpoint uncertainty, and off-target conditions can differ.

Endpoint conditioning can manufacture convergence by construction. A bridge earns empirical relevance only if a frozen conditioning rule predicts held-out transitions, interventions, or endpoint-support behavior beyond the event used to define it. Fit to the conditioned endpoint alone is circular.

The distinction protects causal interpretation. Terminal fit may reveal selection or conditioning rather than a law governing native dynamics.

The split should be enforced at the data level. One module fixes the endpoint class and terminal set; another, held out from that choice, scores pre-endpoint drift, covariance, or hazard predictions. Cross-fitting or external replication can recover power, but no observation may both define the ending and serve as evidence that the path anticipated it.

Flexible endpoint conditioning can reproduce terminal convergence after the fact. A native-process candidate must therefore predict transported transition, action, or intermediate-state restrictions that the corresponding conditioning rival does not reproduce. When the conditioning rival predicts the shared pattern and the native-process candidate fails those additional restrictions, the result favors the conditioning explanation for that component.

7.5.2 — Admissible-History Sets

An admissible-history model restricts the path space to trajectories that satisfy a global boundary condition. The restriction can be written as a constrained measure over complete

histories (Léonard, 2014; Léonard et al., 2014; Chetrite & Touchette, 2015).

Global path constraints differ from local control because they need not produce an ordinary forward-time mechanism. They may be time-symmetric, variational, or boundary-conditioned.

Empirical consequences must be derived from the constrained ensemble, including preterminal correlations, perturbation responses, and transport across endpoint classes.

A path-integral construction may assign zero weight to nonclosing histories while preserving ordinary-looking local dynamics. That is a coherent route only if it yields discriminating observables.

An admissible set chosen after observing the path is selection, not a risky law. The constraint and baseline measure must be specified independently.

An admissible-history route earns comparative support through predictions tested against specified local-dynamics and selection models.

The admissible-history set should also be nontrivial under counterfactual paths. A rule that retains only the realized successful trajectory has no predictive content and should fail simulation-based recovery before it is applied to observational data.

7.5.3 — Bridge Laws and Doob h -Transforms

Bridge laws describe a process conditional on reaching a terminal set. The Doob transform provides a precise way to express the

induced drift when the relevant harmonic or space-time function is known (Çetin & Danilova, 2016; Kallenberg, 2002).

The transformed process inherits assumptions from the baseline generator and the terminal event. Errors in either object can be absorbed into the apparent bridge dynamics.

Recovery studies should distinguish native dynamics, conditioned bridges, admissible-history selection, and ordinary mean reversion under realistic observation noise. The benchmark should include generators that produce similar terminal pictures for different reasons and require abstention when the available data cannot separate them.

A bridge to zero at a fixed time produces a characteristic pull that depends on remaining time. A random or uncertain endpoint produces a mixture of such pulls and may soften the apparent singularity.

The transformed drift can resemble the reserve-coupled drift. Conditional slope alone therefore cannot discriminate the routes. If the native and conditioned laws remain indistinguishable on held-out pre-endpoint data, the evidence cannot identify which construction generated the path.

Bridge mathematics is valuable because it turns a vague rival into an exact comparator. It also teaches the program not to claim uniqueness from one terminal signature.

Bridge diagrams should identify the baseline law, conditioning event, h-function, information set, and held-out tests. A terminal curve alone cannot reveal whether convergence was native, selected, or imposed by conditioning.

A bridge is therefore a calibrated rival as much as a mathematical tool. It can reproduce terminal attraction without showing that the unconditioned system contains a completion controller. Evidence for native dynamics requires predictions that survive when conditioning information, terminal selection, and endpoint leakage are withheld.

7.5.4 — Selectors, Policies, and Interventions

A selector determines which histories or actions enter a constructed model, a policy assigns action probabilities, and an intervention changes the data-generating system. These operations can produce similar trajectories while answering different causal questions. Each requires its own estimand, assumptions, and identification strategy (Doob, 1957; Föllmer, 1985; Pearl, 2009).

The downstream regime must be frozen before a policy-mixture claim is interpreted. Physical transitions, later policies, endpoint rules, routing, selection, and measurement reactivity all affect the continuation. If those components change with the behavior being explained, an apparent action effect can be a change elsewhere in the regime.

A policy-support condition says where probability mass lies under a declared factorization. It does not identify psychological motivation, conscious ledger access, endpoint knowledge, or computation of completion probabilities. If every available action already completes with probability one, the condition is exact but behaviorally silent.

Selectors require measurable and time-consistent construction. A completion-compatible set at one history is not yet a policy over time, and a sequence of locally favorable choices need not form an admissible recursively consistent strategy. Empty or nonmeasurable selector sets make the route unavailable.

Under partial observation, policies are adapted to observations or belief states rather than to hidden histories. A robust guarantee requires an action that remains completion-compatible across every live history represented by the observation. Disjoint history-specific action sets reveal an information failure or another causal locus, not a reason to call the policy approximately guaranteed.

Observed choices do not by themselves identify intervention effects. Selection adjustment, inverse weighting, g-methods, randomized contrasts, instruments, and sensitivity analysis are useful only when their assumptions match the operation and data. Conditioning on survivors or communicative participants is not evidence that an intervention generated their terminal pattern (Hernán & Robins, 2020).

Off-policy evidence has a bounded warrant. Data generated under one behavior policy identify another policy only under adequate overlap or a defensible structural bridge, with uncertainty from weighting, model extrapolation, and unobserved actions carried into the result. A route observed under one policy therefore cannot silently become an all-policy or all-intervention conclusion (Hernán & Robins, 2020; Manski, 2003).

Care policies can create state-dependent treatment that resembles feedback control. That complication belongs in the causal model, but care remains governed by clinical need, consent, and ordinary human purposes. A route cannot claim cleaner identification by withholding effective treatment or manipulating endpoint timing.

The scientific gain comes from tracing the same curve to distinct generating operations and asking where their predictions diverge. Native dynamics, conditioning, selection, policy, and intervention should compete under common endpoint, observation, and scoring rules so that a favored route earns its status rather than borrowing it from the analysis design.

7.5.5 — Observation Selection and Equal-Information Rivals

Observation selection occurs when measurement probability, quality, timing, or channel depends on latent state, route state, care, or endpoint proximity. Silence, immobility, dropout, sedation, device removal, and workflow may create apparent compression without latent change, so they first describe the measurement process (Little & Rubin, 2019; Aalen et al., 2008).

Equal-information comparison begins with a frozen contract listing variables, availability times, preprocessing, endpoint labels, missingness, feature construction, tuning, and scoring. A favored route cannot receive a future-informed reserve while rivals receive only baseline covariates.

Information clocks are synchronized. Every model receives each covariate when it would have been prospectively available and

uses the same endpoint and missingness history; otherwise leakage purchases superiority.

The observation process is modeled with its own intensity, quality, channel state, and reasons for stopping. Fatigue, refusal, loss of consciousness, clinical burden, battery failure, and scheduling gaps have different implications, and collapsing them can make declining observability look like declining phenomenal variance.

Denominator flow reports who entered each risk set, who remained observable, why observation stopped, and what other channels still showed. A model that succeeds only among easy-to-observe participants may fail where the terminal claim is most demanding.

Candidate negative controls include technical variables such as battery level and channel outages, provided the protocol independently justifies that they affect observation without changing latent valence. Staffing and prompt schedules require the same exclusion argument because care and measurement reactivity can also alter experience. Outcomes sharing measurement burden but not the proposed completion relation supply another check.

Bridge, frailty, adaptation, observation-collapse, reserve, hidden-state, and selection rivals receive comparable information, tuning, calibration, complexity control, and recovery tests. Equal tables are insufficient when one model receives a richer latent state or endpoint construction (Blackwell, 1953; Gneiting & Raftery, 2007).

Held-out evaluation reports calibration, discrimination, coverage, and transported restrictions rather than only fit. Joint sensitivity is necessary because modest latent, endpoint, and observation errors can combine into a persuasive terminal pattern.

Bounds, pattern-mixture alternatives, selection models, and negative controls can narrow unobserved selection but cannot create missing information. The verdict states which conclusion survives the prospectively specified observation envelope.

Model ambiguity identifies the evidence needed to separate contenders. Comparing them under the same assumptions and observation process makes that next test informative (Mayo, 2018; Tsiatis, 2006; Rizopoulos, 2012).

7.6 — The Reserve-Coupled Route as One Candidate

The reserve-coupled route is a candidate realization of the mechanism-neutral constraints. It introduces a declining nonnegative reserve U_i , a signed arithmetic reference process Y_i , and a positive scale constant c^{LU} , then defines a route state L_i^{rc} as their product. This construction generates linked drift and innovation restrictions for empirical comparison (Protter, 2005; Revuz & Yor, 1999).

The route must remain dimensionally coherent, sign-flexible, independently measurable, and explicit about stochastic calculus. A geometric Brownian reference is unsuitable as the default signed coordinate because it remains positive; Y_i must be able to cross zero unless another representation is declared.

The displays introduce the reference route and its finite-variation special case; §7.6.3 gives the general product-rule conditions and the additional covariation terms.

$$L_i^{rc}(t) = c^{LU}U_i(t)Y_i(t), c^{LU} > 0, dU_i = -r_i^U dt, dY_i = \sigma_i dW_i$$
$$dL_i^{rc} = -(r_i^U/U_i)L_i^{rc}dt + c^{LU}\sigma_i U_i dW_i$$

In the reference case with a continuous finite-variation reserve, r_i^U is the nonnegative reserve-depletion rate and c^{LU} fixes units between reserve times the normalized coordinate and the route state. The product approaches zero if reserve reaches zero at the relevant route boundary and Y_i does not diverge fast enough to defeat the product. Coincidence with the truth-level endpoint is a separate bridge.

7.6.1 — Declining Reserve as Route Coordinate

Reserve represents remaining capacity in this candidate route, not a person's worth, moral credit, life value, or eligibility. It must be defined through independently measurable biological, functional, or process variables (Protter, 2005).

A finite-variation reference reserve satisfies a declared depletion law and remains nonnegative before the endpoint. More general reserves require separately declared dynamics and a product-rule calculation that retains any nonzero covariation terms.

Construct validation should specify raw indicators, units, transformations, context of use, confounds, and transport limits. Reserve cannot be whatever fitted quantity makes the product close.

Frailty indices, physiological capacity, communication ability, and care intensity may all correlate with endpoint proximity while measuring different constructs.

Reserve proxies can confound age, disability, medication, disease severity, access to care, and social support. Those variables are not interchangeable measures of remaining completion capacity. Apparent depletion that follows them but fails the route's independent construct, cross-equation, sign-specific, perturbation, or transport tests should favor the bias, frailty, or prognosis rival.

Reserve is useful only as a testable route coordinate. If it cannot be measured independently, the route may remain mathematically coherent and empirically unadjudicable.

Independent reserve validation should precede the product fit. Before outcome inspection, the protocol should state whether reserve is reflective, formative, or merely prognostic; which indicators can move it; and which perturbations should change it without directly changing the ledger. Failure of those cross-construct predictions retires the coordinate even if the product equation fits.

7.6.2 — Signed Arithmetic Reference Dynamics

The normalized process must support positive and negative values because the ledger-like product can lie on either side of zero. An arithmetic diffusion is the simplest sign-flexible reference case (Karatzas & Shreve, 1991; Jacod & Shiryaev, 2003; Särkkä, 2013).

The reference process may later include drift, jumps, stochastic volatility, or state dependence, but each addition changes predictions and must be justified prospectively.

Estimation should recover the process on held-out data and test whether residuals retain structure. A flexible latent process can absorb every mismatch and make the route unfalsifiable.

A geometric Brownian motion remains strictly positive and therefore cannot serve as a default signed reference without a transformation that changes interpretation.

Ordinary mean reversion and opponent processes can generate signed arithmetic dynamics without reserve coupling. They are natural rivals rather than approximations to the preferred route.

The arithmetic reference is a laboratory for consequences, not a claim that phenomenal experience literally follows Brownian motion.

The signed arithmetic reference should be judged by the reserve-linked restrictions it produces, not by familiar Brownian or mean-reverting notation. Held-out tests should ask whether jointly predicted drift, innovation, reserve, and boundary behavior recover; ordinary Ornstein-Uhlenbeck, opponent-process, and flexible state-space dynamics remain strong rivals whenever those linked restrictions fail.

7.6.3 — Product Rule and Induced Ledger Dynamics

The product rule reveals which assumptions make the compact induced equation possible. A continuous finite-variation reserve has zero quadratic covariation with the reference process; continuous martingale components or shared jumps can produce additional covariation terms (Revuz & Yor, 1999; Kallenberg, 2002).

Writing the general semimartingale product before the special case prevents hidden process-class changes. Filtration, adaptedness, integrability, and boundary behavior belong to the statement.

Simulation and estimation should use the same calculus as the derivation. Discretization can introduce spurious drift or conceal covariation near small reserve.

Correlated physiological shocks and experiential shocks would create a covariation contribution absent from the simplest equation. Ignoring it can make the fitted relaxation look stronger.

A product identity is true by construction. Its empirical burden lies in whether independently measured reserve and normalized dynamics satisfy the linked restrictions.

The induced equation exposes cross-equation tests and a concrete task: establish its relation to the formal phenomenal integral.

The reserve route should be displayed as a coupled system, not as one attractive stochastic differential equation. U , Y , L , their filtration, jump assumptions, shared shocks, and cross-equation restrictions determine whether the product-rule derivation is valid.

The empirical signature changes with the process class. Jumps in reserve, shared shocks between reserve and reference dynamics, or filtration changes introduce terms absent from the smooth finite-variation case. Estimation should therefore begin from the general product identity and justify every term set to zero, rather than reading the simplified equation backward as evidence.

7.6.4 — Drift Dominance, Diffusion Compression, and Scaling

As reserve shrinks, the reference relaxation coefficient can grow while the innovation coefficient shrinks in the finite-variation case. This produces a distinctive conjunction rather than one terminal curve. The route is challenged jointly by the scaling of relaxation, innovation, and reserve, so a terminal decline in variance alone is non-discriminating (Protter, 2005; Revuz & Yor, 1999).

If reserve behaves like a power of remaining time, reserve-space variance and time-domain variance have different exponents. Confusing them leads to incorrect claims about scaling.

A bridge can also show steepening drift, and observation-gain collapse can show shrinking variance. The joint pattern must outperform those rivals on held-out data.

Time-varying depletion and volatility can mimic almost any exponent if chosen after inspection. Their functional forms and priors need prospective constraints.

Scaling is useful when it connects multiple observables with fewer degrees of freedom than the rivals. It is decorative when it merely redescribes the fitted path.

Drift, innovation, and reserve should be estimated jointly, with reserve error and covariance propagated through the induced dynamics and with functional forms frozen before testing. Support requires transported cross-equation restrictions across resolutions and cohorts, not one visually narrowing trajectory or one fitted exponent.

7.6.5 — Noise, Ratio Fragility, Transport, and Retirement

Observation noise sets a floor on estimated compression, while observation gain may collapse as communication or movement declines. Larger samples do not remove systematic observation bias (Karatzas & Shreve, 1991; Jacod & Shiryaev, 2003; Särkkä, 2013).

For $U_i > 0$, the normalized ratio $|L_i^{\text{rc}}|/(c_{LU}U_i)$ equals $|Y_i|$ under the exact product representation and is fragile when numerator

and denominator are uncertain near zero. It remains secondary and is reported with both components, covariance, reserve-floor probability, and bounded or Fieller-type uncertainty.

Transport requires a common reserve coordinate, unit, endpoint relation, observation map, and perturbation interface. Refitting coefficients is permitted; redefining reserve after outcome inspection creates a new route rather than evidence of transport.

Late sensor dropout can imitate declining innovation while latent dynamics remain uncertain. Negative controls and joint observation models are therefore essential.

The route narrows or retires when reserve lacks independent validation, endpoint synchronization fails, normalized dynamics become unstable, cross-equation restrictions fail, or serious rivals predict as well or better.

Retirement preserves narrower achievements, including better reserve measures, endpoint models, observation analysis, and a clearer account of what the target alone does not determine.

Criteria are fixed before protected analysis, with thresholds for construct invalidity, denominator instability, cross-equation failure, endpoint desynchronization, nontransportable parameters, and recovery-qualified rival parity. A route without operational failure conditions is not exposed to defeat (Mayo, 2018; Nosek et al., 2018).

Near the boundary, joint errors-in-variables or state-space models propagate ledger and reserve uncertainty together. A stable ratio can hide two unstable quantities, while an explosive ratio may reflect a denominator artifact rather than failed route dynamics

(Fieller, 1954; Gleser & Hwang, 1987; Carroll et al., 2006; Särkkä, 2013).

Transport varies endpoint class, instrument, cadence, clinical state, and observation regime, not merely geography. The same coordinate and cross-equation restrictions must survive with reserve uncertainty carried into drift and innovation estimates.

Useful subcomponents can survive route retirement. A reserve proxy may retain prognostic value, an observation model may improve terminal-window inference, or a state-space decomposition may clarify error. The record migrates each survivor to its narrower status rather than treating retirement as erasure (Mayo, 2018).

7.7 — Discriminating Signatures and Equal-Treatment Rivals

The reserve realization is discriminated by a conjunction, not by a showcase curve. Negative drift can arise from bridge conditioning or ordinary regulation; shrinking variance can arise from observation loss; reserve correlation can reflect shared disease severity; and endpoint concentration can be imposed by construction. Distinctive evidence therefore requires these components to cohere under independent reserve measurement, prospective endpoint rules, recovery-qualified estimation, and held-out equal-information rival comparison. Failure of a prerequisite remains visible rather than being offset by strength elsewhere (Gneiting & Raftery, 2007; Vehtari et al., 2017).

This section specifies the joint prediction, the signature family for the protocol, and the competing models to be tested. Later chapters develop the study design. The goal is to make favorable evidence informative by comparing the predictions of the candidate and its alternatives.

The reference reserve route has a compact cross-equation prediction. For differentiable $U(t) > 0$, depletion rate $r_U(t) \geq 0$, and constants $c > 0$ and $\sigma > 0$, define its mean-reversion coefficient and innovation amplitude by

$$a(t) = \frac{r_U(t)}{U(t)}, \quad b(t) = c\sigma U(t), \quad \frac{dU(t)}{dt} = -r_U(t).$$

Then

$$a(t) = -\frac{1}{2} \frac{d}{dt} \log[b(t)^2].$$

The same reserve trajectory therefore links relaxation strength to the rate of change in innovation variance. Estimate the drift and innovation features without imposing this identity, propagate their joint estimation uncertainty under the common observation model, and compare the linked prediction with alternatives that allow the features to vary separately. The shared reserve trajectory supplies a testable relation between the two features.

Table 7.3. Candidate signatures, strong rivals, and required evidence.

Signature	Reserve-realization expectation	Strong rival	Needed evidence
Steepening relaxation	κ_i^U grows like r_i^U/U_i under the declared depletion law.	Bridge or homeostatic reversion.	Reserve-linked prospective slope.
Shrinking innovation	$\sigma_{L,i}$ shrinks like $c^{LU}\sigma_i U_i$ in the reference case.	Sensor loss or sedation.	Observation-robust innovation estimate.
Cross-equation restriction	$\kappa_i^U \sigma_{L,i}$ equals $c^{LU}\sigma_i r_i^U$ under the printed assumptions.	Flexible heteroscedastic model.	Protocol-fixed drift-diffusion coupling.
Held-out performance	Joint fingerprint predicts unseen data.	OU, bridge, frailty, medication, observation-only models.	Fair model recovery and rival comparison.

7.7.1 — Steepening Relaxation

The reference case with a continuous finite-variation reserve predicts a relaxation coefficient $\kappa_i^U = r_i^U / U_i$. As reserve falls, the coefficient steepens when the depletion rate falls proportionally more slowly than reserve, remains constant, or increases. This is a conditional route signature, not a generic prediction of PTVC (Protter, 2005).

Negative drift is not the signature. Ordinary homeostasis, regression to a set point, endpoint-conditioned bridges, and smoothing artifacts can all create apparent motion toward zero. The reserve-specific claim is that relaxation strength tracks independently measured reserve depletion as one component of the full prospectively specified conjunction.

A study should therefore estimate κ or an analogue jointly with reserve. It should ask whether the relaxation steepens as U falls, whether the relation survives confounds, and whether the estimate is available prospectively rather than only after endpoint alignment.

The depletion rate r_i^U also matters. If r_i^U changes with time or clinical state, κ may steepen, flatten, or jump. A model that treats r_i^U as constant after observing a favorable slope is too rigid in the wrong way and too flexible in the wrong way. The depletion-rate model must be declared.

Steepening relaxation should be reported with uncertainty, window sensitivity, and rival fits. A Brownian bridge toward zero has its own diverging pull as T approaches. If the bridge receives

the same endpoint information and fits as well, drift cannot support the reserve realization.

The strongest result would be a preterminal, reserve-linked, held-out prediction of relaxation behavior that a bridge, OU process, frailty model, and observation-gain model fail to match. Anything less is component pressure, not validation.

7.7.2 — Shrinking Innovation and Variance Structure

The paired reference signature is shrinking latent innovation amplitude. In the displayed special case, the route-state diffusion coefficient is $\sigma_{L,i} = c^{LU} \sigma_i U_i$, so it contracts with reserve when σ_i and c^{LU} remain stable and the observation bridge is adequate (Protter, 2005; Karatzas & Shreve, 1991).

This signature is stronger when paired with drift because it concerns a different part of the dynamics. Drift describes directional pull. Innovation describes stochastic amplitude. A model that gets one but not the other may be capturing generic reversion or generic quieting rather than reserve-coupled dynamics.

Shrinking innovation must be distinguished from shrinking observed movement. A person may move less, speak less, respond less, or tolerate fewer sensors near the endpoint. That can shrink measured innovation while latent variation remains unknown. The observation model from the previous section is therefore a prerequisite.

Time-varying σ is allowed only when independently identified. If σ is simply reduced near the endpoint to fit variance, the model

loses content. A stochastic-volatility extension must specify why volatility changes, how it is measured, and what rival it beats.

The innovation signature also depends on sampling cadence. Irregular observation can miss bursts. Late windows may be shorter and less dense. Missingness may be informative. A properly fitted model should account for unequal intervals and not treat silence as smoothness.

A favorable innovation result supports the reserve-scaled stochastic-amplitude component under the tested observation model and alternatives.

7.7.3 — Cross-Equation Restrictions

The reference case yields a cross-equation restriction linking relaxation and innovation through the same reserve: $\kappa_i^U = r_i^U / U_i$ and $\sigma_{L,i} = c^{LU} \sigma_i U_i$, so their product equals $c^{LU} \sigma_i r_i^U$ in the constant-volatility special case. The restriction lowers flexibility because drift and diffusion cannot be fitted independently (Protter, 2005).

That restriction is useful only under its printed assumptions: finite-variation reserve, coherent reserve units, a stable or prospectively modeled σ_i , and estimators for κ_i^U , $\sigma_{L,i}$, and r_i^U that do not share hidden outcome information. If an assumption fails, the equation becomes a sensitivity target rather than a confirmatory restriction.

$$\begin{aligned}\kappa_i^U(t) &= r_i^U(t) / U_i(t), \\ \sigma_{L,i}(t) &= c^{LU} \sigma_i U_i(t), \\ \kappa_i^U(t) \sigma_{L,i}(t) &= c^{LU} \sigma_i r_i^U(t)\end{aligned}$$

A cross-equation restriction is scientifically valuable because it reduces freedom. The model cannot choose drift and diffusion separately if one reserve process determines both. Rival models must therefore be scored on the joint restriction, not on whichever component happens to fit.

The restriction should be estimated with joint uncertainty and covariance. Near low reserve, errors in U_i affect both estimated relaxation and innovation, so independent standard errors can overstate agreement. A state-space or errors-in-variables analysis should report whether the apparent product relation survives that shared dependence on reserve.

If the restriction fails, the result is informative. The drift component might fit while innovation does not, or innovation might fit while drift does not. That would suggest ordinary homeostasis, observation noise, stochastic-volatility extension, or failure of the reserve product in that reference class.

A stronger model could replace constant σ with a structured volatility function. But that is a new claim version. It must produce its own cross-equation restrictions rather than simply absorbing any mismatch.

The cross-equation relation belongs in the prospectively specified fingerprint, with direction, tolerance, and failure rule fixed before endpoint alignment. A favorable terminal slope and variance contraction remain separate component observations when the relation between them is free; they become route-specific only when the same reserve process predicts both within declared uncertainty.

7.7.4 — Prospective Endpoint Separation

A signature evaluated after aligning everyone at the endpoint can be useful, but it is not the same as prospective prediction. Endpoint-conditioned processes can mimic terminal pull and variance shrinkage. The reserve realization must therefore show what it can forecast before the endpoint is known or without using outcome-selected alignment (Gneiting & Raftery, 2007; Vehtari et al., 2017).

Prospective separation can be achieved in several ways. The endpoint rule can be protocol-fixed through independent unity-proxy channels. Reserve and ledger estimators can be cross-fitted. Model parameters can be trained on one subset and tested on held-out trajectories. Forecasts can be made for windows not used to define the endpoint.

The Brownian bridge rival should be given the endpoint information allowed by the study design. If the PTVC candidate uses endpoint alignment while the rival does not, the comparison is unfair. If both use the endpoint and perform similarly, the PTVC-specific interpretation weakens.

A stronger result would show that reserve-linked dynamics predict endpoint approach better than an endpoint-conditioned bridge using only information available before the endpoint. That result would support the predictive contribution of the reserve realization and motivate replication across endpoint settings.

Prospective separation also prevents public misreading of beautiful retrospective graphs. A curve smoothed after death may teach researchers about possible dynamics, but it cannot serve as

a confirmatory forecast. The figure label must tell the reader whether the curve is filtered, forecast, smoothed, or retrospectively adjudicated.

Terminal alignment organizes trajectories for comparison. Evaluate the aligned predictions under the same information rules for every model, with endpoints and evaluation criteria specified independently of the result being tested.

Prospective separation protects the model from hindsight. If the endpoint is selected, shifted, or retrospectively aligned to the path that looks most favorable, a Brownian bridge or conditioning rival may win before the Law is even tested. The endpoint rule must be declared before the signature is evaluated or protected by cross-fitting that prevents leakage.

7.7.5 — Observation-Model Robustness

The joint signature must survive observation rivals. A reserve-linked pattern that disappears when sedation, frailty, medication, missingness, sensor quality, or observation gain is modeled is not a reserve-realization success. It may be a measurement lesson (Talts et al., 2018; Wilson & Collins, 2019; Munafò et al., 2017).

Observation-model robustness requires more than adding covariates. The study should include generative observation models capable of producing false compression. It should simulate data from those rivals and verify that the analysis can distinguish them from latent reserve coupling.

Sedation is a particularly strong rival. It can reduce responsiveness, physiology, movement, report, and observable distress. It may coincide with terminal care and reserve decline.

A model that treats sedation merely as missingness can overinterpret the quieting it helps create.

Frailty and age-only models are also strong. Declining variance may reflect general biological weakening, not PTVC-specific reserve coupling. A fair comparison gives those models real parameters, real data access, and a chance to win.

Robustness should include negative controls. Channels that should respond to observation gain but not latent valence, device-quality indicators, care-timing variables, and non-affective physiological streams can reveal whether the supposed ledger signature is tied to measurement conditions.

A result that survives these checks is still component-level. It says the reserve signature was not explained away by specified observation rivals. It does not remove the need for replication, endpoint discipline, measurement validity, or formal bridge resolution.

7.7.6 — Held-Out Superiority to Strong Rivals

The final empirical test is comparative. After development, the reserve realization must outperform strong rivals on held-out trajectories under the declared comparison rules. This separates an explanation fitted to existing observations from a prediction that earns support on new evidence (Nosek et al., 2018; Mayo, 2018).

The rival set should include endpoint-conditioned bridges, OU and homeostatic processes, age-only decline, frailty-only decline, medication-only decline, observation-shutdown models, shared-driver disease models, and unconceived-model sensitivity. Each

rival should be implemented as a generative model where possible.

Held-out superiority should be evaluated on components that matter: drift, innovation, reserve coupling, endpoint forecasting, variance shape, observation robustness, and prediction calibration. A single aggregate score can hide a prerequisite failure. The gates should remain noncompensatory.

Compare the reserve realization with OU and bridge alternatives using common predictive and calibration criteria. At equivalent performance, a simpler adequate model merits preference in the tested reference class.

Model recovery is a precondition. If synthetic data generated by the reserve model cannot be recovered by the analysis, then a real-data failure is uninterpretable. If synthetic data generated by rivals are falsely classified as reserve support, then a real-data success is suspect.

The public verdict should be exact. Held-out advantage can support the reserve-realization component. Rival parity narrows or suspends PTVC-specific interpretation. Rival superiority retires the tested realization in that reference class unless a new, prospectively risky version is proposed.

7.7.7 — Conjunctive Signatures Rather Than Single Curves

Ordinary state reversion is not accumulated-ledger closure. An Ornstein-Uhlenbeck state can return toward its mean while the variance of its time integral continues to grow, so reduced reactivity near an endpoint may reflect medication, fatigue,

disease, family presence, or good care rather than PTVC (Uhlenbeck & Ornstein, 1930; Gillespie, 1996).

A candidate route must therefore survive a modular conjunction: route-state validity, drift and innovation restrictions, endpoint separation, observation robustness, and held-out rival superiority. The component vector remains visible because a win on drift cannot average away failed innovation, endpoint leakage, or an invalid bridge.

The signature package is a dependency graph, not a bag of p-values. Shared measurements create dependence, while route validation and endpoint assumptions feed multiple tests. Joint analysis and sealed-world model recovery must show that repeated views of one signal are not being counted as independent confirmation.

Exploration may compare proxies, lags, volatility models, and kernels, but confirmation freezes the surviving objects, tuning ranges, and scores in a new cohort or protected site. Negative controls should include false endpoints, shuffled route states, synthetic dropout, bridge generators, and ordinary mean-reverting worlds; support in those worlds disqualifies the pipeline.

Replication should include an adversarial team with independent code, alternative reasonable implementations, and no obligation to preserve the preferred interpretation. Transport tests the mapped coordinate, units, depletion direction, endpoint relation, and joint restriction, not merely shared vocabulary (Nosek et al.,

2018; National Academies of Sciences, Engineering, and Medicine, 2019).

A strong rival victory is informative. If OU, bridge, frailty, observation, or flexible hidden-state models reproduce the joint signature with fewer unsupported assumptions, the route narrows or retires while measurement, endpoint, and recovery knowledge remains.

Verdicts should preserve states such as route failed, drift compatible but innovation failed, endpoint separation unavailable, rival favored, bridge failed, and open-set inadequate. A single confidence score would restore the flexibility the conjunction was designed to remove.

Held-out superiority earns route attention only after simulation recovery, calibrated uncertainty, prospectively fixed conjunction logic, negative controls, transport, and a real possibility that a strong rival wins (Gneiting & Raftery, 2007; Talts et al., 2018; Mayo, 2018).

7.8 — Formal Failure, Open Theorems, and Route Retirement

The chapter closes with a research agenda and explicit tests of the reserve realization. Its precision creates opportunities for derivation, simulation, and independent evaluation. Progress requires retaining adverse results as evidence that can revise or reject the tested proposal (Popper, 1959; Lakatos, 1978). Publishing reproducible derivations and simulation code would let independent teams examine the same proposal and locate disagreements in specific assumptions or results.

The formal questions identify the next mathematical and empirical tasks: connect the phenomenological integral to the product semimartingale, validate the reserve construct, establish endpoint synchronization, and characterize when the normalized process remains finite or explodes. Joint comparison with rival models tests the resulting predictions. Any formal change proceeds through the declared change-control process. These tasks can be ordered by dependency, allowing measurement work to focus on the quantities that the mathematical analysis identifies as useful for distinguishing competing predictions.

This section separates mathematical questions, measurement questions, rival-model outcomes, and changes requiring formal review. Each result can guide the next version of the research program. A narrowed claim remains scientifically useful when its revised scope and supporting evidence are explicit, and every substantive change requires a visible record and a new test where appropriate.

Table 7.4. Route falsifiers, open problems, and retirement consequences.

Problem or falsifier	Why it matters	What would count against the realization	Route after failure
Integral-product bridge	Connects formal ledger to stochastic candidate.	No defensible mapping of path class and dimensions.	Formal change request or reduced status.
Reserve construct validity	U must be a measured object, not a fit label.	Proxy instability, bias, or shared measurement artifact.	Not instrument-ready.
Endpoint synchronization	Reserve collapse must meet independent endpoint.	Systematic early or late mismatch.	Reference-class narrowing.
Rival dominance	Science is comparative.	Strong rivals match or beat predictions.	Retire or revise candidate version.

7.8.1 — Integral-to-Route Bridge Failure

The largest open formal problem is the bridge between the phenomenological ledger and the reserve product. The received ledger is an integral over unity-gated valence rate. The product realization is a stochastic process involving reserve and a normalized signed component. The open task is to specify and prove the conditions under which the product represents the received ledger (Popper, 1959; Lakatos, 1978).

The bridge problem includes path class. An ordinary integral of an integrable rate has finite variation. A Brownian product can

have nonzero quadratic variation before the endpoint. If both are to describe the same construct at the same level, the mapping must explain that difference.

Possible resolutions include a reduced-form interpretation, a coarse-grained limit, a generalized derivative relation, a semimartingale integral, or a state-space bridge that connects phenomenological rate to stochastic increments. Each option has assumptions and consequences.

The product provides a candidate reduced-form realization of consequences associated with the latent cumulative process. The interpretations above define several routes for developing a stronger bridge. A later bridge must name its assumptions, preserve the distinction between route state and target ledger, and generate predictions that can fail independently of terminal fit.

A bridge theorem would need filtration, integrability, regularity, approximation norm, dimensional interpretation, endpoint behavior, and measurement implications. It would also need to explain how a latent valence-rate contribution gives rise to the normalized diffusion component.

The product model supplies component signatures while the relation to the formal integral is investigated. Resolving that relation is a central mathematical task for the program.

The bridge problem is not cosmetic notation. The received formal ledger is an accumulated phenomenological object, while the product realization is diffusion-bearing and reserve-coupled. Until a theorem, approximation regime, or formal amendment

connects them, the product should be called a candidate realization rather than the definition itself.

7.8.2 — Reserve Construct Invalidity

Reserve must be a separately measurable biological or functional quantity with stable enough units for its intended use. Its definition and validation criteria should be fixed independently of terminal-model fitting, giving the reserve model a meaning that can be tested across settings (Mayo, 2018; National Academies of Sciences, Engineering, and Medicine, 2019; Vehtari et al., 2017).

A reserve construct needs raw indicators, transformations, units, uncertainty, context of use, calibration population, confounds, transport limits, and failure rules. A frailty index, metabolic marker, arousal proxy, neurological reserve measure, or composite clinical score may all be candidates, but none is automatically the reserve U of the model.

Confounds are central. Medication, disability, illness, age, care quality, social support, sensor placement, and clinical workflow can all affect reserve proxies. Some are part of the biological process; some are observation artifacts; some are social burdens that the model must not erase.

Reserve construct validity also has equity implications. A proxy that systematically misreads disabled bodies, older bodies, sedated bodies, nonverbal persons, or people with different baseline physiology would create both scientific and ethical failure. Such a proxy cannot support public claims.

Validation should be local before transport. A reserve measure that works for one endpoint class should not be generalized to

sudden death, coma, dementia, pediatric care, nonhuman animals, or artificial systems. Reference class names must travel with results.

If reserve cannot be measured independently in a reference class, the reserve realization may still be a formal possibility, but it is not empirically testable there. The correct verdict is not support; it is not-yet-instrument-ready or unusable for that context.

7.8.3 — Endpoint Synchronization Failure

Endpoint synchronization failure occurs when reserve collapse and independently defined truth-level stream endpoint do not align in the relevant way. This can happen if reserve reaches near-zero while conscious stream activity continues, or if the endpoint occurs while reserve remains materially positive (Munafò et al., 2017; Nosek et al., 2018).

Such failure is not a mere inconvenience. It strikes a central premise of the reserve realization. If the product closes because *U* collapses, but the endpoint is elsewhere, then the realization has not explained terminal valence closure at the endpoint. It may explain a different process.

Synchronization failure should be measured prospectively where possible. Reserve trajectories and endpoint-proxy trajectories should be compared under rules that allow early reserve collapse, late endpoint, sudden endpoint, ambiguous endpoint, and no-estimate outcomes.

Clinical complexity matters. Sedation, resuscitation, withdrawal of life support, fluctuating consciousness, delirium, and low-signal states can all create uncertainty. The study should not force

synchronization by choosing the most convenient endpoint after seeing reserve behavior.

If synchronization repeatedly fails in a reference class, the reserve realization narrows for that class. A different reserve definition may be proposed, but only as a new version with new risky predictions. Reinterpreting the same failure under a new reserve label without public versioning is ad hoc rescue.

Synchronization failure is scientifically valuable because it tells the program where its candidate mechanism is wrong or incomplete. A theory that permits such a result is stronger than one that hides every mismatch inside endpoint language.

7.8.4 — Normalized-Process Explosion

Normalized-process explosion is the failure mode already illustrated by the Y equals one over U counterexample. As reserve declines, the normalized process grows too quickly for the product to approach zero. The product may remain away from zero or become unstable (Popper, 1959; Lakatos, 1978).

Explosion can be mathematical, biological, or observational. Mathematically, the process class may permit growth rates that defeat closure. Biologically, terminal distress, delirium, pain, fear, or conflict may create large normalized excursions. Observationally, denominator error can make a stable process look explosive.

The model must distinguish these possibilities. A joint posterior for L_p , U , and Y can reveal whether explosion is robust or driven by reserve uncertainty. Observation-quality metrics can reveal

denominator artifacts. Clinical covariates can reveal treatable causes.

The decisive closure question is whether the product approaches zero. Divergence of Y alone is insufficient: for $U > 0$, the mathematical example $Y = U^{-1/2}$ gives $UY = U^{1/2}$, which still tends to zero as U tends to zero. A finding can reject a bounded- Y or fixed-volatility subbranch without rejecting every closing product. Failure of the required product limit, after accounting for denominator and observation error, is adverse to the declared reserve route.

7.8.5 — Rival-Equal or Rival-Better Prediction

The reserve realization earns distinct evidential support when it improves explanation or prediction relative to capable rivals under a fair comparison. Equal or better rival performance identifies which claims remain unresolved and where revision is needed (Mayo, 2018; National Academies of Sciences, Engineering, and Medicine, 2019; Vehtari et al., 2017).

Rival equality is already important. If an endpoint-conditioned bridge, observation-gain model, frailty model, or OU homeostatic model performs equally well on held-out data, the reserve realization has not distinguished itself. It may remain a candidate, but its public status must narrow.

Rival superiority is stronger. If a rival predicts terminal dynamics better while using fewer PTVc-specific assumptions, the tested reserve realization should be retired for that reference class. Retirement of a component is not defeat of every metaphysical possibility, but it is real scientific loss.

The comparison must be fair. Rivals need enough flexibility to be serious. They should receive the same covariates, endpoint information, observation model, and training data permitted to the PTVC candidate. A weak rival set creates false victory.

A favorable reserve result must also be robust to unconceived-model sensitivity. The book cannot pretend that its named rivals exhaust possibility. It can require that current serious rivals be beaten and that new rivals receive a route into future updates.

The verdict follows the comparison. Equal performance leaves the tested models unresolved; better rival performance directs revision or retirement; better prospective performance by a recoverable reserve candidate supports the specified components.

7.8.6 — Formal Change Control and Route Retirement

Formal change control prevents repairs from silently replacing the target or route. A new process class, reserve definition, endpoint convention, bridge, or policy assumption receives a new identifier and dependency record. Improvement is welcome; invisible replacement is not.

Retirement begins with a typed failure. The reserve may be unmeasurable, the product may lack a bridge to the phenomenal ledger, endpoint synchronization may fail, the normalized process may become unstable, or a strong rival may perform as well or better. Each failure withdraws a different object.

Formal and empirical failures follow different routes. A false theorem is corrected formally; an unidentifiable route is narrowed, reclassified, or retired; and an open theorem stays open

until proved under matching assumptions. Simulation cannot promote it.

A supersession matrix compares retired and successor routes across object, endpoint, filtration, state, parameter, observable, intervention, and failure condition. Results depending on an altered column are rerun or marked nontransportable, while valid components may survive independently.

Evidence maturity and theory maturity remain separate. Replicated route failure may justify retirement while the mechanism-neutral target stays open, and a coherent theorem or simulation cannot raise empirical maturity without valid data.

Negative results are packaged for reuse. Code, synthetic worlds, failed recovery cases, parameter regions, numerical pathologies, observation burdens, privacy constraints, and recruitment failures receive stable identifiers, turning the completed research path into a reusable benchmark (Munafò et al., 2017; National Academies of Sciences, Engineering, and Medicine, 2019).

Retirement should sharpen the next study. Observation failure calls for a better observation model, endpoint failure for better adjudication, and rival victory for the earliest transported restriction on which the surviving models make distinguishable predictions.

Corrections propagate to summaries, diagrams, presentations, websites, translations, and excerpts. Retired equations and claims are removed or relabeled, and cached copies point to a successor or withdrawal notice.

No route verdict authorizes a personal inference. Success would not predict destiny or rank lives; failure would not erase independent advances in measurement, endpoint science, reachability, or rival comparison, or change any participant's dignity.

An open-theorem register names each proposition, proved assumptions, missing extension, countermodels, numerical evidence, and specialist review. Keeping several routes under common object and observation rules reduces pressure to rescue any one.

Part II closes with explicit exits and preserved value. The target can narrow, representation can yield an identified set, an endpoint branch can fail, a route can retire, a rival can win, and a study can return No adequate estimate. The hypothesis can therefore learn without moving its target while measurement, endpoint science, reachability, and recovery continue to advance (Lakatos, 1978; Mayo, 2018).

Part III — Measurement and Psychometrics

Measurement is the point at which a compact, consequential candidate hypothesis accepts disciplined contact with the world. Parts I and II established the scientific jurisdiction, formal target, and mechanism-neutral consequences of PTVC. Part III now builds the bridge from privately lived experience to evidence that can be inspected, challenged, corrected, and, when necessary, declined. Its task is not to manufacture a number that resembles the target, but to determine which features of experience can be represented, which observations carry information about them, which comparisons remain licensed, and which claims must stop at an identified set or a No adequate estimate outcome (American Educational Research Association et al., 2014).

The opportunity is larger than a single instrument. A rigorous measurement program can clarify the structure of valence, mixed affect, duration, memory, response shift, missingness, and cross-context transport even before PTVC receives a terminal test. It can reveal when first-person reports, choices, physiology, neural activity, clinical observations, and contextual records converge on one construct, when they illuminate different constructs, and when their disagreement is itself the most informative result. The achievement is a transparent relation among target, observation, model, uncertainty, and decision, not a device that claims possession of another person's inner life.

Lived experience remains the target because circumstances become burden or relief through consciousness. Housing, illness, disability, safety, money, law, relationship, medication, culture, and time remain indispensable causes and constraints, but none is interchangeable with the experience it helps shape. The scientific

challenge is therefore double. The program must preserve the reality of material conditions while refusing to treat appearance, preference, productivity, memory, or a sensor trace as the phenomenal object itself. That distinction protects both causal explanation and the person whose experience cannot be reduced to an administrative proxy.

The Part proceeds in three movements. Chapter 8 asks what kind of object lived experience can be for science, including ordinal, interval, scalar, vector-valued, mixed, path-dependent, and partially identified representations. Chapter 9 turns those possibilities into a qualified measurement pipeline that separates measurement map, estimand, analysis map, estimator, observation process, uncertainty, and decision rule. Chapter 10 asks when any resulting coordinate can travel across time, language, culture, disability, treatment, device, clinical state, or site. The sequence prevents a precise instrument from becoming a precise answer to the wrong question.

Measurement also creates an exposure of its own. A prompt interrupts a day. A sensor changes clothing, sleep, or movement. A clinic loses time. A family notices a device. A participant decides whether honesty is safe. A model may increase burden precisely when distress is greatest. Contemporary human-participant guidance and good-clinical-practice standards make participant welfare, proportionality, meaningful consent, and data quality part of the scientific design rather than decorative ethics. Part III treats burden, refusal, withdrawal, and care events as features of the observation process that can alter both validity and

dignity (World Medical Association, 2024; International Council for Harmonisation, 2026).

A qualified result must carry both its boundary and its measurement history. The output should identify the construct, measurement model, context of use, population, state range, instrument and model versions, scoring and transformation rules, observation window, missingness regime, uncertainty, comparison tier, and prohibited uses. Current clinical-outcome-assessment and psychometric reporting guidance reinforces this fit-for-purpose discipline. Transparent reporting of measure selection, modification, scoring, and validity evidence is part of the warrant for a conclusion, not administrative detail. These standards make later PTVC tests interpretable and help identify measurement relations that need improvement (U.S. Food and Drug Administration, 2025b; Gagnier et al., 2025; Flake & Fried, 2020).

Plural evidence is a strength when roles remain distinct. First-person report can be the closest available witness to phenomenal content, yet report can be shaped by language, memory, demand, fear, fatigue, and access. Physiology can reveal embodied dynamics, yet it can also reflect arousal, medication, exertion, or disease. Behavior and choice can reveal constraints and priorities, yet they are not identical to felt value. Context can explain a trajectory, yet it cannot testify for the person. The pipeline becomes stronger by modeling these relations explicitly rather than forcing every channel into a single agreement score.

Uncertainty is productive when it is typed. A confidence interval describes uncertainty for a target under a specified model and

repeated-sampling guarantee; an identified set contains every target value still compatible with the observed evidence and declared assumptions. The two objects may be combined, but they are not interchangeable. Channel conflict can reveal lag, state dependence, or construct mismatch. Informative missingness can reveal that the calmest-looking record is the most selectively observed. A No adequate estimate outcome identifies where additional evidence is needed before a numerical conclusion is available. The book therefore treats abstention, narrowing, local comparability, and instrument retirement as scientific accomplishments when the evidence cannot support a stronger claim (Manski, 2003; Imbens & Manski, 2004).

Part III establishes an anti-score boundary: research estimates may support declared scientific uses, but they cannot rank persons, set eligibility or care priority, assign spiritual or civic status, or transfer value across streams. No cross-stream comparison can settle PTVC. Privacy, refusal, correction, contestability, and human review govern use. The measurement system must justify its limited authority; participants do not owe legibility to a model.

The scientific workmanship is intentionally field-spanning. Affective science contributes construct and temporal models. Psychometrics contributes validity, invariance, linking, response-process evidence, and measurement-error analysis. Statistics contributes partial identification, missing-data models, uncertainty propagation, and sensitivity analysis. Clinical science contributes context, edge states, treatment effects, and care priorities. Privacy engineering and reproducible research

contribute purpose limitation, provenance, version control, audit, and correction. The value of the Part lies in joining these disciplines without pretending that any one of them has already measured a lifetime phenomenal ledger.

The central benchmark is simple to state and demanding to satisfy: every number must reveal the chain that earned it. A reader should be able to ask what construct was defined, why the measure was selected, what was observed, how the observation was scored or transformed, which estimand was targeted, which assumptions connected measurement to the latent object, what went missing, how versions changed, which rival explanations remained, and what decision the evidence actually licensed. Any modification to items, channels, scoring, exclusions, anchors, or preprocessing belongs in the same record. If a link is hidden, the claim becomes smaller. If a link fails, the result narrows or abstains rather than borrowing confidence from the rest of the pipeline (Flake & Fried, 2020; Gagnier et al., 2025).

Measurement can expose burdens that appearance misses, improve affective and clinical science, identify differences across people and states, and create a shared language for correction. Each advance makes the PTVC research question more tractable while contributing to the wider science of lived experience. Part III develops the instruments and evidence needed to pursue that opportunity.

Chapter 8 — Lived Experience and the Evidence Baseline

A person sits beside a hospital bed after good news that arrived too late. Relief, grief, love, exhaustion, anger, and gratitude coexist. A momentary rating may ask for one number. A memory interview may emphasize the ending. Heart rate may reflect sleeplessness. A choice may reflect duty rather than comfort. None of these observations is useless, yet none can claim to be the whole experience. Chapter 8 begins with that ordinary scientific difficulty: before measurement can be accurate, the target must be represented in a form that the evidence could genuinely support (Russell, 1980; Cacioppo & Berntson, 1994).

Lived experience is the target because the Law concerns what is carried within a conscious stream. This does not demote housing, food, safety, rights, medicine, disability support, relationship, or material justice. Those conditions shape experience through bodily, social, temporal, and interpretive pathways, and they remain independently important even when no phenomenal estimate is available. The chapter asks how goods and harms become lived conditions without turning either the circumstance or the report into a substitute for the experience itself.

Representation comes before instrumentation. The first question is not which questionnaire, sensor, or model should be used. It is whether the relevant relations are ordinal, interval-scaled, cardinal, additive, rate-like, state-like, partially ordered, vector-valued, or path-dependent in the declared context. The measurement model must also state why observations relate to the target. Reflective indicators are treated as effects of a latent state; causal or composite indicators help constitute the score; network models represent mutually dependent components. Those

structures license different reliability, validity, and aggregation claims. Ranking does not license integration, interval structure does not create a neutral origin, and a useful within-person coordinate does not automatically support between-person level comparison (Krantz et al., 1971; Bollen, 1989; Borsboom, 2005).

Mixed affect makes the issue empirical rather than philosophical decoration. Positive and negative experience can coexist, and bivariate representations allow that possibility to be measured instead of forced onto opposite ends of one line. Grief can carry love; relief can carry guilt; chosen effort can carry pain and agency; awe can carry fear; numbness can coexist with physiological threat. The chapter uses these cases to compare one-axis, bipolar, multidimensional, and set-valued models through prediction, discrimination, stability, and recovery rather than through aesthetic preference (Cacioppo & Berntson, 1994; Larsen et al., 2001).

Several neighboring constructs must remain visible without being collapsed. Valence is not arousal. Pain intensity is not suffering. Salience is not depth. Desire is not pleasure. Craving is not relief. Boredom is not neutral absence. Meaning can deepen endurance or deepen loss. Dignity and agency can change the lived character of similar sensory states. Parsimony remains valuable, but every omitted dimension needs an explicit role: irrelevant to the declared use, a moderator, a context variable, an auxiliary outcome, or a noncompensatory constraint. The model becomes simpler only after it shows what its simplification preserves.

Time adds a second representation problem. Much of a life is carried in ordinary duration rather than memorable peaks: the

fourth hour of waiting, the fiftieth morning of fatigue, the long calm after danger, the background freedom created by reliable care. A momentary rate, an episode summary, a remembered evaluation, and a decision utility answer different questions. The chapter keeps duration weighting, sampling coverage, recency, peak-end effects, recovery, order, and hysteresis separate so a vivid ending cannot silently stand in for the experienced path (Fredrickson & Kahneman, 1993; Kahneman et al., 1993).

Memory remains scientifically important precisely because it is not the original moment. Recollection can integrate meaning, compress duration, emphasize peaks, respond to later events, and guide future choice. Those transformations may be psychologically and morally significant, but they do not rewrite the experience that occurred. The chapter treats memory as an auxiliary construct, a possible mechanism, and a rival source of apparent closure. Path-functional comparison asks which summaries predict held-out reports, behavior, physiology, and future states without equating retrospective coherence with a complete phenomenal ledger.

Fairness appraisal and social comparison belong in the baseline because they can alter experience, attention, memory, and action. Inequity aversion, reciprocity, punishment, gratitude, entitlement, relative position, and just-world beliefs can generate local affective dynamics that mimic a fairness process without implying terminal closure. Cross-cultural and developmental recurrence establishes human salience and supplies comparative hypotheses. It becomes PTVC-specific evidence only if prospectively specified predictions outperform serious cultural,

psychological, and methodological rivals (Fehr & Schmidt, 1999; Henrich et al., 2005; Hafer & Bègue, 2005).

The chapter's evidence baseline is deliberately multimethod. First-person report, pairwise judgment, trade-off choice, physiology, behavior, clinical observation, relational context, and intervention response can each contribute to construct validity. Convergence is informative only when the channels are expected to reflect the same target and their shared errors are modeled. Components that cause or constitute a score need not correlate like reflective indicators, while channels aimed at different constructs should not be rewarded for artificial agreement. Divergence can therefore reveal a hidden dimension, response process, medication effect, or observation artifact. No composite gains sovereignty merely because it contains more inputs (Campbell & Fiske, 1959; Cronbach & Meehl, 1955; Bollen, 1989).

Material justice and care do not wait for the representation problem to be solved. A person need not produce a valid valence score before receiving food, shelter, medicine, protection, accommodation, relief, or belief. The chapter separates scientific warrant from ethical obligation so that measurement can improve explanation without becoming a gate to care. That separation also improves data quality because fear of losing treatment, housing, employment, or standing changes what people report and whether they participate (National Commission, 1979; World Medical Association, 2024).

The work remains valuable under every PTVC outcome. A supported scalar bridge would open stronger within-stream

accumulation tests. A vector or set-valued result would narrow the branch while preserving richer affective science. A failed construct would show where the target cannot yet be operationalized. A rival explanation might outperform the proposed representation and teach the program how human experience is organized. Each result advances knowledge when the target, assumptions, channels, and withdrawal conditions remain visible.

Chapter 8 moves from the status of lived experience through representation, mixed affect, scalarization, temporal structure, construct validity, and fairness cognition. Its final product is not a universal score. It is a disciplined menu of candidate representations, evidence roles, failure criteria, and human boundaries that later instruments must respect. Chapter 9 can then build a measurement pipeline whose outputs are useful because the chapter has already decided what they are allowed to mean.

8.1 — Why Lived Experience Is the Target

The phrase lived experience can sound soft until one notices how much science and policy already depend on substitutes for it. Institutions count income, diagnosis, attendance, discipline, productivity, reported satisfaction, legal status, and behavior. Those measures matter, but none of them is the felt life itself. *The Law of Fairness* enters precisely where visible condition and carried burden can come apart (Cacioppo & Berntson, 1994; Russell, 1980).

This section therefore establishes the target without collapsing the world into feeling. Food, housing, safety, legal protection, medical care, political rights, social belonging, and bodily integrity matter materially before they become data. Yet their relevance to the Law runs through a further question: what burden or relief do they create within a conscious stream? A science of fairness must hold both levels at once.

The difficulty is that many common proxies are attractive because they are administratively convenient. Preferences are observable through choices. Life satisfaction is easy to ask about. Public appearance can be seen by others. Social status can be recorded. But each proxy can miss hidden fear, adapted deprivation, shame, chronic pain, numbness, exhaustion, or the quiet relief of safety. The section treats those misses as scientific information.

A mature target must also protect dignity. To say that experience is central is not to say that rights should wait for measurement, or that material harm must justify itself by producing a measured inner state. The target is scientific, not a gate to care. The section

makes this boundary explicit so the later measurement chapters do not become permission to doubt people until an estimator agrees.

8.1.1 — Experience Over Appearance

Appearance is the first temptation of social measurement. A life can look stable from the outside because the rent is paid, the appointments are kept, the child is fed, the smile is reliable, and the work product arrives on time. None of that is false. The error begins when visible functioning is treated as if it exhausts the burden carried by the stream (Russell, 1980; Borsboom, 2005).

The Law of Fairness places lived experience at the target because hidden burden often survives inside acceptable appearance. A person may comply because dependence makes refusal costly. They may succeed while carrying chronic pain. They may perform calm under threat because panic would invite punishment. These are not literary exceptions; they are ordinary routes by which external observers can miss the carried cost.

A scientific target must therefore separate public biography from felt trajectory. Biography records what happened, what was obtained, what role was held, and what others could see. Felt trajectory asks what those events became within consciousness: fear, relief, numbness, humiliation, agency, safety, pressure, boredom, awe, or peace. The two can correlate strongly without being identical.

This distinction leaves the moral force of visible harm intact. An injured body, unsafe home, coercive law, or lack of money already demands attention and repair. Material conditions and lived

experience answer different scientific questions: the conditions establish real causes and obligations, while the Law-facing inquiry asks how those conditions are carried within a conscious stream. Neither level replaces the other.

An estimator of lived experience needs an explicit bridge from observed appearance to the target. Attendance, output, facial expression, and medication dose can be useful clinical or contextual evidence, with roles distinct from phenomenal measurement. The chapter states the proposed bridge and the observations that would require it to be revised or rejected.

The operative question is exact: where is burden carried when appearance conceals it? Composure, productivity, or social fluency cannot answer that question by themselves. Giving lived experience priority over appearance is therefore not a romantic gesture; it is the first rule preventing an external record from being mistaken for the phenomenal quantity the hypothesis concerns.

Proxy variables become most dangerous when they are accurate about the wrong target. Employment, attendance, facial action, speech rate, sleep duration, and medication use may predict distress in a population while failing for a particular person or context. The correct scientific question is therefore not whether a proxy correlates with burden somewhere, but whether its context-specific bridge remains calibrated, transportable, and contestable where the claim is made. A high-performing proxy can still be a poor representation of lived experience (Campbell & Fiske, 1959; Borsboom, 2005).

8.1.2 — Goods Become Lived Conditions

External goods matter because bodies, minds, and relationships are not sealed containers. Housing changes sleep. Money changes horizon. Law changes fear. Care changes dependency. Food changes energy. Safety changes attention. Friendship changes recovery. The science of lived experience cannot float above these goods as if feeling were detached from the material world (Cacioppo & Berntson, 1994; Campbell & Fiske, 1959).

The key word is become. A good does not enter the ledger merely by being listed. It becomes a lived condition through pathways of access, expectation, bodily state, social meaning, perceived control, and continuity. A disability accommodation may reduce pain, but it may also reduce humiliation. A legal protection may reduce danger, but it may also reduce vigilance. A cash transfer may relieve hunger, debt pressure, or shame depending on the surrounding life.

This conversion is not one-to-one. The same resource can carry different experiential meaning across people and contexts. A hospital room can feel safe, abandoned, controlled, humiliating, or hopeful. A public benefit can feel like relief or surveillance. An apology can repair dignity or reopen dependence. The Law needs measurement that asks which conversion occurred rather than assuming that the good itself carries a fixed affective value.

Goods are upstream conditions, not substitutes for experience. Medicine, law, economics, and social policy can describe resources, protections, opportunities, and harms with their own objective measures. This volume asks the additional question of

how those conditions become lived within a conscious stream. Keeping the levels distinct prevents two errors at once: reducing justice to feeling and reducing feeling to a checklist of circumstances (Sen, 1999; Borsboom, 2005).

A construct map should therefore include both external and experiential variables. Money, shelter, safety, clinical care, time, privacy, relationship, disability support, and legal status may be covariates, moderators, or causes of experience. They are not automatically the target. The target is the stream-level consequence under declared representation.

This is why the chapter can be both materialist and phenomenological. It refuses the idea that fairness is only external distribution, but it also refuses the idea that feeling can be separated from the conditions that shape it. Goods become lived conditions through pathways that must be studied, not assumed.

The route from goods to experience is often mediated and heterogeneous. Secure housing may improve sleep through temperature, privacy, reduced threat, and continuity, while the same move can also disrupt community or identity. Clinical treatment may reduce symptoms while increasing fatigue, dependency, or fear. Modeling these pathways prevents a material variable from becoming a one-directional affect label and allows the same good to have different experiential profiles across time and persons (Cronbach & Meehl, 1955; Bollen, 1989).

8.1.3 — Preferences Are Not Experience

Preference is evidence of something, but it is not identical to experience. A person may choose what is least dangerous, most

familiar, socially required, economically possible, or least humiliating among bad options. Revealed preference can record constrained survival rather than felt relief. Willingness to pay can record wealth, bargaining power, hope, fear, or lack of alternatives (Kahneman et al., 1993; Fredrickson & Kahneman, 1993).

This matters for the Law because a preference ordering can look rigorous. Choices generate data. Markets generate prices. Surveys generate rankings. Yet the fact that someone chooses one burden over another does not tell us the felt weight of either burden. A person can choose a painful treatment because they love their child, remain in a job because rent is due, or refuse care because dependence has been made frightening.

Adapted deprivation exposes a special failure of preference inference. People may learn to want less when asking is punished, costly, or hopeless, and may report an unjust condition as acceptable because imagining alternatives is itself painful. The absence of expressed demand for relief can therefore be an effect of constraint rather than evidence of low burden. Preference data remain informative, but only after the feasible set, incentives, and adaptation process are modeled.

None of this means preference data should be ignored. Preferences can reveal priorities, tradeoffs, agency, and practical constraints. They can help design humane studies by showing what participants are willing to bear. They can identify outcomes people value. But they cannot serve as a silent replacement for momentary or path-level experience.

Choice should be labeled as choice evidence, not as direct valence evidence. A preference may encode anticipated experience, moral commitment, social pressure, habit, identity, obligation, risk management, or resource constraint. The study must specify which bridge from choice to felt value it is testing and which observations would break that bridge; otherwise the inference stops at revealed behavior.

A constrained choice does not make suffering disappear. It records what a person selected from the options that remained available, not what the stream carried while selecting it. This distinction is essential whenever deprivation, coercion, dependence, or adaptation has already altered the menu.

Choice data are especially vulnerable to scarcity and path dependence. A repeated choice can reflect learned feasibility, switching cost, habit, coercion, or the expectation that alternatives will disappear. Preference elicitation should therefore record the option set, information, time pressure, consequences, and reversibility of the choice. Without those conditions, a ranking may describe constrained behavior while being reported as a ranking of felt value (Sen, 1999; Kahneman et al., 1993).

8.1.4 — Life Satisfaction Is Not a Momentary Rate

Life satisfaction is a reflective judgment. It asks a person to stand back from the stream and evaluate a life, chapter, role, or condition. That judgment can be profound, morally important, and socially useful. It is still not the same object as a momentary contribution rate. A life can be judged worthwhile while

containing long periods of fear, pain, boredom, exhaustion, or grief (Shiffman et al., 2008; Stone et al., 2007).

The distinction is familiar in experienced-utility research: the experiencing self and the remembering or evaluating self can diverge. A person may remember an episode through its ending, its meaning, or its story rather than its full temporal distribution. The Law's formal ledger, if it is to be tested as a trajectory claim, cannot substitute reflective evaluation for the time-local process without changing the hypothesis.

Life satisfaction also carries cultural and personality differences in aspiration, modesty, comparison, gratitude, religious interpretation, and social desirability. A high satisfaction report may reflect dignity, resilience, or genuine peace. It may also reflect lowered expectation, fear of complaining, or a meaningful life that still contains substantial suffering. The score needs interpretation, not reverence.

Life satisfaction belongs in the evidence system without being promoted into the integrated quantity. Reflective evaluation can serve as an auxiliary construct, validator, rival, or outcome in its own right; it may reveal meaning, standards, aspiration, or narrative coherence that momentary measures miss. It becomes a valence-rate measure only if an explicit and independently tested bridge supports that role.

The difference protects both science and dignity. It lets a person say that a life is meaningful without erasing the suffering inside it, and it lets science study suffering without declaring the life meaningless. That is the boundary a fairness science must keep.

Reflective evaluation can also change the interpretation of an episode. Reappraisal, narrative integration, social conversation, and later outcomes may alter what an earlier event means without altering what was felt at the time. Both objects deserve study, but they answer different questions. A science of terminal valence should preserve the experienced path, the remembered path, and the evaluative judgment as linked but noninterchangeable records (Fredrickson & Kahneman, 1993; Stone et al., 2007).

8.1.5 — Meaning and Dignity Matter Within Feeling

A scientifically useful account must represent how context and meaning shape the quality of experience. Meaning, dignity, agency, violation, loyalty, awe, shame, moral injury, and love alter the felt shape of states. They do not merely decorate valence after the fact. They can change what a moment is like from within (Cronbach & Meehl, 1955; Borsboom, 2005).

Consider pain under two contexts: pain inflicted as humiliation and pain endured in chosen care for someone loved. The sensory intensity may overlap while the experience differs in agency, meaning, threat, resentment, and dignity. The second case does not make pain morally owed payment or credit. It shows that pain is not fully represented by nociceptive intensity alone.

Dignity is especially important because it resists simple scalar capture. A humiliating interaction may be brief and materially minor, yet carry a long felt afterlife. A respectful interaction may not eliminate illness or poverty, but it can reduce fear and restore agency. These effects are experiential while also being moral and social. The chapter keeps both descriptions visible.

Meaning must be represented without being assigned a permanently positive coefficient. It can sustain action, deepen commitment, reframe pain, intensify loss, or coexist with severe distress. A model that automatically lets meaning compensate suffering is as misspecified as one that excludes meaning entirely. The relevant question is how meaning changes phenomenal structure in the declared context, not whether it belongs on a universally favorable side of a ledger.

This requires multidimensional measurement. Some constructs may enter as separate axes, moderators, or context variables rather than as signed components. Agency, humiliation, moral injury, belonging, and sacred meaning may shape how valence is interpreted and how time is carried. Their role must be modeled, not hidden under a pleasure label.

The target must accommodate more than raw pleasure and pain. Burden may be carried as bodily distress, loss of agency, humiliation, fear, moral injury, or the effort of meaningful endurance. Those forms need not collapse into one dimension in advance. The representation should earn any compression through evidence rather than by excluding the experiences that make compression difficult.

Some dimensions may be noncompensatory within the scientific representation. Severe violation, loss of agency, or humiliation may not be responsibly traded against comfort by one fixed weight in every context. Thresholds, lexicographic rules, vector outcomes, or identified sets can preserve that structure instead of forcing every dimension into a smooth utility surface. This approach prevents the measurement model from erasing

distinctions that participants, mechanisms, and evidence treat as qualitatively important (Manski, 2003; Borsboom, 2005).

8.1.6 — Material Justice Does Not Wait

No one waits for affective science to become precise before receiving care, rights, safety, food, housing, medicine, disability support, or protection. Measurement cannot become a gate a person must pass before suffering is believed; people remain people before they are research cases (National Commission, 1979).

That separation is methodological as well as ethical. If report is unavailable, a sensor intolerable, or representation contested, the study has not earned its intended bridge. The person's experience and claim to care do not thereby disappear.

Care conditions shape data quality. Fear of losing treatment, housing, access, family trust, or status can alter reporting and participation, while deprivation can select for unusual endurance. Accessible responses, compensation, transport, flexible scheduling, independent care, and immediate stopping therefore belong to design (World Medical Association, 2024; Council for International Organizations of Medical Sciences, 2016).

A protocol specifies dignity-preserving, reason-coded abstention paths before collection. It records which link failed, what remains interpretable, which claims withdraw, and which care continues unchanged. Uncertainty stays with the instrument and study.

The rule holds under every scientific outcome. Evidence consistent with PTVC does not excuse present suffering, and

evidence against it does not diminish the urgency of repair. Rights and relief are independent of a terminal-boundary verdict.

Measurement can still contribute to justice by exposing burdens that appearance misses without creating new gates or dossiers. The achievement is a bounded account that informs research and care while preserving refusal, privacy, and nonparticipation.

The table below lists the representation questions that must be answered before integration. When ordering, interval meaning, additivity, sign, or transport fails, the program narrows its claim rather than repairing the person or delaying justice.

8.2 — Representation Before Measurement

Measurement becomes serious only after the target has a form. A thermometer measures temperature because temperature has a theoretical role, units, transformations, and expected relations to other quantities. Lived experience will not hand science the same simplicity. Before the book can integrate, compare, or accumulate experience, it must ask whether the relevant quantity can be ordered, spaced, signed, summed, and transported (Russell, 1980; Kahneman et al., 1993; Krantz et al., 1971).

The central question is not whether instruments are sensitive enough. It is whether the proposed representation is meaningful. A person may say one state is worse than another without implying that the difference has a stable unit. A physiological channel may track arousal without tracking valence. A scale may work within one person and fail across people. A neutral point may be chosen by convention and then mistaken for discovery.

The Law needs this section because its formal object is not a general mood report. The ledger requires a valence-like contribution that can enter time. If evidence supports only ordinal ordering, multidimensional comparison, or partial ordering in some contexts, then the scalar additive program must narrow in those contexts. Narrowing is not defeat of human reality. It is protection against false mathematics.

Representation failure is an informative scientific outcome. If a study shows that the target is not scalar, not additive, not stable across states, or not recoverable at the proposed resolution, the result has prevented later precision from being attached to the

wrong object. The program should record which lower-level claims survive rather than hiding the failure beneath denser sampling or a more elaborate estimator.

The order of obligations matters: identify the bearer and target; establish ordering; identify the neutral origin and sign; justify distances and units; test composition; define the temporal path; only then attempt cross-person linking. A later failure does not erase a valid earlier relation, but it blocks every claim that depends on the missing rung. The ladder therefore preserves partial knowledge without promoting rank, local change, or within-stream meaning into a common cardinal scale.

Table 8.1. Representation features and decision consequences.

Representation feature	Question for the chapter	If the answer is strong	If the answer is weak
Ordinal structure	Can states be ordered as more or less burdensome within context?	The program may compare direction and rank without yet summing experience.	The target must split into qualitative or partially ordered descriptions.
Interval structure	Do differences carry stable meaning across nearby states?	Local rates and changes can be estimated under declared conditions.	Additive ledgers must narrow to rank, threshold, or local contrast claims.
Additivity	Can momentary contributions be meaningfully accumulated over time?	Path integrals become candidate summaries rather than metaphors.	Duration and order must be modeled as separate path functionals.

Representation feature	Question for the chapter	If the answer is strong	If the answer is weak
Sign and origin	Is there a non-outcome-selected reference for positive, negative, or neutral?	Signed rates can enter later ledger work with declared uncertainty.	Neutrality claims must abstain or use origin-resistant signatures only.
Within-person transport	Does the representation remain stable across states of the same stream?	Longitudinal measurement can proceed with version labels and drift checks.	The program must use state-specific models or stop comparing phases.
Between-person transport	Can the same representation travel across persons or cultures?	Population summaries become bounded and reference-class-labeled.	The result remains local, personal, or group-specific.

8.2.1 — Ordinal Versus Interval Structure

An ordinal representation says that one state is more burdensome than another. An interval representation says more: that differences between states have stable meaning. The step from ordinal to interval is not cosmetic. A ledger that integrates contributions over time needs distances, not only rankings. If the distance between mild and moderate distress is not comparable to the distance between moderate and severe distress, simple addition becomes unstable (Krantz et al., 1971; Borsboom, 2005).

People can often rank experiences without being able to assign meaningful intervals. Someone may know that nausea is worse

than boredom and panic worse than nausea, while having no stable unit that makes the two gaps comparable. Cultural language can sharpen or blur ranks. Clinical states can change sensitivity. Repetition can make a fixed stimulus feel different. Ordinal information may be valuable but insufficient for additive arithmetic.

Affective science frequently uses rating scales that look interval because they are numbered. The chapter treats those numbers as hypotheses. A zero to ten scale may be approximately useful under some contexts of use, but the spacing must be tested through response models, anchoring, repeated measures, invariance checks, and predictive behavior.

Ordinal evidence supports directional change, rank ordering, and threshold classification. Interval arithmetic becomes available when the additional spacing assumptions have empirical support. Every result should name the level of representation it has earned. Within-person ordinal change, within-person interval approximation, group-level linking, and cross-context common-scale measurement are different accomplishments with different assumptions. They cannot be combined into a single confidence label, and success at a weaker level does not silently authorize the stronger one.

Match the output to the representation: report ordinal direction, threshold crossing, or set-valued comparison where those are the supported operations.

Ordinal structure can support more science than it first appears to permit. Repeated pairwise comparisons may identify stable order

relations, detect reversals, and test whether one context preserves another context's ranking even when equal intervals are unavailable. The key is to report the structure actually identified. A robust order is not an interval scale, but neither is it mere impression; it can constrain models, reject proposed scalarizations, and define partial-order estimands that later work must respect (Krantz et al., 1971; Borsboom, 2005).

8.2.2 — Cardinality and Additivity

Cardinality concerns meaningful magnitude. Additivity concerns meaningful summation. A measure can have ordered categories without cardinal meaning, cardinal approximations without safe addition, and addition within one narrow context without transport across people or states. The measurement model matters here. Indicators treated as effects of a latent state support different tests from components treated as causes or constituents of an index; mutually interacting states require still different dynamics. The ledger needs a defensible magnitude, composition rule, and temporal interpretation in every domain where it is used (Cronbach & Meehl, 1955; Bollen, 1989; Borsboom, 2005).

The additive question is easy to underestimate. Suppose two short intervals each carry mild fear. Is their combined contribution equal to one longer interval of mild fear? Does fear saturate, compound, habituate, or interact with exhaustion? Does relief after fear cancel fear, transform memory, or create a new state? Additivity is a model of time, not a gift from arithmetic.

Temporal addition requires stable units and a defensible contribution at each time. Habituation, sensitization, and recovery

may change that contribution through history-dependent dynamics without violating additivity over disjoint intervals. A nonadditive path functional is needed only when the declared target cannot be represented by integrating the resulting time-local contributions (Krantz et al., 1971; Borsboom, 2005).

Cardinality also determines whether a weight vector can be interpreted. If one dimension is measured on an arbitrary scale and another on a different arbitrary scale, a weighted sum may reflect instrument convention rather than lived tradeoff. Internal consistency does not solve that problem and may be irrelevant for a composite whose components are not expected to be interchangeable effects of one latent state. The model must state what each magnitude means and why the components may be combined before it multiplies and adds them (Bollen, 1989; Flake & Fried, 2020).

A useful scientific program can begin with approximate additivity in bounded contexts. It can test whether repeated episodes concatenate linearly, whether duration doubles contribution, whether recovery resets sensitivity, and whether high-intensity states dominate totals. These tests provide content rather than decoration.

If additivity fails, the Law does not become meaningless. The scalar additive claim narrows. The evidence may shift toward path functionals, thresholds, vector trajectories, or local signatures. The chapter makes this possibility ordinary so that later results cannot be rescued by ignoring failed arithmetic.

Additivity is not earned by writing a sum. It requires representational or empirical conditions under which duration, intensity, context, and interaction can be composed without changing the meaning of the parts. Cancellation failure, saturation, threshold effects, hysteresis, and context-dependent synergy all pressure an additive ledger. A serious program should test those failures directly and retain a nonadditive, vector, or set-valued alternative whenever one common composition rule is not supported (Krantz et al., 1971; Russell, 1980).

8.2.3 — State Versus Rate

A state describes how a moment is. A rate describes contribution per unit time. The difference matters because the formal ledger integrates a rate-like object. If a report says a person feels anxious at a moment, that report has not yet said how anxiety contributes over the next interval. The same intensity may have different duration, recovery, anticipatory load, and aftereffect (Russell, 1980; Cacioppo & Berntson, 1994).

Affective instruments often report levels. A momentary rating of sadness, pain, fear, or calm may be a state estimate. To integrate it, the model must declare whether the level is itself a rate proxy, whether it must be transformed, or whether a different quantity such as change in burden should be used. Multiplying a state score by time does not automatically create a valid unit.

The distinction becomes especially important for sustained conditions. A background dread that is low in momentary intensity but present for months can dominate a life if treated as a rate. A sharp acute pain may dominate memory while occupying

little clock time. The model must decide what time-local contribution means before it claims cumulative burden.

The Law-facing target should therefore label each candidate source. Is it a state, a rate proxy, a transition marker, a recovery cost, an anticipatory cost, or a remembered evaluation? Each label has different implications for integration and comparison. A mixed model may include several of these, but only if the components are not quietly collapsed.

A worked schedule can make the difference visible. Morning nausea, afternoon vigilance, evening relief, and nighttime fear may have similar state ratings at some instants while carrying different interval contributions because duration and context differ. A research design must sample enough of the interval to avoid mistaking snapshots for contributions.

The state-rate distinction states how a momentary score contributes through time, including the exposure rule and the evidence supporting that conversion.

The state-rate distinction also determines sampling design. A slowly changing state can be represented by sparse observations only under assumptions about interpolation, while a rapidly changing rate requires sampling fast enough to avoid aliasing. If the instrument's temporal resolution is coarser than the process, the apparent interval contribution may reflect the observation schedule more than the experience. The measurement map should therefore state the timescale on which the construct is defined and the timescale on which the estimator is permitted to speak (Shiffman et al., 2008; Stone et al., 2007).

8.2.4 — Within-Person and Between-Person Meaning

A scale can work within one person before it works between persons. A participant may reliably report that today's pain is worse than yesterday's, or that safety has increased since a medication change, without the same scale allowing a direct comparison with another participant. Within-person meaning and between-person meaning are distinct representational achievements (Bollen, 1989; Borsboom, 2005).

This distinction matters because the Law is stream-centered. Many early studies may be idiographic: they ask whether changes within a stream follow predicted dynamics under a stable local representation. Such studies can be scientifically valuable even if no universal cross-person scale exists. A within-person model can test temporal shape, response to events, and reliability of local anchors.

Between-person comparison demands more than identical prompts or synchronized devices. Language, physiology, disability, trauma history, medication, cultural display rules, and social expectation can alter how the same response or signal relates to experience. A shared score may therefore be a shared format rather than a shared quantity. Interpersonal arithmetic requires evidence that origin, sign, unit, and response process survive the proposed link (Putnick & Bornstein, 2016; International Test Commission, 2018; American Educational Research Association et al., 2014).

Two ambitions must remain separate. A study may first establish temporal coherence within one participant, then ask whether the

resulting scale can be linked across participants. Failure of interpersonal calibration does not erase valid within-person change, and local validity does not grant a common metric. Idiographic and nomothetic claims require different evidence even when they share a model family (Molenaar, 2004; Hamaker, 2012).

The burden lens makes the separation ethically important. People with atypical bodies, communication styles, cultures, pain histories, or disabilities should not be declared incomparable as persons. The scientific claim may be incomparable; the person is not. Measurement humility must not become social exclusion.

A common scale must earn its scope one bridge at a time. Stability across states of one stream, continuity across instrument versions, transport across clinical conditions, comparison across groups, and transport across languages or cultures are different achievements. Evidence for one does not license the next. The public claim should stop at the last bridge that has been independently supported.

Within-person and between-person relations can even point in opposite directions. A variable associated with relief across people may mark distress within one person when it rises above that person's own baseline, and a stable group difference may say nothing about change over time. Because PTVC is intrastream, population structure may inform calibration, priors, and rivals, but it cannot substitute for the trajectory of the stream being studied (Molenaar, 2004; Hamaker, 2012).

8.2.5 — Neutral Origin and Sign

A signed representation needs an origin. Positive and negative are not free labels. If the origin is chosen by sample mean, instrument midpoint, cultural convention, or terminal fit, neutrality can become an artifact. The Law's strong claim is especially sensitive to this problem because terminal valence closure concerns exact zero in a latent coordinate system (American Educational Research Association et al., 2014; Putnick & Bornstein, 2016).

The formal core owns the abstract origin problem; lived measurement supplies the empirical ways an apparent midpoint can mislead. A person may select 'neutral' because nothing dramatic is happening, because language offers no better option, because dissociation has flattened access, because expectations have narrowed, or because a midpoint feels socially safe. Those response processes define different candidate origins and must be separated before zero acquires cumulative meaning (American Educational Research Association et al., 2014).

Sign depends on construct. High arousal can be joyful, terrified, angry, sexually excited, or medically distressing; low arousal, peaceful, depressed, exhausted, or sedated; pain, threatening, chosen, meaningful, humiliating, or ignored. A one-dimensional physiological sign rule fails when context changes meaning.

A candidate neutral origin must be fixed independently of the closure result it will later help evaluate. It may draw on repeated within-person judgments, contextual anchors, tolerance or indifference tasks, qualitative interpretation, and auxiliary physiology, but no single anchor is self-authenticating. The

protocol should state the origin rule, its uncertainty, its failure conditions, and the consequences of shifting it within the plausible range (Krantz et al., 1971; American Educational Research Association et al., 2014).

When neutral origin is weak, output should become an identified region or directional statement. The study may report decreased burden, movement toward an operational neutral band, or indeterminate sign, but not claim exact zero was observed.

The origin problem is not technical pedantry. It is how the chapter prevents science from manufacturing fairness by choosing the coordinate system that makes the graph look fair. Sign and zero must be earned before they can bear moral or scientific weight.

Positive rescaling preserves zero, while translation changes the origin. An origin error accumulates across exposure and can produce a substantial terminal residual. Independent anchors, cross-sign tasks, behavioral or psychophysical checks, and sensitivity analyses can quantify that influence and guide better calibration (Krantz et al., 1971; Cacioppo & Berntson, 1994).

8.2.6 — Representation Failure as Scientific Result

A representation can fail honorably. Failure of a scalar, additive, signed, or transportable representation is substantive, not a setback hidden by revised language. It shows one empirical bridge cannot carry the claim (Manski, 2003).

Representation can fail in several ways. Reports may remain ordinal; dimensions may resist stable weights; mixed states may be incomparable; groups may use different response processes; clinical states may alter item meaning; physiological channels

may track arousal or illness rather than valence; and temporal aggregation may be path-dependent.

Such findings do not deny lived experience. They reject a proposed simplification. The person remains real, burden remains ethically significant, and care remains urgent. The science may move from scalar to vector language, common to within-person scope, or additive to path-functional rivals.

Abstention is legitimate. A study may return no scalar estimate for a person, context, group, or interval when representation gates fail. That output is more informative than a number forced from incompatible dimensions, uncertain signs, or noncomparable scales (Manski, 2003).

The hypothesis becomes more scientific when representation failure can narrow it. A program that can lose scalarity, additivity, or comparability at the first gate has exposed real ways to be wrong rather than protecting a grand claim behind flexible language.

8.3 — Mixed Affect and Multidimensional States

Human feeling is often not arranged as a single traffic light. People grieve and feel love, dread and feel relief, hurt and feel loyal, suffer pain and find meaning, feel numb while their body remains under threat, or feel joy so intense that it carries fear. These states are not exotic exceptions. They are ordinary evidence that the representation problem is real (Russell, 1980; Cacioppo & Berntson, 1994; Dejonckheere et al., 2022).

Context can change the felt sign of an otherwise identical stimulus. In 16 healthy volunteers, Leknes and colleagues (2013) presented the same moderate heat in two settings: one in which the alternative was nonpainful warmth, and another in which it was intense pain. Average sensation ratings shifted from painful in the first setting to pleasant in the second. The shift accompanied reduced skin-conductance responses in the 12 participants with usable recordings and changes in pain-related and valuation circuitry. This gives PTVC's emphasis on experienced value a concrete experimental foundation: the relation between an event and its alternatives can alter the feeling itself. A context-sensitive valence model can therefore make quantitative predictions about changes in felt sign while the physical input remains fixed, with expectancy and contrast models providing direct comparisons.

A scalar model can handle some complexity if its mapping is declared and tested. Positive meaning within pain may coexist with negative experience, and genuinely positive and negative contributions must be represented under the chosen branch. Their

arithmetic combination does not make a harm morally justified or erase its negative magnitude. Report gross components as well as the net result where the representation permits them; do not change weights to manufacture cancellation or suppress genuine positive feeling because it accompanies suffering.

Affective science offers several neighboring structures: dimensions such as valence and arousal, appraisal processes, motivational action tendencies, interoceptive and allostatic accounts, constructionist views of emotion, and clinical descriptions of pain, numbness, anxiety, depression, trauma, and dissociation. The section does not choose among them as final truth. It uses them to ask what a Law-facing representation must survive.

Mixed states matter because burden can reside in conflict as well as magnitude. Relief may coexist with grief, pride with fear, love with exhaustion, and pleasure with narrowing compulsion. A one-axis model must show that its projection preserves the comparisons required by the study; otherwise the richer state remains the scientifically appropriate object.

8.3.1 — Coexisting Positive and Negative Affect

Positive and negative affect can coexist. A parent can feel fear for a child and love in the same hospital room. A mourner can feel grief and gratitude. A person leaving an abusive situation can feel relief and guilt. An athlete can feel excitement and dread before a dangerous event. The coexistence is not a measurement error by default (Cacioppo & Berntson, 1994; Russell, 1980).

A single bipolar scale compresses coexistence into one rating; an explicit difference score does so by subtraction. That may be useful in some contexts, but it can erase the structure of the state. Grief with love is not neutral because love cancels grief. Relief with guilt is not zero because the signs differ. The experienced state may be high in both positive and negative dimensions, and that joint activation may matter differently from a low-arousal neutral state.

The Law-facing risk is cancellation without understanding. If mixed affect is compressed too quickly, the measured cumulative estimate may understate a burden because another dimension is present. It may also miss resilience, attachment, agency, or meaning that genuinely changes the state. The problem is not that scalarization is forbidden. The problem is that it must explain what happens to coactivation.

Mixed-affect research provides a methodological starting point. Measures can ask separately about positive and negative components, examine intraindividual patterns, use time series, and distinguish simultaneous coactivation from rapid alternation. These are construct tests that should precede any one-axis ledger model.

Coexistence also affects temporal interpretation. Positive and negative elements may have different onset, duration, and aftereffect. Love inside grief may persist while acute pain fluctuates. Relief after fear may be experienced as a separate state rather than as cancellation. A path model should preserve those differences when they are relevant.

The measurement problem is not whether a life can be stamped positive or negative at one instant. It is whether a declared representation can preserve simultaneous burdens, reliefs, arousal, control, and meaning, and whether any scalar projection retains the distinctions required by the study's estimand.

Bipolar measurement and bivariate measurement make different empirical commitments. A bipolar scale forces positive and negative states onto opposite ends of one line, while a bivariate design allows both to be present, absent, or unequal at the same time. Mixed grief, awe, relief after loss, pride under exhaustion, and fear during chosen challenge can therefore expose whether the one-axis representation is adequate. The choice should be compared through predictive and discriminant performance rather than settled by graphical convenience (Cacioppo & Berntson, 1994; Dejonckheere et al., 2022).

8.3.2 — Valence, Arousal, Control, and Meaning

Valence is only one axis commonly used to describe affect. Arousal, control, agency, uncertainty, threat, bodily demand, and meaning can vary independently enough to matter. Calm joy differs from excited joy. Quiet despair differs from terror. Love and grief can coexist without becoming a single midpoint. A one-axis model must show which distinctions it can compress and which mixed states require a bivariate or multidimensional representation (Russell, 1980; Russell & Carroll, 1999; Cacioppo & Berntson, 1994; Larsen et al., 2001).

Dimensional models are useful because they make this pressure visible. A valence-arousal plane already shows that high-energy

positive and low-energy positive states are not identical. Adding control or dominance distinguishes anger from fear, confidence from panic, and helpless pain from chosen effort. Meaning adds another layer because the same bodily state can be interpreted as sacrifice, violation, endurance, or absurdity.

The Law does not need every dimension to become a separate ledger. It needs to know whether the target of fairness can be approximated by a signed rate within a defined context. If arousal or control systematically changes the burden while the scalar ignores it, the scalar is incomplete. If those dimensions only moderate sign or variance, the model should say so.

The construct map therefore separates state dimensions from scalar output. The state vector may include valence, arousal, agency, meaning, pain, social safety, and bodily demand. A scalarization rule may then map the vector into a signed candidate contribution. The mapping is the claim, not an invisible preprocessing step.

The representation should capture the distinct clinical forms of positive and negative experience. Depression can involve low arousal, anhedonia, agitation, numbness, or self-condemnation. Anxiety can involve high arousal, anticipatory simulation, bodily vigilance, and social threat. These differences alter measurement.

The model should be parsimonious and explicit about what it discards. Valence may remain the central coordinate, yet omitted arousal, control, meaning, or bodily demand can become a source of bias rather than harmless noise. A simpler representation earns

authority by preserving the comparisons required by the estimand, not by declaring the other dimensions secondary.

Valence and arousal are often correlated, but their separation matters for interpretation. High arousal can accompany terror, exhilaration, anger, effort, or intense attention; low arousal can accompany peace, fatigue, numbness, or depression. Perceived control and meaning can alter the experiential character of states with similar valence and arousal. A measurement model that omits these dimensions may attribute channel differences to noise when they reflect genuine multidimensional structure (Russell, 1980; Russell, 2003).

8.3.3 — Intensity and Depth

Intensity, persistence, and life-structuring force are different properties. A loud feeling may be brief, while a quiet state can organize attention and action for hours; an acute insult may fade while a persistent sense of threat shapes every later cue. Representation therefore needs to distinguish magnitude from duration, salience, and temporal reach before those features are compressed (Russell, 1980; Cacioppo & Berntson, 1994).

Intensity is tempting because it looks measurable. A scale can ask how strong the pain is, how intense the fear is, how pleasant the moment is. Depth asks harder questions: does the state change the person's horizon, agency, identity, relationship to others, or ability to recover? A model that records only peak intensity may miss the burden that shapes the stream below dramatic thresholds.

The Law-facing target may need both. Some states matter because they are intense. Others matter because they are durable,

recurring, invasive, or meaning-laden. Chronic low-level dread can consume more life than one spectacular panic episode. Ordinary safety can create relief not by dramatic pleasure, but by removing the background tax of vigilance.

Depth also matters in positive experience. Awe, trust, belonging, dignity, and peace may not always score as high-intensity pleasure. Yet they can alter the structure of the stream, reduce defensive effort, open attention, and change the meaning of time. A crude pleasure scale may undervalue them.

A useful state description separates at least immediate magnitude, persistence, salience, functional disruption, recovery cost, and felt significance. A particular study may estimate only a subset, but it should state which dimensions are present, which are omitted, and whether omission changes the comparisons the estimator is expected to support.

This distinction protects the ordinary middle. The burden most likely to be hidden is often not the loudest state. It is the depth of having to carry the same small cost across thousands of moments.

Intensity measurement inherits classic psychophysical difficulties. Equal numerical differences need not represent equal experiential differences, ceiling effects can compress severe states, and verbal categories can widen or narrow across context. Repeated within-person comparisons, magnitude estimation, item-response models, and cross-modal anchors can each help, but none should be treated as a universal solution. The scaling method must match the intended claim and expose where saturation or response style makes depth unidentified (Krantz et

al., 1971; American Educational Research Association et al., 2014).

8.3.4 — Ambivalence and Incomparability

Ambivalence is not indecision alone. It can be the felt presence of reasons, attachments, fears, loyalties, and losses that do not collapse onto one preference or one affective sign. A person may want and dread the same outcome. They may love someone and fear them. They may feel gratitude for care and humiliation at needing it (Cacioppo & Berntson, 1994; Campbell & Fiske, 1959).

Incomparability appears when two states cannot be honestly ranked on a single line without losing what matters. Is numbness better or worse than panic? Is meaningful pain better or worse than empty comfort? Is anger with agency better or worse than despair with quiet? Sometimes the answer is context-specific. Sometimes the representation should remain partial.

A partial order can be more truthful than a forced scalar. It can say that one state is better on safety and worse on agency, or lower in pain but higher in humiliation. It can preserve unresolved tradeoffs rather than hiding them under a composite. This is important for a book that must not imply suffering is morally justified or erased by meaning or joy.

Ambivalence also affects report. People may describe a state as fine because no single label fits, or because naming the conflict would create social consequence. A measurement system that demands one rating can prevent participants from expressing that conflict accurately. The construct should allow people to say that

a state is mixed, unresolved, incomparable, or not representable in the offered categories.

Partial ordering preserves vector trajectories, set-valued estimates, local dominance relations, and explicitly incomparable states. These representations let the study report the structure identified in that context.

Incomparability should not be treated as evidence that a person is beyond science. It is evidence that the model must preserve more structure than a single ordered line can carry.

Incomparability need not mean that nothing can be learned. Some states may be partially ordered: one is clearly more burdensome on every admissible dimension, while two others trade agency against pain or meaning against exhaustion and resist a single ranking. Identified sets can preserve those tradeoffs without selecting a preferred weight after the outcome is known. This approach keeps the model answerable while recognizing that a one-number result may be scientifically weaker than a well-characterized region (Manski, 2003; Borsboom, 2005).

8.3.5 — Vector-State Alternatives

A vector-state representation begins by refusing premature collapse. Instead of asking for one value, it represents experience as a declared collection of dimensions at time t . Candidate coordinates may include valence, arousal, pain, agency, meaning, threat, social safety, bodily demand, and cognitive load, but the list and its interpretation must be justified for the study context rather than borrowed as a universal emotional anatomy (Russell, 1980; Russell, 2003; Cacioppo & Berntson, 1994).

Vector notation is not decorative. It changes what can be tested. A scalar asks whether one signed contribution moves over time. A vector asks whether several dimensions have distinct dynamics, couplings, lags, and failure modes. The measurement pipeline can then test whether any scalar projection preserves the features needed for a Law-facing claim.

A simple vector can also protect mixed affect. Positive and negative components can both be nonzero. Arousal can rise while valence remains uncertain. Agency can increase while pain remains high. Social safety can improve before mood follows. These patterns are lost if every state is forced into one number at entry.

The vector-state alternative does not abandon the ledger. It places the ledger downstream. A later scalarization may map the vector into a signed rate if the weights, signs, and sensitivity are justified. Until then, the vector is the evidence-preserving representation.

Researchers should also distinguish vector dimensions from observed channels. A pain axis is not the same as a pain questionnaire item. A social-safety coordinate is not the same as the presence of another person. Each dimension remains latent until linked to evidence. The vector is a construct map, not a measurement by itself.

For this chapter, $z(t)$ is therefore the honest placeholder: the state of experience before scalarization. It lets the book ask whether the Law's scalar needs can be met without pretending that experience arrived already flattened.

A vector representation permits dimensions to evolve on different clocks and respond differently to intervention. Pain intensity may change quickly while fatigue, control, meaning, or social safety changes slowly. Multivariate dynamics can therefore distinguish an intervention that improves one dimension from one that merely shifts the burden elsewhere. Scalar summaries may still be reported for bounded purposes, but the vector state should remain available for diagnostics, sensitivity, and construct-failure review (Russell, 2003; Bollen, 1989).

8.3.6 — Clinical and Cultural Variation

Clinical and cultural variation reveal a representation's transport boundary. Depression, pain, trauma, dementia, delirium, dissociation, autism, medication, sedation, disability, language, and social norms can alter report, physiology, expression, comparison, and interpretation. A scale may remain useful in one class while changing meaning elsewhere (Cacioppo & Berntson, 1994; International Test Commission, 2018).

Transport is declared by population, state, task, language, time scale, and channel. A model learned in ambulatory adults does not silently extend to childhood, terminal illness, dementia, nonhuman animals, or artificial systems; each extension needs comparability evidence, a local model, a narrower estimand, or abstention.

Sign is context-sensitive. Restlessness may reflect anxiety, pain, delirium, medication, dyspnea, or discomfort, while low expression may reflect comfort, sedation, depression, fatigue,

fear, or limited communication. Context can constrain alternatives, but no display becomes a universal sign rule.

Mixed experience creates another transport problem. Relief and grief, love and exhaustion, or low arousal and distress may coexist, while positive and negative channels change reliability independently. Multidimensional measurement should precede scalar summary so cancellation cannot manufacture neutrality. Keeping the component trajectories visible allows researchers to distinguish a stable net score from substantial changes in both kinds of experience.

Repeated sampling does not repair a weak construct. Momentary items still require response-process, distribution, within-person variability, trend, and level-specific reliability checks; frequent prompting can reproduce the same unstable relation many times (Dejonckheere et al., 2022; Siepe et al., 2025; Castro-Alvarez et al., 2026). A pilot can examine whether participants interpret each item consistently across contexts and whether the sampling schedule captures changes at the timescale relevant to the study.

A transport audit distinguishes item, channel, and construct behavior. Translation may fail while physiology remains usable, medication may alter physiology while communication remains interpretable, or the construct itself may differ. Invariance models test relations but cannot create shared phenomenal meaning (Putnick & Bornstein, 2016; American Educational Research Association et al., 2014). This separation supports targeted repairs, such as revising an item's wording or recalibrating a channel, while retaining the parts of the measurement system that still perform well.

A practical matrix crosses populations and states with items, channels, anchors, lags, and scalarization rules, recording established, partial, unsupported, or prohibited status. One successful channel cannot authorize a universal score, and one failed channel cannot disqualify a person. Each entry can also identify the next validation task, turning gaps in coverage into a prioritized plan for extending the instrument to additional settings.

Variation is information about representation, not nuisance around a preferred display rule. Comparable structure may travel with evidence; where it does not, local models or noncomparability preserve more truth than a common number with hidden bias (Henrich et al., 2005; Mokkink et al., 2024; Gagnier et al., 2025).

8.4 — Scalarization and Identified Sets

Section 6.4 established why scalarization and identified sets belong to PTVC's representation gate. Here the task is psychometric: specify, estimate, validate, and stress-test the projection from multidimensional lived states to a study-specific scalar before that scalar enters a ledger (Fredrickson & Kahneman, 1993; Eldar et al., 2016; Manski, 2003).

A scalar is a declared projection, not a metaphysical primitive. Let the state remain vector-valued until the study states which dimensions enter, which weights or interactions map them to a sign, and which families of maps remain defensible. If the Law-facing conclusion changes across those families, the result is representation sensitivity or an identified set rather than a stronger scalar claim.

Scalarization becomes informative when the analysis reports what is identified, which conclusions depend on the weighting rule, and what evidence would resolve the remaining uncertainty.

Outcome-selected weights are circular. A projection chosen because it makes a trajectory close is not a bridge from experience to measurement; it is a rescue operation conducted with the answer in view. Weight families, exclusions, and tuning rules must be justified and frozen before terminal outcomes are inspected, with any exploratory search reported separately (Manski, 2003; American Educational Research Association et al., 2014; Nosek et al., 2018).

$$z(t) = (v(t), a(t), p(t), c(t), m(t), r(t), s(t), b(t))$$

$$x_w(t) = w^\top z(t), L_w(a, b) = \int_a^b g_\theta(t) x_w(t) dt$$

$$I_W(a, b) = \{L_w(a, b) : w \in W\}$$

8.4.1 — Weight Vector w

A weight vector is the visible form of a tradeoff. If lived experience is represented as a vector of dimensions, a scalar ledger requires a mapping from that vector to one signed quantity. The weights say how much each dimension contributes and in what direction. They are not merely technical coefficients; they are where the model decides what it counts (Manski, 2003; Krantz et al., 1971).

The simplest candidate can be written conceptually as a vector state $z(t)$ mapped by weights w into a scalar contribution. The equation matters less as calculation than as disclosure: it shows that the one-number result is produced by a declared operation, not discovered as though experience had only one natural axis.

Weights can be fixed by theory, estimated from data, elicited from participants, constrained by expert judgment, or compared across plausible families. Each route has different risks. Participant weights may reflect current mood or social pressure. Expert weights may encode professional bias. Data-derived weights may optimize prediction of an outcome that is not lived experience. Theory-derived weights may be elegant but wrong.

Weighting determines which experiences remain visible. Down-weighting pain when meaning is high, ignoring agency, or treating social safety as universally beneficial can transfer the consequences of the modeling choice to the person whose

experience is misrepresented. Scalarization is therefore both a scientific and an ethical commitment: it specifies which dimensions may compensate for which others, and by how much (Manski, 2003).

A rigorous chapter therefore requires weight provenance. Every scalar candidate should state the vector, the sign convention, the weight source, the population, the context of use, the sensitivity range, and the forbidden inference. Without that, a one-number ledger is not a scientific simplification. It is an unmarked judgment.

The weight vector is not the enemy of measurement. It is the honesty that allows measurement to proceed. Once weights are visible, they can be argued with, tested, varied, rejected, or narrowed.

A weight vector is part of the estimand, not merely a computational setting. Changing the weights changes which features of experience count, how mixed states are ordered, and which trajectories appear close to neutrality. The protocol should therefore state whether weights are person-specific, population-level, context-specific, learned from independent data, or fixed by a declared normative convention. A weight rule selected because it produces terminal closure would make the result circular (Manski, 2003; American Educational Research Association et al., 2014).

8.4.2 — Weight Uncertainty

A single weight vector is rarely justified at the start. Several weightings may be plausible given current evidence. Pain may

deserve more or less weight relative to agency. Meaning may moderate pain rather than add to it. Arousal may matter only under some valence states. Social safety may interact with threat. Weight uncertainty should be part of the inference rather than hidden in a selected model (Borsboom, 2005; Bollen, 1989).

The right object may be a family W of admissible weights. W can be defined by theory, validation evidence, participant interpretation, ethical constraints, and empirical sensitivity. A result that holds across W is more robust than a result that depends on one narrow vector. A result that changes sign across W tells the reader that the scalar claim is representation-sensitive.

Weight uncertainty should not be confused with statistical noise. Noise concerns data variation around a declared model. Weight uncertainty concerns which model is being used to translate experience into a scalar. More data under the wrong weight vector can make a wrong estimate precise. The uncertainty about representation must travel separately.

A scientific report should therefore display several outputs: the central candidate, the range across plausible weights, the dimensions driving disagreement, and the conditions under which the conclusion changes. If all plausible weights agree that burden increased, a directional claim may be strong even without a unique scalar. If weights disagree, the honest claim may be an identified set.

Weight uncertainty also protects against moral overreach. The project must not decide after the fact that meaning compensated pain or that fear was outweighed by later relief because that makes

closure appear. The admissible family must be declared before the result is evaluated.

Weight uncertainty should travel into every downstream quantity. Sampling variability is only one component; uncertainty may also arise from task framing, anchor instability, response shift, cultural interpretation, and model choice. Robust or Bayesian analyses can represent a distribution or admissible set of weights, but the output remains conditional on that representation. Narrow posterior intervals do not rescue a misspecified scalarization, and computational precision should never be mistaken for construct identification (Borsboom, 2005; Manski, 2003).

8.4.3 — Sensitivity Across W

Sensitivity across W asks whether a conclusion survives the scalarizations that remain defensible under the declared construct map, population, and use. The task is not to demand agreement across every mathematically possible weight. It is to prospectively specify a scientifically admissible family before outcome inspection, show how status changes within that family, and report the identified set when no single projection is warranted (Krantz et al., 1971; Manski, 2003; American Educational Research Association et al., 2014).

A terminal or longitudinal conclusion might appear under a pain-heavy scalar and disappear under an agency-heavy scalar. A recovery claim might hold when arousal is treated as neutral and fail when agitation is treated as distress. A neutral band might contain one projection and not another. These are not nuisances to average away; they are answers about representation.

The sensitivity report should identify which dimensions control the disagreement. If the conclusion is fragile because meaning and pain are weighted differently, the chapter has found a scientific and ethical pressure point. Future work can study that relation instead of pretending the scalar was settled.

Sensitivity across W can also separate robust partial claims from overbroad claims. If every defensible weight shows decreasing burden during a care intervention, the intervention may have strong experiential evidence. If the neutrality result varies across weights, the report identifies which weighting assumptions determine the conclusion.

A practical report should include graphical or tabular displays in research artifacts, while the surrounding explanation makes the logic visible in prose. The scalar result must be accompanied by its sensitivity class: robust, directionally robust, sign-fragile, magnitude-fragile, or unidentified. These labels prevent a public artifact from displaying one curve as though it were the life.

The Law becomes testable only when it can lose under plausible representations. Sensitivity across W is one of the mechanisms by which representation becomes a real gate rather than a decorative caution.

Sensitivity across admissible weights is most informative when it is structural rather than cosmetic. Researchers should identify which conclusions hold throughout the admissible set, which depend on a narrow corner, and which reverse sign across plausible choices. A robustness frontier can show how much assumption is required before a one-number claim appears. When

the central conclusion depends on particular weighting commitments, the report identifies those commitments and the measurements that could distinguish them (Manski, 2003; Imbens & Manski, 2004).

8.4.4 — Identified-Set Reporting

An identified set contains every target value compatible with the observed data, the admissible measurement models, and the declared assumptions. It is not a confidence interval. A confidence procedure addresses sampling uncertainty for a target under a specified model, while partial identification addresses the possibility that the model and evidence do not select one target value at all. A rigorous analysis may construct a confidence region for the target parameter or for the entire identified set, but it must state which coverage guarantee is intended and preserve both layers (Manski, 2003; Imbens & Manski, 2004).

Set reporting is especially valuable because the Law's public risk is drawn toward clean numbers. A point estimate invites rank, comparison, and certainty. A set shows the reader where knowledge stops. It also allows the project to say something without saying too much. The result can support bounded direction, reject some claims, or abstain from exact scalar language.

Identified sets also make construct failure visible. If the set spans incompatible statuses, the issue may not be sampling error but representation uncertainty. If a terminal valence closure band is reached by only one corner of the weight family, the result is not

robust neutrality. If all defensible weights reject a proposed pattern, that is stronger adverse evidence.

A wide set can narrow the program by showing that a strong claim is not presently identifiable. That is a substantive result, not a protective maneuver. An honest region is preferable to a narrow number produced by hidden assumptions because it exposes exactly what new anchors, bridge evidence, or representation commitments would be required for a sharper conclusion.

An identified set can be used at multiple levels: within-person trajectory, group average, terminal-window increment, intervention contrast, or path-functional comparison. Each use must state which uncertainties are included. A set over weights is not the same as a confidence interval over sampling noise, and the two should not be collapsed.

Set-valued reporting should be designed for interpretation rather than treated as an apology for imprecision. The report can identify the range of terminal residuals, rankings, or path summaries compatible with all admissible weights and measurement models, then show which scientific conclusions remain invariant across that range. A wide set may still reject a strong claim, and a narrow set may still exclude zero. The governing discipline is to preserve uncertainty in the output instead of hiding it behind a point chosen for presentation (Manski, 2003; Imbens & Manski, 2004).

8.4.5 — No Outcome-Selected Weights

Outcome-selected weights are weights chosen because they produce the desired result. In the context of this book, the danger is obvious: a researcher could adjust the scalarization until the

terminal path looks neutral, the intervention looks beneficial, or the rival looks weaker. That would convert measurement into rescue (Manski, 2003).

The prohibition must be explicit because outcome selection can hide inside reasonable language. A team may say that it refined the model after inspecting anomalies, optimized weights for fit, removed a dimension that behaved inconsistently, or chose the psychologically plausible transformation that happened to improve closure. Some refinements are legitimate in development. They are not confirmatory evidence unless locked and retested.

Exploration and confirmation must remain distinct. Exploratory work may compare weight families, discover dimensions, revise items, and inspect failure. Confirmatory work freezes scalarization, population, endpoint, temporal rule, and analysis plan before testing the claim. Changing weights after results are visible creates a new claim version that requires a new test (Munafò et al., 2017; Nosek et al., 2018).

This rule also protects participants. A weight selected to make a result look fair may erase a burden the participant actually carried. If fear is removed as noise, if pain is offset by meaning, or if dignity violation is down-weighted because it disrupts a curve, the model has shifted burden onto the person for the sake of the theory.

Outcome-selected weights are not always malicious. They can arise from pressure to make complex data coherent. But the effect

is the same: the measurement bridge becomes immune to defeat. A bridge that cannot fail cannot bear evidence.

No outcome-selected weights is therefore a scientific and ethical firewall in one sentence. The scalarization must face the result from outside the result. If it changes, the book must say that the claim changed too.

8.4.6 — Withdrawal of One-Number Claims

A one-number claim should be withdrawn when scalarization is unstable, admissible weights cross incompatible statuses, dimensions remain only partially ordered, cultural or clinical variation changes meaning, or temporal functionals disagree beyond the study's ability to resolve them. Withdrawal is not rhetorical defeat; it is the correct status for a construct that has not earned a scalar (Manski, 2003; Borsboom, 2005).

Withdrawal should identify the highest representation tier that survives. A failed scalarization may still permit sign, partial order, within-person direction, a vector profile, or bounded change; it does not automatically invalidate every measurement. The report should state which coordinate claim failed and which lower-dimensional or set-valued object remains scientifically usable.

The decision rule belongs in the preregistration. Separate rows should address sign instability, weight sensitivity, common-origin failure, noncomparability, transport failure, and disagreement among temporal functionals; each row states the evidence threshold, the language that becomes unavailable, and the narrower output that remains permitted. This makes withdrawal

reproducible rather than a rescue invented after an attractive result fails (Manski, 2003; Imbens & Manski, 2004).

Restoration requires genuinely new evidence. The program may not choose a favorable weight family, remove difficult cases, redefine the endpoint, or change the path functional until a clean number returns. A redesigned construct or protocol must be requalified and tested on data that did not generate the repair, preserving the boundary between development and confirmation (American Educational Research Association et al., 2014; Nosek et al., 2018). Restoration should also identify the specific failure being retested and the prospective criterion that would count as recovery, so new data alone cannot restore a claim whose original defect remains unresolved.

Withdrawal also propagates beyond the analysis. Figures, summaries, public excerpts, model cards, and dataset descriptions must be corrected, versioned, or retired when their scalar premise is no longer supported. A clean current result does not close the error if an older one-number image continues circulating without its withdrawal notice (Munafò et al., 2017; Center for Open Science, 2025). The correction record should identify which active public surfaces were checked and which copies could not be updated, making residual exposure to the superseded claim visible rather than assumed away.

Reports should distinguish cardinality loss, comparability loss, transport loss, and aggregation loss. These failures have different remedies and different public consequences; calling all of them ‘measurement failure’ discards information, while silently switching from a shared unit to rank order or from a lifetime claim

to a local association disguises a changed target. Each failure should be paired with the strongest relation that still survives, such as within-person direction, ordering, a vector profile, or a set-valued result, so withdrawal preserves usable information instead of collapsing every limitation into the same verdict.

When a scalar claim withdraws, redesign should return to the path rather than search immediately for another summary. The ordinary-day schedule below illustrates how a study can preserve waking transitions, obligations, waiting, social contact, bodily events, relief, evening recovery, and sleep-related carryover so that later model comparison is not built from peaks alone. Preserving that temporal structure allows competing path functionals to face the same record instead of letting data collection quietly favor whichever summary replaces the withdrawn scalar.

8.5 — Duration, Memory, and Path Functionals

A life is extended in time, but time is not a neutral container once experience enters it. Ten minutes of terror, ten minutes of boredom, and ten minutes of quiet safety have the same clock length. Their felt contributions may not have the same structure. A simple integral treats equal time intervals as equally eligible for accumulation. That assumption needs rivals (Eldar et al., 2016; Fredrickson & Kahneman, 1993; Shiffman et al., 2008).

Psychology has long shown that remembered episodes can differ from experienced trajectories. Peaks, endings, recency, recovery, anticipation, and narrative coherence can influence later evaluation. The Law's target is the experienced stream, but the evidence often arrives through memory, report, expectation, and retrospective meaning. A chapter that ignores that gap would let the measurement source redefine the target.

The ordinary middle is the central correction. Dramatic peaks are easier to remember and easier to write about. Fairness, however, is often carried in unmemorable duration: the commute, the waiting room, the background fear, the long illness, the quiet apartment, the repetitive care task, the night of not quite sleeping. If duration disappears behind peaks, hidden burden disappears with it.

Competing temporal functionals should be compared under common data and scoring rules. Simple addition, kernel weighting, peak-end summaries, hysteresis, recovery penalties, and order-sensitive models make different claims about what history retains. The appropriate functional is the one that survives

prospective prediction, perturbation, and rival comparison in the declared context, not the one that best matches an intuitive story after the outcome is known.

For exploratory ordinary-day work, a coverage matrix can include waking transition, bodily baseline, first social contact, work or care load, waiting, discomfort, relief, meals, movement, solitude, evening recovery, sleep onset, and night interruption. The list is not a surveillance mandate. It is a check that the design samples low-salience duration rather than only dramatic events.

Table 8.2. Ordinary-day sampling windows and omitted-window bias.

Ordinary-day window	Scientific reason to sample it	Bias if ignored
Waking transition	Captures baseline mood, bodily demand, sleep residue, and anticipatory load.	The day begins after the first burden has already been carried.
First obligation	Shows how work, care, school, treatment, or dependency enters felt time.	Visible productivity replaces hidden cost.
Waiting interval	Measures low-drama burden, uncertainty, pain, boredom, or constrained choice.	Only peak events appear to matter.
Social contact	Distinguishes support, threat, loneliness, obligation, and masking.	Relational burden is mistaken for external circumstance only.

Ordinary-day window	Scientific reason to sample it	Bias if ignored
Bodily event	Tracks pain, nausea, breathlessness, fatigue, hunger, or medication effect as lived condition.	The body becomes a confound rather than part of the target.
Relief or repair	Tests recovery dynamics, contrast effects, gratitude, exhaustion, and partial repair.	The model sees harm but not release, or sees release as total compensation.
Evening recovery	Captures accumulation, rumination, meaning, memory, and return of agency.	The path is reduced to isolated moments.
Sleep onset or interruption	Links affective residue to rest, dreams, and next-day carryover without making sleep a proof source.	Night becomes invisible even when it carries the day forward.

8.5.1 — The Ordinary Middle

The ordinary middle is the part of life most likely to be erased by dramatic measurement. Peaks are memorable. Endings are narratively powerful. Crises attract attention. But a life is also made of waiting, commuting, washing dishes, monitoring bills, checking on someone, being too tired to answer a message, walking in a safe street, sitting without fear, and repeating care (Kahneman et al., 1993; Fredrickson & Kahneman, 1993).

Ordinary duration matters because hidden burden is often distributed thinly across many intervals. A small daily vigilance cost can become large over years, while a quiet daily relief can alter whether life feels merely survivable or genuinely open. A design that samples only dramatic events can miss the cumulative structure the ledger is meant to represent.

The ordinary middle also tests dignity. Some conditions are not spectacularly painful but are persistently narrowing: lack of privacy, unreliable transport, low-grade disrespect, sensory overload, chronic uncertainty, bureaucratic delay, or the constant need to explain one's body. These may not produce high peaks, but they occupy time and attention.

Experience sampling and ecological momentary methods are useful here because they can catch life closer to its occurrence. They still have burdens and biases, but they resist the habit of asking memory to summarize the stream after the most narratively salient moments have taken over.

A fairness science that ignores the ordinary middle becomes endpoint obsessed. It would study how lives end while missing what most of the life was like to carry. This chapter keeps ordinary duration in the target before the book turns toward terminal signatures.

The ordinary middle is also where sampling burden and scientific value meet. Brief random prompts, end-of-day reconstruction, passive context, and time-use records each reveal different portions of extended experience. A design that samples only when emotion is intense will overrepresent peaks; a design that samples

mechanically may burden the very routines it seeks to observe. The schedule should be justified by the temporal process and tested for reactivity, missingness, and coverage of low-salience intervals (Stone et al., 2007; Shiffman et al., 2008).

8.5.2 — Duration Weighting

Simple integration treats each unit of clock time as equally eligible for contribution. That is a clear starting point, but it may not be the only plausible rule. Duration can be weighted by attention, consciousness level, salience, suffering intensity, effort, recovery cost, or availability of agency. The question is not whether time matters, but how (Shiffman et al., 2008; Stone et al., 2007).

Equal clock weighting has virtues. It is transparent, preregistrable, and hard to manipulate after the fact. It gives ordinary life a place because long low-intensity states count. It also matches the intuition that a burden carried for hours matters more than the same burden carried for seconds. But even this simple rule has assumptions.

Saturation, habituation, sensitization, and exhaustion can make the tenth hour experientially different from the first. An additive integral can represent those differences through a changing rate; equal clock weighting does not require constant experience. A separate duration-weighting rule needs its own justification and must not count intensity or aftereffects twice.

The analysis should distinguish clock duration, conscious-access duration, attention-weighted duration, burden-weighted duration, and recovery-inclusive duration. Equal clock time is a transparent

initial model, not a protected conclusion. The design must permit prospective challenges from attention, consciousness level, saturation, sensitization, and recovery; if equal weighting fails, the response is a better path functional rather than deletion of duration from the target.

The temporal question has an empirical foundation. Cui et al. (2023) synthesized 95 effect sizes from 31 studies involving 3,776 participants and found that valence, arousal, stimulus type, and timing task moderated emotional duration judgments. Negative rather than positive valence, and greater arousal, generally accompanied greater overestimation. This gives the program measurable alternatives to compare: physical duration, reported duration, and any independently qualified phenomenal-exposure model. It makes the choice of clock an explicit research question, with its rule fixed before the cumulative result is examined.

Duration weighting also affects public interpretation. A short intense peak may draw sympathy while a long dull burden is ignored. Measurement can correct that bias only if duration is represented rather than treated as background. The Law's burden lens makes invisible time scientifically visible.

8.5.3 — Peak-End and Memory Effects

Remembered experience is a reconstruction, not a transparent archive of momentary experience. Peaks, endings, narrative coherence, later meaning, and current state can change retrospective evaluation. That makes memory scientifically important and also prevents it from being substituted for the path

that was lived without an explicit reconstruction model (Fredrickson & Kahneman, 1993; Kahneman et al., 1993; Stone et al., 2007).

Peak-end effects are not merely cognitive curiosities. They can make a temporally longer and more painful episode remembered more favorably if the ending improves. They can also make a mostly tolerable experience remembered harshly because it ended badly. A ledger that substitutes remembered evaluation for momentary trajectory would become a different construct.

Memory can still be evidence. Retrospective evaluation matters to future choice, identity, narrative meaning, and suffering that reappears as recollection. Memory should not be discarded. Remembered utility, experienced utility, predicted utility, and decision utility must remain separate so that each source speaks in its own status.

The Law-facing risk is endpoint contamination. If terminal calm changes memory of a painful period, a retrospective report near death may appear to support neutrality while the experienced trajectory remained non-neutral. Conversely, a frightening ending may make a life period remembered as worse than its momentary distribution. Both directions matter.

Study designs can compare momentary sampling with retrospective ratings, episode reconstructions, narrative interviews, and physiological traces. Divergence is not an error to average away. It indicates that time-local experience and remembered evaluation are different objects.

The chapter keeps this distinction early so later terminal research cannot treat last reports as if they fully summarize the life. Memory is part of lived experience, but it is not the whole path.

Peak-end effects are not a universal law of memory, and one simplification should not replace another. Their magnitude varies with episode structure, delay, attention, meaning, and the question asked. The scientific use of the phenomenon is comparative: experienced trajectory and remembered evaluation are different targets whose divergence can be measured, modeled, and sometimes predicted. That divergence becomes a rival to any attempt to infer cumulative experience from retrospective summary alone (Kahneman et al., 1993; Fredrickson & Kahneman, 1993).

8.5.4 — Recency and Kernel Models

A kernel model assigns different weights to moments depending on their location in time or relation to an event. Recency kernels give more weight to recent states. Anticipatory kernels weight future expectation. Recovery kernels carry the cost of a state beyond its immediate interval. Such models may fit some psychological phenomena better than a flat integral (Eldar et al., 2016; Russell, 1980).

The timing of earlier events can improve predictions of present mood. Keren and colleagues (2021) compared a primacy model with several recency models across random, structured, and adaptive reward environments, including adult and adolescent samples and participants with depression. The primacy model, whose expectations incorporate earlier outcomes, predicted

successive mood ratings more accurately in the tested comparisons. Its expectation-related parameters also corresponded to activity in frontal regions involved in mood regulation. This supplies a concrete benchmark for cumulative research: compare flat, recency-weighted, primacy-weighted, and latent-state histories on the same future observations.

Kernel models are rivals to unweighted temporal accumulation. They can explain why recent fear colors a day, why recovery after an insult matters, why anticipatory dread can dominate before an event, and why a painful episode can have aftereffects. They also create risk because a flexible kernel can be tuned after the fact to produce the desired pattern.

Kernel status labels are therefore required. A kernel may be theoretical, empirically estimated, exploratory, or confirmatory. It must declare whether it weights attention, memory, physiological recovery, narrative evaluation, or momentary contribution. A kernel chosen because it improves terminal valence closure is no better than outcome-selected weights.

Recency models are especially useful for separating near-end reports from longer historical contributions. A terminal-window study can compare local dynamics under explicit memory kernels, with the kernel's form and coverage stated in the analysis.

Kernel models can represent how a past threat changes later experience. A flat integral of an adequately specified, history-dependent rate already includes those later effects. A separate recovery kernel is useful when it improves that representation, but

it must not count the same experienced aftereffect once in the rate and again as an added historical cost.

Kernels should be treated as competing scientific hypotheses. Simple integration, recency, recovery, anticipation, and memory-weighted forms should be frozen, compared prospectively, and allowed to fail. A kernel that predicts held-out experience within a declared construct earns bounded local use, not universal authority.

Recency kernels are themselves estimands that require identification. A rapidly decaying kernel, a long-memory kernel, and a reconstruction rule based on salient transitions can produce similar retrospective summaries under limited sampling. Prospective experience reports, controlled delays, and held-out prediction of later recall can help separate them. If several kernels remain observationally equivalent, the analysis should retain the family instead of selecting the one that produces the cleanest cumulative path (Kahneman et al., 1993; Särkkä, 2013).

8.5.5 — Order, Recovery, and Hysteresis

Two trajectories can contain the same set of momentary states and still feel different because order matters. Pain followed by relief differs from relief followed by pain. Fear followed by safety differs from safety followed by fear. A humiliation after a long recovery can reopen burden differently from the same event before recovery began.

Hysteresis names the dependence of current state on path history. The same present condition may mean different things depending on what came before. A quiet room may feel restful after overload

and lonely after abandonment. A medical monitor may feel reassuring after crisis and oppressive after repeated alarms. The state cannot always be interpreted without sequence.

Recovery also has its own burden. A harmful event may end while the person continues to pay in sleep disruption, vigilance, avoidance, pain flare, relationship strain, or cognitive effort. If the model counts only the event interval, it may undercount what the stream carries. Recovery time belongs to the path if it changes experience.

Order effects challenge simple ledger addition. If the total contribution of A followed by B differs from B followed by A, then the path functional is not merely the sum of unordered moments. The model may still use integration with state variables that include history, but it must declare that history is part of the state.

A study can test order by comparing episodes, interventions, or natural sequences that share similar components but differ in arrangement. It can examine whether recovery slopes, anticipation, or re-exposure alter later contribution. The result may support a path-dependent model without eliminating the possibility of quantitative study.

Sequence can carry burden even when an unordered total cannot. The same events can have different consequences when relief follows pain, threat follows safety, or recovery remains unavailable. Temporal order, opportunity for repair, and carryover therefore belong in the candidate functional whenever the evidence shows that permutation changes the experienced path.

Hysteresis indicates that present experience may depend on the route by which the present state was reached. Equal current pain ratings can carry different meanings after escalation, relief, failed treatment, or prolonged uncertainty. When history matters, the state representation must be enlarged to include the relevant memory, adaptation, or control variables; otherwise a non-Markov process will be forced into a misleading memoryless model. Closed loops and recovery trajectories are therefore diagnostic tools for discovering missing state rather than evidence of a preferred mechanism (Särkkä, 2013; Dejonckheere et al., 2022).

8.5.6 — Path Functional Model Comparison

A path functional maps a trajectory into a summary, but different functionals answer different questions. The additive ledger weights eligible duration; peak-end, recency, recovery, hysteresis, vector, and set-valued forms preserve other structures. Fit alone does not make any one of them the target.

Comparison begins from common observations, inclusion rules, and a prospectively fixed functional set. Each candidate declares its invariances, cadence, missing-interval rule, endpoint sensitivity, and held-out predictions. Allowing every model to choose a favorable representation would confound fit with target selection (Kahneman et al., 1993; Fredrickson & Kahneman, 1993).

Structural contrasts are often decisive: reorder the same states, extend a low-intensity interval, alter the final minutes, or repeat

recovery episodes to separate additive, hysteretic, duration-weighted, peak-end, and return-dynamic accounts.

Held-out prediction is matched to use. A functional may predict remembered evaluation, behavior, treatment preference, or later reports without measuring experienced cumulative contribution. Predictive success therefore supports its declared target, not automatically the ledger (Stone et al., 2007; Shiffman et al., 2008).

Identification depends on observation. Sparse prompts may leave order and duration unresolved, reconstruction may preserve narrative while missing brief episodes, and passive channels may improve timing while leaving sign uncertain. The honest output may be an observationally equivalent model set.

Outcome-selected functionals are prohibited. Development may explore kernels, weights, and scalarizations, but confirmation freezes the family, reports sensitivity, and keeps failure language valid under unfavorable ordering (Nosek et al., 2018; Munafò et al., 2017).

First-person, physiological, behavioral, clinical, relational, and intervention evidence constrain different parts of the path model. Their combination can reveal connections that a single channel misses.

8.6 — Evidence Baseline and Construct Failure

After representation and time come evidence. No channel is pure. First-person report is privileged because the subject lives the moment, yet report can be shaped by memory, language, demand, fear, fatigue, culture, and access. Physiology and behavior can reveal change that a person cannot report, but they can also track arousal, illness, medication, effort, or context rather than felt valence. The evidence baseline must therefore compare channels by role and failure mode rather than by prestige (Shiffman et al., 2008; Stone et al., 2007; Khalsa et al., 2018; Campbell & Fiske, 1959).

The evidence baseline combines source families according to their roles. Affective science, pain science, ecological momentary assessment, behavioral observation, clinical context, relational testimony, and intervention studies each contribute information about the construct. The matrix records those contributions, the checks needed to interpret them, and the conditions requiring revision.

Construct validity is the discipline that keeps this section from becoming a list of interesting findings. Convergent evidence should relate to the intended experience. Discriminant evidence should show that the construct is not merely arousal, illness severity, compliance, speech rate, social desirability, or device tolerance. Known-groups and intervention tests can help only when the direction of change is ethically and theoretically justified beforehand.

Failure is allowed. If the proposed scalar target fragments into several dimensions, if instruments mostly track arousal, if reports and physiology disagree in systematic ways that cannot be resolved, or if interventions change behavior without changing experience, the construct must be redesigned or narrowed. That is not a problem for science. It is what science is for.

Table 8.3. Evidence families, orienting value, and construct-failure routes.

Evidence family	What it can orient	Interpretation requirement	Typical failure route
First-person report	Access to felt quality, meaning, burden, and context.	Independent tests of units, sign stability, and temporal coverage.	Memory, demand, language, fear, fatigue, and response shift.
Physiology	Timing, arousal, interoceptive load, stress, pain correlates, and treatment state.	A calibrated relation to the target experience under the relevant bodily state.	Medication, illness, disability, sensor gain, and nonspecific arousal.
Behavior	Approach, withdrawal, speech, activity, sleep, social contact, and care use.	Contextual evidence about motivation, constraints, and the experience of the act.	Masking, coercion, habit, culture, access barriers, and survival strategy.

Evidence family	What it can orient	Interpretation requirement	Typical failure route
Clinical context	Pain, dyspnea, nausea, delirium, fatigue, diagnosis, and care burden.	Integration with participant reports and other available evidence.	Overmedicalization, underreporting, protocol burden, and role pressure.
Relational context	Familiar patterns, social safety, loneliness, dependence, and witnessed change.	Participant consent, source provenance, and consideration of alternative interpretations.	Projection, conflict, loyalty, grief, and privacy invasion.
Intervention response	Whether changes in pain, safety, rest, agency, or support alter reported and observed experience.	A construct specified before analysis and checks on the intervention's active mechanisms.	Multiple active mechanisms, placebo/context effects, and unmeasured mediation.

8.6.1 — First-Person Report

First-person report is privileged because the person lives the experience. No external channel has equal access to what it is like from within. If a study of lived experience systematically ignores testimony, it has already drifted away from its target. The subject is not one sensor among many in the same way a device is a sensor (Cronbach & Meehl, 1955; Borsboom, 2005).

Privilege is not sovereignty. Reports can be shaped by memory, language, fear, shame, expectation, demand characteristics,

fatigue, medication, clinical state, culture, and lack of concepts. A person may not know how to describe numbness, dissociation, moral injury, mixed grief, or chronic low-level dread. They may also report strategically because consequences attach to honesty.

The correct posture is respectful modeling. Reports should be collected in ways that minimize burden, protect privacy, allow uncertainty, invite context, and separate immediate experience from memory and evaluation. The model should know whether it is using momentary report, episode reconstruction, narrative interview, symptom scale, or life evaluation.

First-person report can also contest the model. If a participant says the labels are wrong, the timing missed the event, a device changed the feeling, or a question forced a false choice, that information belongs in data quality. Contestability is not an administrative courtesy. It is part of construct validity.

Silence also deserves respect. Refusal to answer, inability to answer, or choosing not to disclose should not be treated automatically as low burden or missing at random. Nonresponse can itself reflect burden, privacy, distrust, exhaustion, or dignity. The study must decide when to abstain rather than infer.

First-person report gives the baseline its moral center and its scientific vulnerability. It brings the target closest to view while reminding the project that even the closest source requires interpretation.

First-person report is privileged by target relevance, not infallibility. Reports can be affected by language, demand, memory, privacy, fear, fatigue, alexithymia, dissociation, and the

available response scale. Good design therefore varies prompt wording, protects refusal, compares concurrent and retrospective reports, and studies when disagreement is systematic. Treating reports as defeasible evidence respects the person more than either declaring them transparent truth or dismissing them whenever they complicate the model (Stone et al., 2007; Shiffman et al., 2008).

8.6.2 — Physiology and Behavior

Physiology and behavior are fallible correlates, not replacements for the subject. Heart rate, variability, skin conductance, sleep, respiration, facial movement, posture, speech, activity, medication use, and clinical observation can all carry information. They can also track exertion, illness, temperature, pain medication, device fit, disability, social masking, or environmental demand (Campbell & Fiske, 1959; Bollen, 1989).

The danger is physiological overconfidence. Arousal is not valence. Stillness is not peace. A smile is not joy. Low speech is not absence of experience. Agitation is not always distress in the same way. The chapter requires every external channel to state the construct it is meant to inform and the rival interpretations it cannot eliminate alone.

Behavior can be especially misleading under constraint. Compliance may reflect fear. Productivity may reflect economic pressure. Withdrawal may reflect safety seeking rather than depression. Politeness may reflect dependency. A fairness science should ask what burden a behavior hides before it treats the behavior as evidence of inner state.

Physiology remains important because first-person report can be unavailable, delayed, socially constrained, or altered by memory. External channels can detect changes, support timing, reveal arousal, help model sleep and pain, and identify conflicts that merit human review. They are most useful when they are combined with context and not granted authority alone.

A baseline matrix should therefore list for each channel: intended construct, raw unit, plausible interpretation, major confounds, expected lag, participant burden, missingness mechanism, and failure condition. If a channel cannot survive that specification, it should not contribute to a Law-facing estimate.

Physiology and behavior serve as witnesses rather than rulers. They can constrain, challenge, or contextualize a latent account, but they do not become the stream they help study.

Neuroscience provides a concrete reason to investigate shared structure across different feelings. Chikazoe and colleagues (2014) found orbitofrontal population patterns that tracked affective valence across visual and taste experiences. Later work separated shared from modality-specific patterns across several aversive experiences (Čeko et al., 2022). Such results make a common affective dimension a productive empirical target while preserving the distinctive qualities of each modality.

Pleasure itself is becoming a more specific measurement target. Kragel and colleagues (2023) developed a distributed neural signature using 28 fMRI studies and evaluated it in independent datasets. A pooled analysis of four independent validation studies found larger signature differences for hedonic contrasts than for

monetary contrasts. In a separate 19-person placebo-controlled crossover study, naloxone reduced the signature's response to erotic images. These results provide a candidate for distinguishing pleasure-related responses from incentive-value responses in the tested settings. Combining such a measure with independently validated unpleasantness channels could test whether cross-sign comparison is stable within a person.

Positive experiences now have a similarly concrete research opening. In 52 adults, Savalia and colleagues (2026) predicted responses to personalized music, videos, positive memories and monetary rewards from distributed neural activity and connectivity. Combining the two feature families improved held-out prediction. Their measure asked how much participants wanted an experience again, making separation of wanting from felt pleasure a valuable next validation step. A PTVC-oriented measurement study can retain this positive range while testing direct pleasantness and unpleasantness independently.

Valence assignment is also experimentally tractable at the circuit level. In mice, Li et al. (2022) identified a neurotensin pathway from the paraventricular thalamus to the basolateral amygdala that biased learning about rewarding and punishing outcomes. Activating this pathway promoted reward learning; removing neurotensin from the pathway strengthened punishment learning. Related work identified partially segregated ventral hippocampal cell populations associated with appetitive and aversive memory engrams, together with distinct molecular and projection features (Shpokayte et al., 2022). These findings give the project concrete examples of biological systems that distinguish valence-related

learning and memory without establishing PTVC. A declared route can be tested against independent appetitive and aversive learning models by asking whether its specified coupling predicts previously unseen changes in report and choice under ordinary, nonharmful variation. This makes the proposed coupling available for direct comparison.

8.6.3 — Clinical and Relational Context

Clinical context can make evidence interpretable. Diagnosis, medication, pain history, oxygenation, delirium risk, disability, sleep disruption, infection, hydration, and treatment burden can explain why reports or signals move. Without those records, a physiological pattern may be mistaken for affective change when it is actually illness, treatment, altered access, or sensor failure. Context is therefore part of the observation model, not a descriptive appendix (Shiffman et al., 2008; Khalsa et al., 2018; Giacino et al., 2018).

Relational context also matters. Close others may know patterns of expression, withdrawal, fear, relief, and comfort that a one-time researcher would miss. Caregivers may notice when a facial expression means pain rather than annoyance, or when quiet means peace rather than shutdown. But close others can also project, pressure, misremember, minimize, exaggerate, or carry their own burden into interpretation.

Clinical and relational evidence can inform the target without owning it. Clinicians are not mind readers, family members are not automatic translators, and researchers are not neutral by position alone. Each witness has proximity, expertise, bias,

missingness, and a context of use. Convergence among witnesses is evidence only when their errors are not treated as interchangeable (Cronbach & Meehl, 1955; Campbell & Fiske, 1959).

Clinical context is especially important in palliative and terminal research, but this chapter keeps it general. Medication, fatigue, social dependence, fear of being a burden, and care quality can shape experience across many populations. A baseline that ignores these pathways will confuse construct with context.

Relational evidence also raises privacy and bystander issues. A person's experience should not become available to others simply because those others provide context. Consent, purpose limits, and data minimization remain necessary even when close observers help interpret evidence.

A defensible evidence baseline is triangulated but not totalizing. Clinical and relational context can improve interpretation while preserving the participant's authority to contest, refuse, or remain partly unobserved.

8.6.4 — Convergent and Discriminant Validity

Validity evidence must match the measurement model. In a reflective model, indicators should behave as consequences of the proposed latent state under the declared conditions. In a causal or composite model, components may jointly define the score without being interchangeable or highly correlated. In a network model, relations among components may be the object of interest. Convergent and discriminant tests therefore depend on what the model says the observations are. A lived-experience estimator

should relate plausibly to reports, contexts, known contrasts, and interventions without merely reproducing arousal, illness severity, social desirability, compliance, or device tolerance (Cronbach & Meehl, 1955; Campbell & Fiske, 1959; Bollen, 1989; Borsboom, 2005).

A channel can be convergent for the wrong reason. Skin conductance may rise during fear, pain, excitement, heat, exertion, or medication effects. Activity may fall during depression, fatigue, rest, disability, or safety. A model that predicts many states because it tracks general physiological activation has not yet identified valence.

Discriminant tests should therefore include rival constructs. The evidence baseline should ask whether the candidate target can be separated from arousal, physical illness, fatigue, sleep, medication, social pressure, language ability, and observer expectation. If it cannot, the estimate should not be used as lived valence.

Convergent evidence should come from more than one method, but a count of channels is not enough. Momentary self-report, qualitative context, physiology, behavior, and ethically justified interventions can align or diverge. Agreement raises confidence only when the methods do not share the same wording, scoring, training labels, missingness, or contextual confound. Shared method bias is not independent convergence, and a composite built from redundant witnesses should not be treated as stronger merely because it has more inputs.

The chapter also needs ecological validity. A construct validated only in artificial laboratory stimuli may fail in the ordinary middle of life. A construct validated only during acute pain may fail for boredom, shame, safety, or awe. Evidence must match the range of experiences the claim intends to cover.

Validity is not a single stamp. It is a chain of relations that can break. The chapter treats each link as a place where the Law-facing measurement bridge may narrow.

Convergent validity is strongest when methods share a target without sharing the same bias. Agreement among several self-report items may reflect common wording or response style rather than independent access to experience. Disagreement between report, behavior, physiology, and clinical context can reveal construct breadth, lag, or method failure. Multitrait-multimethod designs, explicit latent-variable models, causal-composite alternatives, and held-out intervention tests can locate that disagreement, but none creates direct access to phenomenology (Campbell & Fiske, 1959; Bollen, 1989; Borsboom, 2005).

8.6.5 — Known-Groups and Intervention Tests

Known-groups tests ask whether a construct distinguishes groups or states that theory and ethics expect to differ. Intervention tests ask whether the construct changes when conditions change. Both can support a lived-experience target, but only if the comparison is justified before the result and does not exploit vulnerability (Munafò et al., 2017; Nosek et al., 2018).

Examples can be humane and ordinary. A noise-reduction intervention in a hospital ward, a better pain-control plan, a

privacy improvement, a caregiving respite, a debt-relief process, or a mobility accommodation may be expected to reduce burden. If the proposed construct does not move when participants report relief and context supports the change, the construct is under pressure.

Relief research provides a particularly useful separation of expectation, sensation, and positive feeling. Willems et al. (2025) studied 31 adults and found that omission of an expected painful stimulus produced reported relief that increased with expected threat intensity and probability. Omission also recruited parts of reward and salience circuitry. The neural pattern was prediction-error-like rather than a complete canonical reward-prediction-error signal: one required axiom failed, and the ventral tegmental probability effect did not reach the conventional significance threshold. The substantive opportunity is that relief can occur when the anticipated harm never happens. A phenomenal account must therefore record experienced anticipation and experienced relief in their own windows, while the omitted event contributes no unexperienced pain. Approved reanalysis or naturally occurring relief records can compare expectation-based and event-only models. These findings give temporal and appraisal models a concrete event sequence to explain.

Known-groups tests are dangerous when they turn identities into expected feeling. Disability, culture, age, poverty, diagnosis, or family status should not define burden by stereotype. The comparison must concern specific conditions and pathways, not the worth or presumed inner life of a group. Experts should ask whether the group label is scientifically and ethically appropriate.

Intervention tests can also mislead. An intervention may change behavior without changing experience, change report without changing burden, or reduce one burden while increasing another. A privacy intervention may reduce observation stress while making data sparse. A medication may reduce physiological arousal while increasing numbness. The construct must be able to show tradeoffs.

Learning from pain and learning from its avoidance can follow different processes. In a randomized, blinded study of 83 healthy adults, Jepma et al. (2022) found that a model with separate learning rates for received and avoided pain fit behavior better than a single-rate model. Under placebo, estimated group learning rates were 0.72 for received pain and 0.32 for avoided pain. Levodopa and naltrexone each increased learning from avoided pain, while imaging associated the two learning processes with different systems. No reduction in the number of painful outcomes was detected between the treatment groups. The study identifies a concrete, modifiable learning asymmetry. For this program, independently estimated positive and negative learning kernels can be compared with a declared coupled model using existing approved data, with future observations reserved for scoring. This comparison can identify which coupling mechanism best explains the observed learning asymmetry.

The best intervention tests include participant interpretation, predeclared expected mechanisms, alternative outcomes, and adverse pathways. They ask not only whether a score moves, but whether the movement corresponds to the burden the intervention was meant to alter.

Known-groups and intervention tests help the chapter avoid pure abstraction. They give the construct a chance to fail against humane changes in the world. If a measure cannot notice a real reduction in carried burden, the measure must change before the Law can use it.

8.6.6 — Construct Failure and Redesign

Construct failure occurs when evidence does not support the target as represented: channels fail to converge, meaning or sign drifts, interventions move indicators without the intended experience, or scalarization collapses states that participants and experts distinguish. The conclusion concerns the construct, bridge, or measurement practice, never the participant's credibility (Cronbach & Meehl, 1955; Campbell & Fiske, 1959; Flake & Fried, 2020).

Redesign begins with the smallest failed relation. An unstable item is revised or removed, a nonspecific channel is narrowed, a failed scalar becomes a vector or identified set, and a target without stable content is retired locally. More channels do not repair a construct if they merely combine arousal, illness, device gain, or response style. The redesign should preserve successful relations from the earlier instrument so correction does not erase evidence that still holds.

Every redesign records the failed use and context, contrary evidence, changed items or transformations, timing relative to outcome inspection, affected claims, and required validation. A familiar name does not let the successor inherit the predecessor's evidentiary status (American Educational Research Association

et al., 2014; Borsboom, 2005). The redesign record should also state which observed failure the new version is expected to correct, creating a prospective criterion for improvement rather than assuming it.

The revised object must return to content, response-process, structural, external, and consequential validation, including time-sensitive reliability and repeated-administration effects. Independent teams should recover both the improvement and the original failure (Nosek et al., 2018; Munafò et al., 2017; Vogelsmeier et al., 2024). Recovering the original failure is important because an instrument that only looks better on favorable cases may simply have hidden the condition that exposed its weakness.

Some failures close the route, including unidentified origin, irreducible sign ambiguity, intolerable burden, nontransportable observation, or persistent mismatch with lived reports. That outcome preserves useful knowledge about what cannot presently be measured and prevents a failed bridge from returning under a new label. A closed route should remain discoverable in the archive so later teams can distinguish a genuinely new bridge from a renamed version of a previously unsuccessful one.

8.7 — Fairness Appraisal and Cultural Recurrence

Fairness appraisal is itself a scientific domain. People do not merely register pleasure and pain; they interpret distributions, procedures, intentions, promises, status, reciprocity, and relative position. Those appraisals can alter attention, arousal, anger, gratitude, trust, shame, and willingness to cooperate. For this book, they matter because a theory about carried burden must distinguish the experience of an outcome from the judgment that the outcome was fair (Fehr & Schmidt, 1999; Bolton & Ockenfels, 2000).

The distinction is not ornamental. A person may reject an unequal allocation at personal cost, accept an equal allocation that feels humiliating, or prefer a procedure whose result is materially worse because the procedure recognizes agency. Fairness judgments can therefore generate affect, organize memory, and change behavior without serving as a direct meter of phenomenal value. They are evidence about appraisal processes and social dynamics, not automatic entries in a cumulative ledger.

Recurrence across societies and developmental stages creates a comparative research opportunity. Shared social problems, evolved cooperative capacities, convergent institutions, learning, cultural transmission, experimental demand, and narrative habits offer distinct explanations whose predictions can be examined across settings (Henrich et al., 2005; Blake et al., 2015).

The empirical starting point is substantial. In a controlled study of 40 participants, Tricomi and colleagues found that neural reward responses and subjective appeal depended on whether

monetary transfers reduced or increased an initially unequal distribution (Tricomi et al., 2010). These results give fairness appraisal a measurable place in value processing: external rewards are evaluated in a social context. For PTVC research, the gain is a concrete set of variables and experimental contrasts through which social events can alter experience within a stream.

8.7.1 — Inequity Aversion and Fairness Appraisal

Inequity aversion describes the possibility that people care not only about their own payoff but also about how outcomes compare. Formal models distinguish disadvantageous inequity, in which another receives more, from advantageous inequity, in which one receives more than another. These terms capture recurrent behavior in allocation tasks, but they are models of preference and appraisal rather than direct measures of lived valence (Fehr & Schmidt, 1999; Bolton & Ockenfels, 2000).

The experiential structure can be mixed. Disadvantage may bring anger, humiliation, threat, envy, or resignation. Advantage may bring pleasure, guilt, responsibility, fear of retaliation, or no salient feeling at all. A scalar fairness score that treats all departures from equality as the same burden would erase the very mechanisms the experiment is meant to reveal.

Procedure and intention also matter. An unequal result produced by chance may be experienced differently from the same result produced by favoritism, contempt, or broken promise. Conversely, an equal result can feel unfair when it ignores effort, need, risk, or prior commitment. Outcome equality is therefore neither a complete construct nor a universal neutral origin.

Neurochemical work gives this contextual distinction another experimentally accessible layer. During clinically indicated awake surgery in four people with Parkinson's disease, Batten and colleagues measured dopamine and serotonin while participants responded to economic offers attributed to humans or computers. Social source changed decisions, and the two transmitters carried distinguishable contextual and value information (Batten et al., 2024). This small clinical study demonstrates a route for investigating how social interpretation enters valuation.

Heterogeneity is part of the science. Participants differ in sensitivity to disadvantage, willingness to reject, interpretation of the task, expectations about deservedness, and trust in the experimenter. Population averages can hide subgroups whose appraisal functions differ in sign or shape. The model should preserve that heterogeneity before deciding that one fairness parameter explains a community.

Inequity aversion matters here because it shows how external arrangements become lived conditions. The same material difference may be carried as threat, insult, motivation, indifference, or responsibility. Studying that conversion connects external conditions with the subsequent course of experience (Fehr & Schmidt, 1999; Henrich et al., 2005).

A strong study should prospectively specify the allocation rule, information available to participants, intention cues, reference group, stakes, rejection costs, and candidate affective mediators before inspecting the target outcome. It should compare preference models, appraisal models, norm-compliance accounts, and experimenter-demand explanations. The result may identify

a local fairness process even if it says nothing about lifetime closure.

8.7.2 — Reciprocity, Cooperation, and Punishment

Reciprocity links present action to remembered treatment. Positive reciprocity can support trust, gratitude, help, and durable cooperation; negative reciprocity can support retaliation, withdrawal, punishment, and refusal. Laboratory games, field observations, and institutional records show that people sometimes incur costs to reward cooperation or sanction defection (Fehr & Gächter, 2002; Tomasello & Vaish, 2013).

Concern about fairness also extends beyond direct retaliation. In a study of 535 children aged 5 to 15 across communities in Canada, India, Peru, Uganda, the United States, and Vanuatu, children were more likely to intervene against maximally unequal than equal sharing between two absent peers. Some interventions required sacrificing the child's own rewards, and sensitivity to cost and age varied across settings. This makes immediate personal gain or repayment of a personal injury an incomplete account of the observed behavior. Learned norms, social evaluation, and evolved cooperative capacities remain live explanations. The useful PTVC research question is whether independently measured affective dynamics add a distinctive prediction beyond these mechanisms (McAuliffe et al., 2025).

Costly punishment is not experientially simple. Anger may motivate the act, anticipated relief may sustain it, and the act may later produce guilt, social approval, or escalation. A punishment decision can therefore be both behaviorally costly and affectively

reinforcing. Treating it as a clean negative or positive contribution would confuse action, motive, appraisal, and felt consequence.

Cooperation also depends on expectations and institutions. Repeated interaction, reputation, communication, group identity, enforcement, and perceived legitimacy can change whether cooperation feels safe or exploitable. The same cooperative act can be carried as generosity, duty, fear, belonging, or coerced compliance. A science of fairness must model these meanings rather than use cooperation as a proxy for well-being.

Cooperation can also contribute positively to the experience of the person who helps. Aknin and colleagues combined surveys from 136 countries with experiments, including charity-versus-self purchasing in Canada and South Africa; the experimental prosocial purchases increased reported positive affect even without an opportunity to build social ties (Aknin et al., 2013). More recently, three two-month randomized studies of daily online micro-donations, with samples of 125, 296, and 462, reported improvements in depressive symptoms and emotional positivity relative to waitlists (Y. Zhang et al., 2025). The first two studies registered their plans after recruitment and baseline measurement; the third registered before data collection. These findings offer concrete, testable pathways from voluntary social action to better reported experience.

Prosocial spending supplies a complementary finding about the giver's experience. A registered replication with 712 students found greater momentary happiness after purchasing for a stranger in need than after purchasing for oneself. A recall experiment with 1,950 adults found no corresponding advantage,

while a revised recall task with 5,199 participants found a small benefit. The full pattern supports a conditional connection between generosity and positive feeling and identifies task engagement and measurement as issues for replication. Material expenditure can therefore coexist with positive experience, which is a reason to measure felt consequences directly. The contrasting tasks also show where the relation is most reliable (Aknin et al., 2020).

The Law-facing question is not whether cooperation is good in the abstract. It is how reciprocal structures alter the stream of experience and which local dynamics might generate apparent compensation, adaptation, or burden transfer. A failed partnership may produce immediate anger and long recovery. A repaired relationship may change future threat sensitivity without erasing the experienced past.

Repair can also change the emotional state of the person who acts. Donohue and Tully randomly assigned 97 children aged 6 to 10 to conditions separating guilt from the opportunity to make amends. Children led to believe they had upset a peer showed more reparative behavior than children in a no-guilt condition. Guilt declined when children had an opportunity to offer stickers and a note, whereas it did not decline in the condition without that opportunity. This provides a concrete local sequence linking appraisal, constructive action, and relief. It motivates time-resolved observation of naturally occurring repair as a regulatory process. The opportunity to make amends offers a specific action pathway for investigating emotional recovery (Donohue & Tully, 2019).

Serious rivals must remain visible. Reciprocity can be explained through strategic learning, reputation, norm enforcement, kin and coalition psychology, reinforcement, or institutional selection. Those accounts may fit the evidence without any terminal constraint. The research program becomes stronger when it asks which predictions differ rather than treating cooperative behavior as thematic confirmation.

A useful protocol combines choices with time-resolved reports, physiological channels, expectations, relationship history, and follow-up. It separates the cost paid, the norm invoked, the emotion carried, the social consequence, and the later interpretation. That architecture lets fairness science inform the measurement problem without turning a social game into a miniature proof of the Law.

8.7.3 — Social Comparison and Relative Position

Social comparison concerns the use of other people, past selves, or imagined standards as reference points. Upward comparison can motivate, inspire, shame, or discourage. Downward comparison can reassure, isolate, or provoke guilt. The direction of comparison does not determine its valence; meaning, controllability, identification, and perceived legitimacy matter (Festinger, 1954; Suls et al., 2002).

Relative position helps explain why identical material conditions can produce different experiences. Income, recognition, safety, workload, or illness may feel different when a peer group changes, when inequality becomes visible, or when a former standard remains psychologically active. This does not make

objective conditions irrelevant. It shows that their experiential effect is mediated by reference structure.

Reference groups are dynamic. People compare with coworkers, siblings, neighbors, online networks, prior selves, cultural ideals, and expected futures. Platforms and institutions can manipulate salience by repeatedly displaying exceptional outcomes. A measurement system that ignores the comparison field may attribute resulting distress to an intrinsic trait or to the wrong event.

Social comparison also complicates adaptation. A material improvement may fail to produce sustained relief when the reference group rises faster, while a stable condition may feel better after a threatening comparison disappears. Such changes are scientifically important, but they do not retroactively alter earlier experience. Past-fixity requires the model to represent reference-dependent change without rewriting the past.

Social comparison is a psychological process that can change experience within a stream. Measuring its effects connects interpersonal events with individual affective responses.

A time-resolved experiment makes this relation quantitative. In 47 participants, Rutledge and colleagues found that both receiving less than a partner and receiving more could lower momentary happiness. Adding social-inequality terms to a recent-reward model increased mean explained variance from .39 to .44, and the asymmetry between the two inequality sensitivities correlated with generosity in a separate anonymous allocation ($\rho = -.48$; Rutledge et al., 2016). The study therefore connects

relative outcomes, felt appraisal, and generosity in a separate task within one testable account. It also provides an important comparison model for PTVC research: recent rewards, expectations, and social comparison already explain meaningful structure. Happiness ratings were standardized within participants.

A disciplined study records the reference target, comparison direction, perceived similarity, controllability, justice appraisal, exposure frequency, and resulting affect over time. It tests whether comparison variables improve held-out prediction beyond material conditions and individual history, thereby refining the local model of experience.

8.7.4 — Just-World Cognition and Narrative Balance

Just-world cognition is the tendency to expect that people generally receive outcomes they deserve or that the world is meaningfully ordered. Such beliefs can support persistence and trust, but they can also encourage victim blame, denial of structural harm, and retrospective moralization. For a project named around fairness, this is a central adversarial risk (Lerner, 1980; Hafer & Bègue, 2005).

Narrative balance can shape memory and meaning-making. A redemptive ending may organize the telling of a life that still contains substantial burden; a tragic ending may overshadow relief that the person experienced. Recording both narrative evaluation and time-resolved feeling makes their relationship available for study.

Just-world beliefs can also shape reports. Participants may minimize suffering to protect a worldview, exaggerate agency to avoid stigma, or reinterpret harm as deserved, educational, or spiritually necessary. These interpretations can be sincerely held and experientially consequential. They still require separation from the scientific question of what was felt and when.

Public communication is especially vulnerable to moralized readings of balance. Explain conditional net requirements without using them to justify suffering, delay care, rationalize inequality, or assign spiritual purification. Just-world stories and retrospective event pairing are not evidence of PTVC. An accurate account can preserve the arithmetic while rejecting those additional inferences.

Research can examine framing effects directly. Experiments can vary deservedness cues, narrative framing, outcome order, and information about structural causes, then measure changes in memory, fairness judgment, blame, and affect. Comparing explicitly balanced framing with neutral framing helps distinguish a reproducible experiential pattern from a response to the expectations introduced by the task.

The constructive lesson is not to remove meaning from science. It is to model meaning as a variable with causes and consequences. Narrative coherence may reduce distress, increase agency, or support social repair. Those are worthwhile outcomes. Studies can compare how well specified PTVC, appraisal, and learning models predict the timing and course of those outcomes.

Beliefs about moral consequences also have experimentally measurable effects. White and colleagues (2019) found that reminders of karma reduced selfish allocations among karmic believers across religious affiliations, while reminders of God reduced selfishness among believers in God. These findings identify a connection between culturally learned expectations and choices about sharing. They give the study of fairness a concrete social mechanism to investigate alongside material incentives, reputation, relationship history, and the feelings associated with cooperation.

8.7.5 — Developmental and Cross-Cultural Recurrence

Fairness behavior changes across development. Children become more sensitive to disadvantage, later show greater concern about advantageous inequity in some settings, and learn how local norms interpret equality, need, merit, and group membership. Developmental findings therefore reveal trajectories of appraisal and norm learning rather than a single fairness instinct frozen at birth (Blake et al., 2015; House et al., 2020).

The scale of this evidence deserves to be visible. Blake and colleagues studied 866 pairs of children aged four to fifteen in seven societies. Rejection of disadvantageous inequity developed across all seven, whereas rejection of advantageous inequity appeared later and in three societies (Blake et al., 2015). In complementary experiments, jointly earning rewards increased equal sharing among three-year-olds compared with windfall or parallel-work conditions (Hamann et al., 2011). Together these findings identify recurrent developmental capacities that social arrangements can cultivate. They supply clear contrasts among

disadvantage, advantage, collaboration, learning, and local norms.

Cross-cultural work likewise shows both recurrence and variation. Small-scale societies, market-integrated communities, urban populations, and institutional settings can differ markedly in offers, rejection, punishment, cooperation, and interpretation. The shared presence of fairness concerns is scientifically interesting, while the variation prevents a local task from becoming a universal psychological meter (Henrich et al., 2005; Henrich et al., 2010).

Ethnographic evidence adds a broader map of cooperative values. Curry and colleagues examined seven forms of cooperation in records from sixty societies and found positive moral evaluation in 961 of 962 coded observations (Curry et al., 2019). Coverage differed across domains; fair division of disputed resources was documented in nine societies. Recurring problems of kinship, coordination, reciprocity, conflict, and possession repeatedly invited moral solutions.

A later machine-reading study extended coverage to 256 societies and detected most of these moral themes in most societies across world regions (Alfano et al., 2024). Its expanded corpus included the earlier records. Together, these studies provide a large comparative record of cooperation-centered moral evaluation and a basis for investigating how social practices shape experience.

Task equivalence is not guaranteed. Currency, anonymity, experimenter authority, household obligations, reputational risk, and local meanings of sharing can change what an allocation

game measures. Translation must include institutions and incentives, not merely words. A numerical difference may reflect task ecology rather than a deeper difference in felt fairness.

A 2026 study sharpens the distinction between broad fairness sensitivity and particular institutional norms. Among 697 children aged three to eleven in Norway, Japan, the United States, and Italy, aversion to unequal allocations emerged across settings by age ten, while rejection of bribes appeared in late childhood only in some contexts (Reyes-Jaquez et al., 2026). The dissociation is informative: related moral judgments need not be expressions of one interchangeable faculty. It gives future research a practical strategy: compare closely related judgments under the same task framework and identify which developmental and cultural conditions carry each pattern.

Development and culture also interact with expression. Children may lack concepts for mixed motives. Adults may follow politeness rules that mute complaint. Communities may treat open anger, direct refusal, or individual entitlement differently. These patterns affect reports and behavior without making any group less capable of experience.

Recurrent concern with distribution, reciprocity, and repair identifies questions for the science of lived burden. It supplies candidate mechanisms and contrasts across social settings.

Religious traditions also supply observable social mechanisms. In eight communities, a study of 591 participants associated beliefs in knowledgeable, punitive gods with more impartial allocations to distant co-religionists (Purzycki et al., 2016). An expanded

two-wave study covering 2,228 participants in fifteen societies, including the earlier sample, further examined this relation and its limits across religious groups (Lang et al., 2019). These findings make belief, accountability, group boundaries, and cooperation experimentally and comparatively tractable. Analyses of this evidence should account for the overlapping samples and shared cultural histories. Their contribution is a better map of the meanings and social conditions that can alter experience within a stream.

A strong comparative program uses local collaborators, measurement-invariance tests, qualitative interpretation, task redesign, and within-site replication. It reports commonalities and differences without forcing one global parameter. When a pattern fails to transport, the failure improves the theory by showing which social and developmental assumptions were carrying it.

Developmental and cross-cultural recurrence should be studied at the level of tasks, meanings, and institutions, not only labels. Children's responses change with cognitive capacity, norm learning, relationship, and stakes; adult patterns vary with market integration, kinship, religion, authority, and experimental framing. Similar behavior may therefore rest on different appraisals, while different behavior may express a shared concern under different constraints. Comparative models can test which shared processes and local conditions account for the observed recurrence (Henrich et al., 2005; Blake et al., 2015).

The comparative frontier remains active and increasingly precise. A primary-data synthesis of twenty-three studies across eighteen nonhuman species found no inequity-aversion evidence in the

accept/reject paradigms analyzed (Ritov et al., 2024). Subsequent bonobo experiments found greater refusal under unequal rewards, including controls for disappointment in a human experimenter, although the second study was only partly consistent with an inequity-aversion account (Radovanović et al., 2025). A 2026 group study of twenty-seven participating chimpanzees found responses that depended on food quality and the social partners present (Martinez et al., 2026). These results invite stronger tests of context, reward, and relationship effects rather than a universal animal-fairness verdict. Developmental research supplies the same lesson: a coordinated study testing 1,018 infants, with 567 included across thirty-seven laboratories, found no helper preference in the specific hill paradigm (Lucca et al., 2025). Such coordinated work makes claims more precise while leaving other tasks and capacities open.

8.7.6 — Recurrence as Hypothesis Generator, Not Validation

Fairness themes recur in moral psychology, economics, anthropology, religion, politics, childhood development, and ordinary storytelling. This breadth gives researchers several explanations to connect and compare: shared social problems, cognitive capacities, cultural diffusion, convergent institutions, narrative preferences, and specified PTVC-related processes. The next step is to identify observations on which their predictions differ (Munafò & Davey Smith, 2018).

The constructive use of recurrence is to turn a recognizable pattern into a discriminating question. Existing social-value, cooperation, developmental, religious-cognition, and affect

studies identify variables, candidate processes, and feasible designs. A PTVC-related route can then be compared with cultural learning, reciprocity, social-preference models, and bounded-memory reward learning under the same observations. For example, if a particular route predicts a history-dependent change beyond current affect, recent rewards, expectations, resources, and norms, that residual-history prediction must be derived, fixed in advance, and tested in held-out observations. The evidential gain comes when a specified route successfully predicts a difference that capable rivals do not, with identification and observation error accounted for. Recurrence supplies the research opportunity; comparative prediction determines which explanation earns additional confidence.

A practical starting point is the Global Preference Survey, which measured experimentally validated preference items in approximately 80,000 people across 76 countries, including reciprocity, altruism, and trust. Its larger variation within countries than between countries encourages person-sensitive analysis rather than national stereotypes (Falk et al., 2018). These data can help choose contexts and social-preference measures. A new, low-burden longitudinal study could combine such measures with repeated affect reports and naturally occurring episodes of help, disappointment, and voluntary repair. Candidate PTVC relations and appraisal, learning, reputation, and norm-based alternatives would make protected predictions using the same observations. A PTVC realization can add a prospectively specified restriction to this shared comparison.

This rule also protects negative results. If a fairness motif is absent in a population, a developmental stage, or a well-designed task, the project should not redefine the motif until it appears. Absence may reveal a boundary condition, a task failure, or a genuine limit. Scientific progress requires all three possibilities to remain open.

Demand characteristics deserve special attention. Participants may infer that a study expects equality, balance, redemption, or moral concern and respond accordingly. Researchers and readers may also select memorable fairness-shaped outcomes while ignoring ordinary counterexamples. Blinding, neutral task language, preregistration, and complete reporting reduce that risk.

The evidence baseline establishes phenomena and measurement problems that PTVC must explain: affect is dynamic, multidimensional, state-dependent, culturally mediated, and imperfectly observed. Those literatures do not themselves support terminal valence closure. Their role is to constrain representation, identify ordinary mechanisms and confounds, and provide benchmarks that any PTVC-specific model must outperform.

Chapter 9 — The Measurement Pipeline

A measurement pipeline is not a dashboard placed over a person. It is a sequence of accountable translations: a lived target is represented, sampled through one or more channels, transformed into data, linked to an estimand, analyzed by a declared map, summarized by an estimator, and interpreted under a decision rule. Measure selection, item content, scoring, modifications, exclusions, and versions belong inside the same chain. Every step can add information, lose information, or change the question. Chapter 9 makes that sequence visible so that a final number cannot hide the decisions that produced it (Flake & Fried, 2020).

Qualification begins with a declared context of use; §9.1 specifies the conditions that bound what an instrument may validly support.

The pipeline then separates objects that are often compressed into the word measure. The measurement map specifies how observations arise. The estimand states the scientific quantity or contrast being targeted. The analysis map records preprocessing, feature construction, exclusions, and transformations. The estimator produces an estimate and uncertainty object. The decision rule states what the result can license, reject, narrow, or leave unresolved. Keeping these objects distinct makes post hoc rescue visible and lets model recovery test whether the procedure answers the question it claims to answer.

Candidate channels contribute different kinds of evidence. First-person reports and pairwise judgments can witness phenomenal content and comparative intensity. Trade-off choices and behavior can reveal priorities, constraints, and anticipated consequences. Autonomic and interoceptive signals can track embodied change. Neural and clinical channels can locate state transitions or

confounds. Contextual and relational records can explain exposure, care, threat, and opportunity. The pipeline assigns each channel a declared role instead of treating a larger sensor array as automatic access to experience. The received candidate momentary estimator remains physiological; the other witnesses are auxiliary unless a broader multimodal estimator is separately declared.

First-person report remains central because the target is lived, but central does not mean infallible or sufficient. Language, recall, social desirability, fear of consequences, communication access, fatigue, demand characteristics, and scale interpretation can shape an answer. These influences are not reasons to demote the participant. They are features of the response process that the measurement model must investigate. Pairwise judgments, repeated anchors, qualitative interviews, and participant challenge can improve interpretation without replacing the person's authority over consent and correction.

Intensive longitudinal methods create both opportunity and risk. Repeated observations can reveal within-person dynamics, context dependence, lag, and ordinary duration that one retrospective survey misses. They can also reproduce the same unstable item hundreds of times, create burden-related missingness, and mix between-person, within-person, and person-specific reliability. Recent reviews document substantial variation in experience-sampling design and reporting, while recent psychometric work shows why item distributions, time trends, measurement structure, level-specific reliability, and person-specific performance must be examined directly

(Shiffman et al., 2008; Wrzus & Neubauer, 2023; Vogelsmeier et al., 2024; Siepe et al., 2025; Castro-Alvarez et al., 2026; Peeters et al., 2026).

A serious momentary-to-interval estimation pipeline must answer those questions before claiming scientific value. Its qualification dossier should define the construct, justify the measure and channels, report every modification and scoring rule, specify the context of use and state range, name the exact estimand, and identify the decisions the output may never support. The dossier also records whether the system is exploratory, protocol-fixed, or publicly preregistered, and when it must return No adequate estimate instead of improvising a number because the pipeline wants completion (Flake & Fried, 2020; Gagnier et al., 2025).

Cross-channel conflict is evidence, not clutter. A participant may report calm while physiology remains elevated after exertion, or report distress while a wearable records little change because medication, disability, device contact, or individual physiology weakens the channel. The scientific question is which observation processes and constructs could generate the disagreement. A strong pipeline can widen uncertainty, split by channel, narrow the claim, or return No adequate estimate without treating the person as inconsistent or the sensor as sovereign.

The measured-to-latent bridge is the chapter's central inferential gate. Calibration, invariance, linking, construct validity, and observation coverage determine whether measured outputs support a local trajectory, a bounded contrast, an identified set, or any claim about latent phenomenal value. Bridge strength must match licensed language. A well-predicted report is not

automatically a recovered latent state, and a recovered momentary state is not automatically a complete-stream cumulative object.

Section 9.6 treats missingness as part of the observation model, including informative and missing-not-at-random processes relevant to intensive longitudinal data (Tsiatis, 2006; McNeish, 2025).

Provenance and versioning determine whether an estimate can be interpreted later. Hardware, firmware, item wording, language, sampling cadence, preprocessing, model weights, calibration sample, missingness rules, and public claim templates can all change the measurement relation. Each output therefore carries the versions and transformations that produced it. Migration studies test which comparisons survive updates; backward compatibility is demonstrated, not presumed. A correction must be able to locate every figure, summary, model, and downstream claim that depended on the retired relation. Version provenance should be queryable at the individual result level, allowing a later defect to find exactly which outputs require recalculation.

The pipeline also needs a reproducibility model suited to sensitive data. Independent checking does not require public release of person-level records. Synthetic fixtures, controlled-access environments, privacy-preserving summaries, code tests, data dictionaries, and provenance logs can make transformations auditable while protecting participants. Current reproducibility and reporting standards support this layered approach, and current good-clinical-practice guidance treats reliable information, proportional processes, and participant protection as connected

design duties (Wilkinson et al., 2016; Center for Open Science, 2025; International Council for Harmonisation, 2026). The chosen reproducibility layer should be declared before analysis so privacy restrictions do not become a post hoc reason why an unfavorable result cannot be checked. The declaration should also state which independent checks remain possible at each access tier, making any verification limits created by privacy protection explicit.

Section 9.7 implements anti-score and non-deployment governance for the measurement pipeline through context-of-use limits, access control, contestability, record separation, deletion, retirement, and human review. Technical enforcement matters because purpose limits that rely only on user discretion can disappear when outputs move between systems. Context-of-use restrictions should therefore travel with derived outputs through persistent provenance or policy metadata, so transfer between systems does not silently detach an output from the conditions that licensed its use.

Participant authority travels through the entire stack. People can refuse, withdraw, correct context, challenge an interpretation, report burden, and learn what an output can and cannot mean. Clinicians and caregivers can flag medication, workflow, state, or device effects without becoming substitute reporters of inner life. These routes improve both dignity and validity because unchallengeable instruments preserve their own mistakes. The burden of justification stays with the pipeline. Contestability also provides calibration data: recurring participant corrections may reveal systematic context errors that ordinary validation samples

miss. Correction pathways should distinguish amendments to contextual information from changes to the original record, preserving provenance while allowing the interpretation built from that record to be challenged.

Chapter 9 specifies an end-to-end measurement dossier, from context of use through maps, estimands, channels, dynamics, missingness, provenance, privacy, and retirement. An implemented pipeline earns qualification only through the validation work described here. Chapter 10 then examines whether origin, sign, unit, linking, and invariance support comparisons across time and context. Qualification therefore attaches to a versioned pipeline rather than to an instrument name, allowing later changes to be evaluated without inheriting unsupported authority.

9.1 — Context of Use and Qualification

Qualification begins with a question, not a device. The context of use should name the construct, population, state range, setting, sampling cadence, decision purpose, participant-burden ceiling, tolerated error, and prohibited uses before performance is summarized. Evidence adequate for exploratory within-person tracking may be inadequate for clinical interpretation, cross-group comparison, or a terminal-window claim. Current fit-for-purpose clinical-outcome-assessment guidance and measurement-property reporting standards reinforce this claim-specific discipline (FDA-NIH Biomarker Working Group, 2016; U.S. Food and Drug Administration, 2025b; Gagnier et al., 2025).

The chapter uses qualification as a scientific discipline rather than a badge of approval. A candidate momentary estimator may be qualified for one purpose and unusable for another. It may track within-person change in ordinary ambulatory conditions while failing in severe pain, support exploratory association without supporting confirmatory terminal inference, or work in one device version without surviving transfer to another. The context of use is the border around every claim.

Qualification protects both inference and participant. Saying that an instrument is not qualified for a decision does not say that a person is unknowable, unreliable, or outside care. It says only that the instrument has not earned that use. The cost of overreach is carried by the person interpreted outside the population, state, purpose, and error tolerance for which the system was evaluated.

9.1.1 — Research Question First

A research instrument is defined by the question and measurement model it is asked to serve, not by the volume of data it collects. The same physiological stream can support questions about arousal, autonomic instability, sleep disruption, pain response, stress recovery, or affective valence. A candidate momentary estimator begins only when the study declares the target construct, the relation between target and observations, the estimand, and the conditions under which the output may be interpreted (American Educational Research Association et al., 2014; Bollen, 1989; Borsboom, 2005; FDA-NIH Biomarker Working Group, 2016).

The minimum question has five parts. It must name the target state or rate, the time scale, the population, the intended inference, and the decision boundary for failure. For example, a development study might ask whether a physiological composite tracks within-person changes in signed burden over two waking weeks in ambulatory adults. A confirmatory study might ask whether a locked estimator predicts a prospectively specified endpoint-window trajectory better than rival observation models. Those are different instruments for different claims, even if the sensors are identical.

A candidate momentary estimator targets latent valence rate or a declared proportional proxy. Its estimand specifies the quantity, population, time window, and comparison the study will investigate.

A declared estimand also protects future failure. If the estimate fails to track self-reported burden in one population, that is not

automatically a defeat of all measurement. If it fails to identify sign under the declared context, sign-bearing claims must narrow. If it fails only under a device-shift analysis, the instrument version may be retired. The result changes the claim that was actually declared.

A candidate momentary estimator begins with the research target and loss function. For this volume, that target is signed contribution to a unified stream over time. General affect detectors provide useful starting tools; qualification establishes which observations reliably inform that cumulative target.

Qualification asks two practical questions: which claim can this instrument make reviewable, and what burden could an incorrect result create? Answering both before data collection connects predictive performance with construct validity, reactivity, missing-state bias, and the intended use.

9.1.2 — Population and State Scope

Population and state scope must be explicit. Age, language, disability, clinical condition, medication exposure, device placement, sleep-wake state, sampling cadence, and setting can all change the observation relation. A qualification result confined to one envelope does not become general by omitting the envelope from the abstract, model card, or public graphic (FDA-NIH Biomarker Working Group, 2016; Putnick & Bornstein, 2016; American Educational Research Association et al., 2014).

State scope is as important as demographic scope. A person resting after exercise, a person under opioid medication, a person in panic, a person with fever, a person sleeping, a person in delirium, and a person receiving palliative sedation can produce

physiological channels that resemble or invert one another. The same raw channel may carry different meaning across states. A model that ignores state cannot claim to read through state.

The stack should therefore distinguish ordinary ambulatory qualification, clinical qualification, terminal qualification, and edge-state qualification. Each carries a different burden of proof. Ordinary use may tolerate frequent prompts and wearable devices; terminal research may not. A clinical ward may provide medication and care-procedure records; private life may not. An endpoint window may have high missingness precisely when the state is most relevant.

Population scope also includes who is excluded by design. If the model performs only in fluent speakers using one device under low burden, it must say so. If people with disability, skin-tone sensor artifacts, autonomic neuropathy, arrhythmia, movement disorders, chronic pain, or medication profiles are underrepresented, the model's silence is not neutral. It is an unqualified region.

This creates a reference-class ceiling. Evidence from one population supports only that population and context until transport is defended. A hospice cohort in one care system cannot silently generalize to all terminal states, and an adult ambulatory sample cannot establish developmental, disability, or communication-limited validity.

Explicit scope helps protect participants whose circumstances differ from the development sample. The order should remain strict: define scope, estimate within scope, test travel, and only then write public language.

9.1.3 — Development Versus Confirmatory Use

Developmental measurement and confirmatory measurement are different scientific acts. In development, investigators may explore features, compare transforms, inspect lags, test candidate channels, and learn where the instrument breaks. In confirmatory use, the construct, measure selection, item or channel set, scoring, estimator, preprocessing, signs, weights, cadence, missingness model, endpoint separation, and analysis plan must be fixed before the test begins, or every later modification must be disclosed as a new version requiring fresh evaluation (Shiffman et al., 2008; Stone et al., 2007; Flake & Fried, 2020).

To test the intended pattern prospectively, the confirmatory pipeline fixes channels, signs, weights, lag corrections, smoothing windows, and neutrality bands before examining the terminal-window outcomes. Development data can guide those choices; independent observations evaluate their predictive performance.

Developmental work is not inferior. It is where the instrument learns to respect the world. Sensor placement, artifact rejection, self-report timing, context annotation, calibration anchors, and burden endpoints must be refined somewhere. The danger begins only when development is marketed as confirmation, or when exploratory performance is treated as public evidence for the Law.

A practical stack should carry visible labels. Exploratory feature work is not a protocol-fixed candidate momentary estimator. A locked composite is not a dynamic latent-state model. A model tuned on one site is not externally replicated. A smoothed

retrospective trajectory is not a prospective forecast. These labels are not bureaucratic. They are the reader's map of claim status.

The same separation should govern code and artifacts. Development code may change rapidly. Confirmatory code should be versioned, frozen, recoverable, tested on synthetic fixtures, and resistant to silent rescoring. A model card or measurement card should state the purpose, evidence base, abstention rules, and known invalid regions before the model is used in a study that can change public language.

The Law becomes more answerable when development is allowed and confirmation is disciplined. It becomes less scientific when every promising pattern is treated as if it had been predicted all along.

9.1.4 — Performance Requirements by Use

Performance is not one number. A system that separates high-arousal from low-arousal states may fail sign orientation; one that tracks within-person change may fail between-person comparison; one that predicts next-hour report may fail terminal dynamics. Reliability itself can differ across persons, levels, occasions, and states. The performance burden must therefore be matched to the declared use, estimand, and measurement model rather than summarized by one global accuracy or internal-consistency score (American Educational Research Association et al., 2014; Hernán & Robins, 2020; Vogelsmeier et al., 2024; Castro-Alvarez et al., 2026).

For association studies, performance may begin with reliability, artifact control, convergent validity, discriminant validity, and plausible relation to known state changes. For within-person

tracking, it must also show responsiveness, temporal stability, lag handling, and sensitivity to the individual's own baselines. For prediction, it needs time-forward validation, calibration, and error under distribution shift. For terminal inference, it needs all of that plus comfort-first feasibility, independent endpoint adjudication, missingness modeling, rival comparison, and abstention rules.

Validation architecture should mirror the intended use. New-stream transport requires person-held-out evaluation; forecast claims require time-forward splits; hardware portability requires device or firmware holdouts; and care-system transport requires site holdouts. These are not interchangeable checkboxes, and failure in one lane must narrow the claim that depends on that lane rather than being averaged into one global score.

Performance requirements should be reported as a profile rather than collapsed into one validation score. The profile may include analytical performance, technical reliability, construct and discriminant validity, sign validity, temporal responsiveness, state and group invariance, clinical robustness, prospective prediction, and independent replication. A use is qualified only through the components it actually passes, and the reader must be able to see where the evidence stops (American Educational Research Association et al., 2014; Campbell & Fiske, 1959; Putnick & Bornstein, 2016; Nosek et al., 2018).

Performance also includes humane feasibility. If a device is accurate only when it wakes participants, interrupts care, requires frequent adjustment, or pressures families to maintain signal, the instrument has created burden that may alter the data. The score of the device is not separate from the cost of obtaining it.

Qualification is claim-specific. An instrument is adequate only for a named construct, population, state range, cadence, estimand, decision, missingness regime, and surviving rival set. That grammar replaces the vague judgment that a tool is good with an inspectable scientific permission whose limits, expiration conditions, and failure consequences can be audited.

9.1.5 — Abstention and Exclusion Rules

A reason-coded abstention is a valid and informative measurement output. Apply §24.2's canonical evidence-state rules, and record the measurement, calibration, consent, or participant-protection condition that blocked the estimate. An explicit abstention route protects participants and keeps each claim within the evidence (National Commission, 1979; Council for International Organizations of Medical Sciences, 2016).

Abstention rules should be declared before use. The system should withhold a candidate momentary estimate when required channels fail, sign-bearing evidence disappears, missingness is informative beyond modeled sensitivity, device contact is poor, medication or care procedure makes the channel uninterpretable, context falls outside qualification, or participant burden exceeds the protocol threshold. Each rule protects both the science and the person.

Exclusion is different from abandonment. A participant excluded from one analytic claim remains a participant whose data, experience, and care matter. The chapter's no-score discipline means exclusion is about the model, not the person. It says the instrument cannot answer a specific question. It does not say the person is unclear, unreliable, or unavailable to dignity.

Abstention should also appear in cumulative outputs. If three intervals in a running ledger are outside context of use, the ledger should show gaps, identified sets, or sensitivity bounds rather than silently imputing continuity. If a version migration is invalid, the stack should report version-separated estimates. If a retrospective smoother uses later observations, it should be labeled and barred from claims of prospective prediction based only on earlier information.

Abstention has to be audited. A system that abstains more often for disabled participants, darker skin tones, terminal patients, nonfluent speakers, people in pain, or people without stable housing may be revealing a fairness defect in the instrument. The answer is not to force estimates for equity optics. The answer is redesign, narrower claims, or retirement.

9.1.6 — Prohibited Contexts

Some uses lie outside the instrument's authority regardless of predictive performance. A candidate affect estimator is not an employment screen, insurance price, policing signal, civic or spiritual rank, donor score, loyalty test, or basis for denying care. Those exclusions require purpose limitation, access control, audit, and retirement rather than a note beside a reusable dashboard (National Commission, 1979; Council for International Organizations of Medical Sciences, 2016).

The prohibition protects people and inference. Participants cannot consent freely when access, employment, treatment, schooling, insurance, or public benefits depend on compliance, and may change reports when outputs may be used against them. Clinical care precedes measurement; a No adequate estimate outcome may

never deem a person insufficiently suffering for relief or too uncertain for attention (World Medical Association, 2024; International Council for Harmonisation, 2026).

A context-of-use contract defines the population, state space, sampling window, target construct, estimand, error and burden limits, development stage, abstention rule, and prohibited uses. It states when changes in instrument, software, treatment, language, population, or setting end qualification. A blank field leaves the tool promising, not qualified (FDA-NIH Biomarker Working Group, 2016; U.S. Food and Drug Administration, 2025b).

Consider a momentary estimator for adults recovering at home during the first fourteen waking days after surgery. The question is whether a locked physiological model tracks within-person change under known devices, medication patterns, language, prompt burden, and care events without using recovery outcomes to select signs or weights. The result concerns within-person postoperative tracking under those specified conditions.

Performance requirements follow that use. Analytical reliability, artifact control, within-person responsiveness, medication and motion negative controls, time-forward validation, participant burden, and contestability may be required, while between-person comparability and whole-life inference remain outside scope. A participant with device intolerance, missing anchors, or unusual medication effects can remain fully included in care and descriptive observation while the estimator abstains.

Table 9.1 applies the performance profile in §9.1.4 as bounded use tiers. Each requirement retains its own failure language, and

progress on one cannot compensate for failure of a requirement needed by the claim.

Table 9.1. Measurement-use tiers and interpretation scope.

Use tier	Minimum evidence before use	Scope of interpretation
Exploratory development	Transparent features, artifact rules, basic reliability, burden monitoring, and clear labels.	Exploratory associations and development results.
Within-person tracking	Repeated anchors, time-forward validation, lag tests, missingness model, and participant contestability.	Within-person change under the qualified conditions.
External replication	Independent data under the declared context of use, with person, site, device, or state holdouts matched to each claimed form of transport.	The tested reference class and context of use.
Confirmatory Law-facing study	Frozen estimator, protocol-fixed estimand, endpoint separation, rival models, and abstention rules.	Protocol-specified target contrasts within the qualified construct, context, and scale.

Partial progress should be publishable. A channel may pass analytical and technical checks but fail sign validity; a model may support within-person tracking but fail site-held-out transport; a device may work in ordinary life and become unusable near terminal care. The qualification file records the exact rung, population, state, version, untested conditions, and participant burden endpoint rather than advertising that the instrument works.

Current guidance reinforces this context-specific discipline. Fit-for-purpose clinical outcome assessments require a clear concept

of interest, context of use, content-validity evidence, appropriate measurement properties, and documentation of modifications, while digital technologies add verification, validation, risk-management, and data-integrity duties. Psychometric guidance also requires transparent reporting of validity, reliability, measurement error, responsiveness, and cross-cultural invariance. Intensive longitudinal measurement adds item-level, level-specific, temporal, and person-specific checks that cross-sectional summaries can miss. These standards inform the pipeline without serving as evidence for PTVC (U.S. Food and Drug Administration, 2023; U.S. Food and Drug Administration, 2025b; Mokkink et al., 2024; Gagnier et al., 2025; Vogelsmeier et al., 2024).

Prohibited contexts must be enforced technically. Purpose-bound schemas, separated identifiers, role-based access, deletion schedules, query restrictions, audit logs, and release controls should prevent persistent rankings, cross-system dossiers, secondary training, and eligibility dashboards. Qualification expires outside the tested envelope; a supported research context never grants permanent authority to an evolving system (National Institute of Standards and Technology, 2020; National Institute of Standards and Technology, 2024; Wilkinson et al., 2016).

9.2 — Maps, Estimands, and Estimators

The pipeline is a typed sequence of maps. A latent phenomenal state and its context jointly generate reports, behavior, physiology, and neural activity through channel-specific observation processes; an analysis map transforms those records; an estimator targets a declared quantity; a decision rule converts the estimate into bounded language. Conflating any two stages makes it impossible to tell whether failure belongs to the construct, channel, model, or decision.

Four objects must be separated. The measurement map describes how the latent target and context generate observable records. The estimand states the exact quantity the study seeks to learn. The analysis map specifies how raw records become analyzable variables. The estimator is the finite-sample procedure that returns an answer with uncertainty. Validation at one layer cannot be borrowed by another.

This grammar matters acutely for the Law because a polished trajectory can hide several substitutions. A sensor feature may become a state estimate; a state estimate may become an interval contribution; an interval contribution may become a cumulative curve; and the curve may be described as if it were the latent phenomenal ledger. Each step requires its own assumptions, calibration, recovery tests, and failure language.

The section builds a pipeline that can fail locally. A measurement map may be misspecified even when the estimator is numerically stable. An estimand may be scientifically incoherent even when software computes it precisely. A reported quantity may be clear

but unlicensed for the context of use. Local failure is a strength because it shows where the claim must narrow.

The distinctions can be made operational by treating each layer as a separate object with its own failure test. The matrix below is not a workflow convenience. It is a claim-control device: a study cannot repair a poorly specified estimand by fitting a more elaborate estimator, and it cannot repair a poor measurement map by reporting a narrower confidence interval.

Table 9.2. Measurement-pipeline objects and observable rejection conditions.

Pipeline object	What it must specify	Observable rejection condition
Measurement map	How states, events, reports, sensors, and context become recorded variables, including timing, units, transformations, and failure codes.	The record cannot distinguish a target-relevant change from device, language, task, or context change.
Scientific estimand	The exact population, stream, time window, contrast, functional, and conditioning set the study seeks to learn.	The reported number answers a different question from the protocol-fixed scientific target.
Analysis map	Preprocessing, alignment, feature construction, missing-data handling, calibration, and transformations applied before estimation.	A reasonable alternative analysis map reverses sign, changes scope, or materially alters the conclusion without prior justification.

Pipeline object	What it must specify	Observable rejection condition
Estimator	The finite-sample rule that maps the analysis record to an estimate or identified set, with uncertainty and regularization declared.	Simulation or held-out checks show bias, instability, nonrecovery, or unjustified certainty under plausible generators.
Reported quantity	The exact object shown to readers, such as an observed channel, local contrast, interval estimate, path estimate, or identified set.	Language, labels, graphics, or captions imply a stronger latent or cross-person claim than the analysis supports.
Decision or verdict rule	The protocol-fixed rule connecting evidence to abstention, narrowing, route comparison, correction, or withdrawal.	The rule changes after outcomes are seen or allows downstream success to compensate for an upstream gate failure.

9.2.1 — Measurement Map and Observable Record

The measurement map links a latent phenomenal target and its context to the records a study can actually collect. Those records may include reports, pairwise judgments, autonomic channels, interoceptive signals, neural measures, behavior, medication timing, clinical observations, and missingness indicators. The map must state whether each record is modeled as an effect of the target, a cause or component of an index, a contextual moderator, or an auxiliary witness. It is a scientific model of access, not a declaration that any record is experience itself (Bollen, 1989; Borsboom, 2005).

A complete map identifies the raw unit, sampling window, transformation, expected lag, noise source, context variable, burden of collection, and failure condition for each channel. It also identifies what is never observed. Silence, device removal, sleep, care escalation, refusal, and communication loss are not empty cells; they are outcomes of the observation process.

Reactivity belongs in the map. Prompts can alter attention, devices can change sleep or movement, clinical observation can change behavior, and repeated ratings can teach participants a vocabulary that reshapes later reports. A channel that changes the state it measures may remain useful, but its intervention effect must be modeled or bounded.

The map must preserve person and time structure. A signal collected at one minute does not automatically represent the same temporal interval as a report made ten minutes later. A channel that tracks arousal during exercise may not have the same relation to valence during pain, medication, or social threat. State and context determine the link.

Missingness and selection are generated inside the map, not appended after estimation. If high burden reduces device tolerance or report capacity, observed records overrepresent easier intervals. If a terminal window ends observation before the truth endpoint, the resulting curve is a record of observation shutdown as well as possible experience.

The practical output is a measurement-map table that can be audited before analysis. For every channel it names the proposed target relation, measurement-model role, unit, time window,

transformation, lag, confounds, burden, missingness route, version, and prohibited inference. It also records the source of the measure, any modifications, and the validity evidence available for the declared use. A pipeline without that table asks the estimator to hide conceptual debt (Flake & Fried, 2020; Gagnier et al., 2025).

9.2.2 — Scientific Estimand and Target Contrast

An estimand is the precise scientific quantity a study intends to learn. It includes the population or stream class, state and time window, treatment or exposure condition where relevant, outcome definition, handling of intercurrent events, and contrast of interest. An estimand is not the observed score and not the algorithm that estimates it (International Council for Harmonisation, 2019; Hernán & Robins, 2020).

For this program, candidate estimands include a within-stream directional change in phenomenal-value rate, an interval contribution under a declared representation, a difference between two time windows, a response to an ethically permissible intervention, a trajectory feature, or an endpoint-window contrast. These are different objects and require different measurement and causal assumptions.

A momentary estimand must name what momentary means. It may refer to an instantaneous idealization, a short window, a latent state at a time point, or an average over a sampling interval. A rate estimand must say how its unit relates to time. That statement makes time accumulation dimensionally interpretable.

An interventional estimand also separates experience from assignment and adherence. Treatment, care, context, device use, and participant choice can change both the target and observation. The protocol should state whether it seeks a treatment-policy effect, an effect under adherence, a principal-stratum contrast, or a descriptive within-person response.

Intercurrent events, such as a relevant treatment change, can alter the interpretation or existence of the outcome and must be addressed in the estimand. Device removal, missed prompts, and study withdrawal may instead create missing data; they are not automatically intercurrent events. Record the underlying clinical event separately from the loss of observation, and align the estimation and sensitivity analyses with the declared target (International Council for Harmonisation, 2019).

These choices must be fixed before the result is known. An estimand selected after inspecting which definition approaches neutrality is not the original target but a rescue construction. A protocol-fixed estimand may still be wrong, but it can fail cleanly and support an honest redesign.

9.2.3 — Analysis Map and Preprocessing

The analysis map converts raw records into variables used by the estimator. It includes synchronization, artifact rejection, filtering, feature extraction, normalization, missingness coding, lag adjustment, channel exclusion, item scoring, scale modification, and any learned representation. Each decision can create or remove the pattern the study later claims to discover, so the

complete map must be visible and versioned (Munafò et al., 2017; Nosek et al., 2018; Flake & Fried, 2020).

Preprocessing must therefore be locked or nested inside a transparent development process. Exploratory work may compare filters, features, and windows, but confirmatory work must test the chosen pipeline on held-out persons, sites, devices, or time periods. A favorable result that depends on one undocumented filter is not a robust measurement finding.

Preprocessing choices are specified before evaluation of the target outcome. Centering, smoothing, baseline subtraction, endpoint normalization, and channel weighting can alter apparent convergence or sustained burden. The protocol states the purpose of each operation and evaluates its effect on the target estimand.

The analysis map should preserve multiple views when they answer different questions. Filtered estimates use information available up to the present; smoothed estimates use future observations to revise the past; forecasts predict later states; imputed values fill missing intervals under assumptions. A single line that mixes those products hides time and evidence.

Versioning belongs here. Firmware, preprocessing code, feature definitions, annotation rules, and model inputs may change during a longitudinal program. Every output should carry the exact analysis-map version, and bridge studies should determine whether old and new outputs can be linked, compared, or only reported separately.

A reader-facing methods statement should reconstruct the map without requiring access to source code. It should name raw

inputs, item or channel content, scoring, transformations, exclusions, timing, training data, validation split, version changes, and uncertainty contribution. Code remains essential for reproducibility, but prose must reveal the scientific choices and their chronology rather than outsourcing them (Flake & Fried, 2020; Peeters et al., 2026).

9.2.4 — Candidate Momentary Estimator

A candidate momentary estimator is a procedure for producing a bounded estimate of a declared momentary or short-window target. It may be a transparent weighted composite, a state-space model, a Bayesian latent-state model, or another recoverable architecture. Its status comes from the identified target, the declared measurement model, a qualified observation map, model recovery, and out-of-sample performance, not from mathematical sophistication (American Educational Research Association et al., 2014; Bollen, 1989; Borsboom, 2005; Gelman et al., 2013).

A transparent composite can be scientifically valuable because its transformations and weights are inspectable. Its weakness is that standardized channels may not share units or construct meaning. Equal weights can hide unequal reliability, while learned weights can overfit outcome labels. The result should therefore display component contributions and sensitivity to plausible weights.

A dynamic latent-state estimator can model continuity, lag, missingness, and state evolution. Its flexibility is also a risk. Time-varying loadings, process noise, contextual covariates, and smoothing can absorb the very burden the model is meant to

recover. Model recovery and synthetic fixtures are necessary before the estimator is trusted on human data.

Sign, location, and scale must be identified independently of the Law-facing outcome. A factor can fit the data while remaining reversible in sign, shiftable in origin, or arbitrary in unit. An estimator that cannot distinguish positive from negative experience may still report magnitude or arousal, but it cannot support a signed cumulative claim.

Uncertainty should be a distribution or identified set when the model permits it. Pointwise standard errors alone do not capture model choice, sign ambiguity, channel conflict, missingness, or calibration uncertainty. The estimator should widen, split, or abstain when those uncertainties dominate.

Qualification is context-specific. A model may track within-person change in ordinary ambulatory life and fail in pain crisis, sedation, childhood, another language, or a new device generation. The correct label states the population, state scope, time scale, version, permitted use, and failure conditions.

9.2.5 — Candidate Interval Estimator and Path Integration

An interval estimator requires more than multiplying a momentary score by time. The momentary quantity must have a defensible rate interpretation or declared proportional relation to experienced exposure. The interval, clock, unity conditions, and handling of gaps must be specified before integration (Shiffman et al., 2008; Stone et al., 2007).

Irregular sampling makes the temporal problem visible. Reports may arrive minutes apart, sensors may sample at different rates,

devices may fail, and care events may change both state and observation. Sparse or uneven cadence can alias rapid dynamics, while interpolation and smoothing can invent continuity or suppress extremes. The estimator must decide prospectively whether to interpolate, forecast, impute, abstain, or return bounds, and each decision must propagate into path uncertainty (Shiffman et al., 2008; Stone et al., 2007; Peeters et al., 2026).

Posterior path integration is preferable to summing isolated point estimates when dynamics and serial dependence matter. The model should draw coherent trajectories, integrate each trajectory over the declared interval, and report the resulting distribution of interval contributions. That procedure carries timing, lag, covariance, and missingness into the cumulative object.

Filtered, forecast, and smoothed paths must remain distinct. A filtered path is eligible for prospective claims because it uses information available at the time. A smoothed path may be useful for retrospective sensitivity analysis but cannot be presented as if it were observed online. A forecast is a prediction and should be scored as such.

Version-spanning accumulation needs linking studies. If sensors, channels, code, calibrations, or models change, the path may need to split. Historical rescoring can support comparison, but it must not erase the original contemporaneous output. The record should show what was known then and what a model estimates.

The resulting cumulative estimate is a distribution or identified set over paths under stated assumptions, never an account balance. It should carry observed and modeled intervals,

abstained regions, version boundaries, lag and cadence uncertainty, missingness assumptions, and invalid windows. A smooth curve without that status line is a visualization, not a defensible ledger estimate.

9.2.6 — Reported Quantity, Decision Rule, and Abstention

The reported quantity is the public-facing output of the pipeline. It may be a point estimate, interval, posterior distribution, identified set, directional statement, component profile, conflict report, or abstention. The report must name which quantity it is and which estimand and estimator produced it (Gneiting & Raftery, 2007; Manski, 2003).

Decision rules should be declared before the outcome is inspected. They should specify evidence thresholds, equivalence bands where appropriate, calibration requirements, rival comparisons, uncertainty ceilings, missingness limits, and conditions for No adequate estimate. A rule declared after a striking curve is an interpretation, not a confirmatory procedure.

For confirmatory held-out evaluation, fix the outcome, horizon, information set, and scoring rule before inspecting the evaluation data. A scoring rule's mathematical propriety is distinct from whether its selection and use support a confirmatory claim. Calibration, sharpness, coverage, and decision loss answer different questions; predictive success supports the declared forecast relation unless construct and measured-to-latent bridges justify more (Gneiting & Raftery, 2007).

Abstention is a first-class output. The pipeline should abstain when sign is unidentified, calibration fails, observation is too

sparse, burden is excessive, context shifts outside qualification, or model disagreement overwhelms the target. Abstention protects both the participant and the claim. Abstention rates should be reported by context and subgroup, because a pipeline that works only for the easiest cases may create hidden selection in downstream inference.

Public language must remain smaller than the model. It may report a declared within-person contrast, a compatible interval, or a failed bridge. It may not claim to read the person, measure worth, discover a soul, or prove exact terminal closure. This boundary is easier to preserve when every public output names the estimand before presenting the numerical estimate.

Every output must remain traceable to its decision rule, estimator, analysis map, estimand, measurement map, and raw record. That chain separates evidence from an authoritative-looking number. Traceability also permits error propagation: when an upstream map changes, dependent outputs can be located and recomputed rather than silently surviving under obsolete assumptions.

9.3 — Phenomenal-Value Channels and Auxiliary Witnesses

No single channel has direct, complete, and context-free access to lived phenomenal value. First-person report is closest to the person's experience but can be delayed, constrained, shaped, or unavailable. Physiology, behavior, neural activity, clinical observation, and context can reveal important structure while remaining many-to-one with respect to valence. A serious pipeline therefore uses plural evidence without creating a new oracle (Campbell & Fiske, 1959; Shiffman et al., 2008).

The chapter distinguishes candidate phenomenal-value channels from auxiliary witnesses. A candidate channel may contribute to a declared estimator under explicit transformation, sign, lag, and calibration rules. An auxiliary witness helps validate, challenge, contextualize, or explain the channel model. Usefulness does not silently promote a witness into the target.

Plurality also makes disagreement visible. A participant may report fear while physiology suggests low arousal; behavior may look calm while clinical context indicates severe pain; neural and autonomic channels may diverge after medication. The right response may be model revision, state-specific interpretation, wider uncertainty, or abstention. Averaging is not understanding.

The evidential channels perform different jobs. First-person report has privileged access but is affected by language, safety, memory, and response process. Behavior and choice reveal action under constraints. Autonomic, interoceptive, neural, and clinical signals provide auxiliary witnesses with their own lags and

confounds. Context records explain opportunities and exposures. No channel becomes the target merely by being objective or direct.

A plural pipeline also benefits from an explicit assignment of roles. The table below identifies the contribution each channel can make without allowing any one of them to become a universal meter. A channel remains usable only within the context in which its sign, timing, construct relation, and error process have been established.

Table 9.3. Evidence channels, scientific contributions, and retirement triggers.

Evidence channel	Primary scientific contribution	Principal limits and retirement trigger
First-person report	Construct meaning, sign, language, timing, salience, and participant challenge to the model.	Fear, demand, communication limits, recall, reinterpretation, or nonresponse can invalidate the proposed use.
Pairwise or trade-off judgment	Local ordering, bounded contrasts, and possible within-person calibration under declared options.	Choices reflect power, information, obligation, stakes, and opportunity, not experience alone.
Behavior	Approach, avoidance, persistence, withdrawal, performance, and response to intervention.	Many-to-many relation with experience; strategic behavior or context change defeats simple interpretation.

Evidence channel	Primary scientific contribution	Principal limits and retirement trigger
Autonomic physiology	Timing of arousal, effort, threat, recovery, and regulation under local calibration.	Sign ambiguity, medication, movement, illness, device artifact, and person-specific gain require narrowing or removal.
Interoceptive evidence	Awareness and interpretation of bodily states, including mismatch between physiology and felt state.	Access, language, learned meaning, and interoceptive accuracy vary; bodily signal is not self-interpreting.
Neural evidence	Mechanistic, temporal, or state-classification information relevant to pain, reward, salience, memory, and consciousness.	Task and population transport failure, many-to-many mapping, and classifier drift prohibit direct valence or personhood inference.
Clinical observation	Illness, medication, care context, delirium, pain behavior, communication capacity, and acute change.	Observer bias, workload, familiarity, institutional routine, and care effects must enter the observation model.
Contextual or relational witness	Confounds, timing, social setting, bystander evidence, and explanation of missing or conflicting channels.	Purpose creep, dossier formation, bystander privacy, and narrative overreach require minimization or deletion.

9.3.1 — First-Person Reports and Pairwise Judgments

First-person report remains indispensable because the participant is the only source with direct experiential access. Momentary

ratings, free text, event-contingent reports, pairwise comparisons, and ordinal judgments can reveal qualities that external channels miss. Their privileged position is epistemic, not infallible (Shiffman et al., 2008; Stone et al., 2007).

Reports vary in what they ask. A rating of intensity, unpleasantness, relief, agency, meaning, or desire is not interchangeable with a global mood score. Pairwise judgments may be easier than numerical ratings when a person can say that one interval was more burdensome without knowing how much more. The representation level should match the response task.

Timing matters. Retrospective reports can be shaped by peaks, endings, memory, present mood, and narrative reconstruction. Immediate prompts can reduce recall error but increase burden and reactivity. The protocol should declare which form is used, why, and what temporal object it can support.

Language and access also matter. People may lack concepts, fear consequences, communicate atypically, or choose silence. Accessible response modes, participant-chosen vocabulary, supported communication, and qualitative context can improve interpretation. Nonresponse should not be coded as low burden by default.

Reports can falsify a model locally. If a participant says that the labels are wrong, the sign is reversed, the timing is mistyped, or the instrument misses a central dimension, the disagreement is evidence about construct validity. The model may ultimately retain its estimate, but it must record and adjudicate the challenge.

First-person report should be neither sovereign nor dismissed. It anchors construct meaning, supplies sign and context, supports calibration, and can reveal model failure, while remaining vulnerable to memory, language, demand, fear, and missingness. Its evidential role must be declared rather than inflated or erased.

9.3.2 — Trade-Off Choices and Behavioral Evidence

Choices and trade-offs can reveal what people are willing to accept, avoid, delay, or exchange under specified conditions. Pairwise choices, willingness-to-pay or willingness-to-wait tasks, effort allocation, and approach-avoidance behavior can contribute evidence about relative burden or relief. They remain behavior under constraints, not transparent windows into experience (Kahneman et al., 1993; Hernán & Robins, 2020).

Section 8.1.3 establishes why constrained choices are not direct valence readings. In the measurement pipeline, behavioral evidence enters only through an explicit model of the option set, incentives, obligations, risks, and information that shaped the choice; without that bridge, the inference stops at observed behavior.

Behavioral evidence is also state dependent. Withdrawal can indicate fear, relief, fatigue, protest, depression, sensory overload, or strategic privacy. Productivity can coexist with severe burden, while inactivity can coexist with peace. A behavior channel must name the candidate mechanism and its confounds.

Trade-off tasks may help with local scaling when designed ethically. Repeated within-person choices can indicate ordinal or interval-like relations among bounded states, especially when

paired with reports and contextual anchors. The task must not manufacture suffering, withhold care, or impose stakes that make refusal costly.

Experimental demand is a live rival. Participants may infer that the researcher values consistency, bravery, equality, or a particular sign and adjust responses. Neutral framing, randomized order, comprehension checks, debriefing, and alternative models can reduce but not eliminate this pressure.

Choice and behavior can test predictions, identify discrepancies, and support within-person calibration. Their interpretation becomes stronger when compared with reports and other independently characterized channels.

9.3.3 — Autonomic and Interoceptive Channels

Autonomic channels include heart-rate dynamics, electrodermal activity, respiration, temperature, vascular measures, pupil responses, and related signals. Interoceptive channels concern sensing and interpretation of internal bodily states. These measures can track arousal, effort, threat, pain, recovery, and regulatory demand, but none has a fixed one-to-one relation with signed valence (Cacioppo & Berntson, 1994; Khalsa et al., 2018).

The same heart-rate increase can accompany fear, exercise, joy, fever, medication, or pain. Reduced movement can indicate calm, sedation, exhaustion, disability, or device removal. Sign therefore requires context-specific evidence independent of the outcome the study hopes to support.

The body can participate causally in affective regulation. Hsueh et al. (2023) used an optical pacemaker to increase heart rate in

mice and found increased anxiety-like behavior in risky contexts. The same cardiac manipulation did not produce a detectable preference or aversion in a neutral place-preference test, and inhibition of posterior insular cortex attenuated its anxiety-related effect. This pattern supports a context-sensitive body-to-brain pathway rather than a fixed emotional meaning for heart rate. It supplies a useful constraint for affect models: bodily state and environmental appraisal must be allowed to interact. In noninvasive human observational work, the corresponding model comparison can ask whether a prespecified physiology-by-context interaction improves held-out predictions of reported feeling beyond either channel alone. A declared PTVC route can extend that comparison with its own predicted timing or state interaction.

Channel specifications should include raw units, sampling windows, artifact rules, transformations, expected lags, state scope, and negative controls. Sensor placement, skin contact, posture, hydration, ambient temperature, illness, and hardware version can alter the signal. Technical quality is part of construct validity.

Within-person calibration is often more defensible than cross-person comparison. A channel may track change reliably for one participant while differing in baseline, gain, or state sensitivity across participants. Hierarchical models can borrow strength, but they must not erase person-specific channel behavior.

Interoception adds another layer because bodily signals are not identical to the experience of those signals. Two people with similar physiology may differ in awareness, interpretation, fear,

or learned meaning. A science of valence should model this bridge rather than treat the body as self-interpreting.

Experiments have begun to separate current bodily state from its neural anticipation. In mice, Livneh et al. (2020) found that insular population activity tracked hunger and thirst, while learned food or water cues rapidly shifted activity toward patterns associated with future satiety before physiological replenishment. Artificially activating hypothalamic hunger or thirst systems could restore seeking in sated animals while ongoing insular activity continued to reflect satiety. These dissociations give predictive interoception an empirical architecture: motivation, present physiology, and anticipated physiology can be measured separately. They support a biologically grounded route through which expected bodily consequences may shape affect. A human measurement study can compare models of current physiology, anticipated need, reported feeling, and choice using ordinary eating and drinking records without deprivation or care alteration. The resulting dissociations provide a basis for comparing anticipatory and accumulated-history mechanisms.

Autonomic and interoceptive channels contribute timing, state information, and diagnostic evidence within a plural measurement architecture. Joint interpretation with reports and other channels can identify conflicts and improve the model of experience.

9.3.4 — Neural and Clinical Channels

Neural measures provide temporal, spatial, and mechanistic evidence about processes related to pain, reward, salience,

regulation, memory, and consciousness. Clinical observations identify state, illness, medication, distress, communication limits, and care context. The measurement model specifies how these observations inform the target construct (Giacino et al., 2018; Feldman et al., 2024).

Neural patterns are many-to-many. A network associated with pain can also participate in salience, attention, expectation, or control. A classifier trained on one task may fail in another population or under medication.

Person-specific neural measurement has already advanced beyond brief laboratory snapshots. Shirvalkar et al. (2023) paired repeated pain reports with ambulatory intracranial recordings over months in four people with refractory neuropathic pain and decoded fluctuations in chronic pain severity within individuals. Huang et al. (2025) extended naturalistic acute-pain work to 12 people undergoing clinically indicated epilepsy monitoring, combining neural recordings, reports, and facial dynamics. Their within-person neural classifier distinguished high from low reported pain with a mean area under the receiver-operating-characteristic curve of 0.70. Together these studies demonstrate feasible repeated measurement of a limited experiential dimension in real clinical settings. With consent and existing clinical oversight, approved secondary analyses can test temporal stability, channel disagreement, and generalization to later recordings without adding implants or changing care. These are concrete measurement milestones on which a future phenomenal bridge can build.

Clinical channels carry their own expertise and limits. Nurses, physicians, therapists, and caregivers may recognize pain behavior, delirium, fatigue, dyspnea, or sudden change that a device misses. Their judgments can also be shaped by workload, bias, familiarity, communication style, and institutional routine.

Clinical intervention can also test whether an individualized neural marker connects to a change in lived symptoms. Scangos et al. (2021) mapped symptom-related activity and stimulation responses in one person with severe treatment-resistant depression, then used a chronically implanted device to trigger stimulation when the selected biomarker appeared. Symptoms improved rapidly and remained improved during the reported follow-up. The intervention links a timed internal-state estimate with an independently reported improvement. Consented secondary analysis of clinically approved records could compare symptom-responsive, time-only, and state-insensitive models while preserving treatment and privacy. The scientific gain would be a better bridge between measured dynamics and reported experience.

Clinical context can transform other evidence. Sedation may reduce report and movement; fever may alter autonomic signals; analgesia may change pain while leaving fear; delirium may alter expression and memory. These variables should enter the observation model rather than appear later as excuses.

Consciousness and communication assessments identify retained capacities, available response channels, and state-specific uncertainties. Those findings guide the choice of measurements and the intervals in which each channel is interpretable.

The proper role of neural and clinical evidence is triangulation under declared context. They can support state classification, timing, rival discrimination, and construct revision. They cannot overrule the person by default or transform a candidate measurement system into a consciousness oracle.

9.3.5 — Contextual and Relational Witnesses

Context records the conditions under which reports and signals acquire meaning. Medication, care procedures, sleep, temperature, noise, privacy, social contact, workload, language, legal pressure, and material security can alter both experience and observation. A channel without context may be technically precise and scientifically wrong, while a context record without minimization can become an unnecessary private dossier (Shiffman et al., 2008; Little & Rubin, 2019; Nissenbaum, 2010).

Context collection must be purpose limited. A study should record what is needed to interpret the declared estimand, not every detail that might later become interesting. Rich context can easily become a life dossier containing relationships, habits, disability, health, religion, location, and conflict.

Relational witnesses can help when communication is limited or patterns are familiar. Family members and clinicians may notice changes in fear, pain, relief, sleep, or engagement. Their observations remain interpretations shaped by closeness, incentives, grief, fatigue, culture, and power.

Bystander privacy is therefore part of the measurement design. A participant's experience may reveal information about relatives, caregivers, coworkers, or clinicians. Consent, minimization,

access separation, redaction, and deletion rules should extend to those whose lives enter the record indirectly.

Context also provides rival explanations. A change in signal after a device update, room move, care escalation, visitor arrival, or medication change may defeat a Law-specific interpretation. The pipeline should prefer the explanation that survives contextual controls, not the one that best fits the project's hopes.

A contextual or relational witness earns influence through a specific task: explaining timing, identifying confounds, supporting sign, clarifying missingness, or challenging a model. It should never become a general moral narrative, loyalty profile, or substitute testimony about the whole person.

9.3.6 — Plural Evidence Without Composite Sovereignty

Plural evidence is necessary because each channel has different access, error, burden, and failure modes. The multitrait-multimethod tradition shows why convergence is informative only when methods do not share the same confound. Agreement can strengthen a claim, while disagreement can reveal construct failure or rival structure (Campbell & Fiske, 1959; Bollen, 1989).

A composite becomes sovereign when component identities disappear. Self-report says fear, physiology says arousal, behavior says stillness, context says coercion, and the dashboard outputs calm. Such compression is not integration; it is an unrecorded decision about which witness was allowed to matter.

Fusion should therefore preserve channel-level estimates, uncertainty, missingness, lag, negative controls, and disagreement. Early fusion, late fusion, hierarchical models, and

ensembles answer different questions. Each should be compared under held-out validation and model-recovery tests rather than selected for visual smoothness.

Channel ablation is an ethical and scientific diagnostic. The study should show whether one channel drives the result, whether removal changes sign, and whether the model remains calibrated for participants with missing or inaccessible channels. A system that works only for one bodily or communicative template is not universally qualified.

Participant interpretation adds another check. People should be able to see which channels contributed, what the model inferred, where uncertainty entered, and how to contest an obvious error. Contestability does not make every objection dispositive; it makes the measurement relation answerable.

9.4 — Dynamic Measurement and Channel Conflict

Channels run on different clocks. Reports may be delayed by reflection, response-time features may capture uncertainty rather than valence, autonomic signals can rise and recover on different timescales, and device records can be shifted by clock drift or late synchronization. A dynamic model must therefore estimate or bound channel-specific lag before disagreement is interpreted as psychological conflict (Shiffman et al., 2008; Sosa-Hernandez et al., 2024).

Cross-channel disagreement is a diagnostic object. It may reveal mixed affect, lag, medication, sensor failure, context change, or a misspecified latent state. Fusion should preserve the pattern long enough to test these explanations; a composite that becomes more confident by averaging away conflict has converted uncertainty into decoration.

The technical burden is therefore local: every channel needs a response model, a link function, a lag strategy, an artifact strategy, and a removal rule. These specifications make fusion interpretable and open to independent evaluation.

9.4.1 — Impulse-Response Functions

An impulse-response function describes how a channel reacts over time to a change in the latent state. One signal may spike immediately and decay. Another may rise slowly and persist. Another may respond only after a threshold. Without response functions, a model may compare channels at the wrong moment and call the disagreement psychological (Shiffman et al., 2008; Dejonckheere et al., 2022).

For a causal linear time-invariant channel, or a justified local approximation to one, the following continuous-time representation makes the lag structure explicit before fusion or deconvolution:

$$X_k(t) = \int_0^{\infty} h_k(r)F(t-r)dr + \varepsilon_k(t)$$

The kernel $h_k(r)$ describes how channel k weights past latent states. A narrow kernel means the channel tracks rapid change. A broad kernel means it smooths history. A delayed kernel means the channel carries old burden into the present. The kernel is a scientific assumption about physiology, not a mathematical ornament.

Impulse-response functions help prevent false compression. If a slow channel is aligned to a fast channel without deconvolution, both may appear to converge near an endpoint because the slow channel cannot respond quickly enough. Conversely, a fast artifact may look like a sudden valence shift when the true state has not changed. The kernel makes these errors testable.

The response function also affects burden. A device or prompt cadence chosen for mathematical convenience may miss rapid suffering or overmeasure slow change. The stack should choose cadence by the dynamics of the channel and the burden of observation, not by the convenience of uniform rows in a table.

When a response function cannot be estimated, the system should mark lag uncertainty. It may still use the channel for broad state classification or auxiliary validation, but it should not let the channel dominate a fine-grained interval-contribution path.

9.4.2 — Ordinal and Non-Gaussian Observation Models

Observation families require distribution-specific models. Reports may be ordinal, behaviors counted, device outputs bounded, and physiological signals censored, saturated, skewed, heavy-tailed, or zero-inflated. Forcing all channels through one Gaussian observation model can manufacture apparent agreement, attenuate extremes, and distort uncertainty (Bollen, 1989; Särkkä, 2013; Shiffman et al., 2008).

The observation model, including its link function, should match the measurement process. An ordinal report may need a cumulative link model. A count of awakenings may need a count distribution. A bounded probability may need a logit-scale model. A saturated sensor may require censoring. A rare artifact may require a mixture or outlier model. These are not statistical luxuries; they define what the observation can say.

A misspecified observation model can create false certainty. Treating ordinal categories as equal intervals may overstate change. Treating bounded data as unbounded may invent extremes. Treating heavy-tailed artifacts as normal noise may pull the latent state. Treating a thresholded channel as continuous may make the model insensitive near the very state it is supposed to capture.

Non-Gaussian observation models also affect fusion. A high-confidence continuous channel may dominate a low-resolution ordinal channel unless the model respects each source's information content. Conversely, a coarse report may carry sign

information that the physiology lacks. The model should not rank channels by mathematical smoothness.

Public communication need not teach every link function, but it must expose the consequences. The reader should know when a channel is coarse, censored, delayed, saturated, thresholded, or uncertain. The governing principle is translation without category theft: mathematical smoothness must not make a channel appear to have spoken in a richer language than it did.

9.4.3 — Lag Estimation and Deconvolution

Lag estimation asks how far each channel is from the latent event it is meant to reflect. Deconvolution asks whether the observed channel can be unsmoothed enough to recover the underlying trajectory. Both are inverse problems whose answers depend on the kernel, cadence, regularization, noise, and missingness model. They can improve temporal alignment, but they can also create patterns that were not present in the observations (Särkkä, 2013; Shiffman et al., 2008).

A confirmatory candidate momentary estimator should fix in the protocol which lags are fixed, which are estimated, which priors are allowed, and how lag uncertainty enters the result. A development study may compare lags freely. A confirmatory study may not choose the lag that best produces terminal convergence. Endpoint-tuned lag selection is a hidden form of post hoc rescue.

Deconvolution can amplify noise and become unstable when the channel is strongly smoothed, sampling is irregular, or high-frequency information was never observed. A slow signal may be

biologically slow, technically slow, or both; no algorithm can recover frequencies that the design and noise have erased without adding assumptions. The stack should report regularization, lag sensitivity, simulation recovery, and failure cases before any deconvolved trajectory enters a ledger (Särkkä, 2013; Peeters et al., 2026).

Temporal alignment also creates fairness risk. A person in pain may remove a device, delay a report, move less, or receive medication. If the lag model interprets the resulting timing as state recovery, it has turned burden into apparent improvement. The missingness and context layers must travel with lag estimation.

Time is part of the construct, not an index column. A rate proxy needs the correct relation to clock, exposure, cadence, and channel lag before it can become an interval contribution. If that relation is not identified, the pipeline may retain broad temporal ordering or state classification while withdrawing fine-grained path integration.

A clean stack reports both aligned and unaligned views during development. If the conclusion exists only after one favorable alignment, the result belongs to sensitivity analysis, not confirmation.

9.4.4 — Conflict as Evidence

Channel conflict is not a nuisance by default. It may be the most informative part of the measurement event. A participant reports calm while physiology shows arousal. Facial muscle activity suggests positivity while respiration suggests distress. Sleep improves while reported dread worsens. Clinical observation

notes pain while the wearable appears stable. Each conflict has to be interpreted, not averaged away (Bollen, 1989; Tsiatis, 2006).

Conflict can reveal mixed states. It can also reveal mismeasured states. It can identify a model outside context of use, a lag problem, a sign problem, a device problem, or a confound. The chapter's rule is that conflict increases the burden of explanation before it increases authority. A composite should not become more confident by hiding disagreement inside a total.

A good stack should preserve channel-level traces, contribution plots, posterior disagreement, and ablation results. It should show whether the final estimate depends on one channel, whether auxiliary report supports or contradicts physiology, and whether conflict clusters by person, site, device, state, or time. Conflict with pattern is evidence about the instrument.

Conflict can also protect participants. If a person says the model is wrong, the system should have a route for contestability. Their challenge may reveal a context not recorded, an artifact not flagged, a meaning dimension outside scalar valence, or a state that the instrument has never learned. Contestability is not a courtesy; it is a source of validity evidence.

Hidden burden often appears where indicators diverge: outward function with exhaustion, calm behavior with fear, reported numbness with sustained mobilization, or caregiving warmth with depletion. Preserving disagreement is therefore not indecision. It is how the pipeline avoids making the easiest channel sovereign over the rest.

Fusion is licensed only after conflict has been interrogated. Until then, discordance is not clutter. It is the site where the stack learns whether it is measuring burden or merely organizing signals.

9.4.5 — Medication and Device Effects

Medication, sedation, and treatment can alter observed channels without changing lived experience in the same direction. They can affect heart rate, respiration, movement, sleep, arousal, facial expression, report capacity, and response timing, while illness and relief may change simultaneously. The protocol must therefore model treatment timing and plausible channel effects instead of reading pharmacology as a change in the Law-facing construct (Shiffman et al., 2008; Khalsa et al., 2018; Giacino et al., 2018; Feldman et al., 2024).

Device effects can be just as strong. Sensor placement, skin contact, temperature, battery behavior, firmware updates, charging routines, device removal, data compression, sampling frequency, and manufacturer preprocessing can change the signal. These changes may correlate with burden because people remove devices when uncomfortable, staff adjust devices during care, or batteries fail during long sleep or hospitalization.

A measurement pipeline should record medication windows and device status as structured provenance when needed for the declared context. This does not mean recording every possible clinical fact or turning research into a surveillance inventory. It means documenting the variables that can invalidate the channel interpretation.

Medication and device effects should be included in negative-control designs. If a care-procedure flag explains a large apparent candidate momentary estimator change, the Law-facing interpretation should narrow. If a firmware update shifts estimates across participants, version migration must occur before historical and current data are combined. If device contact quality predicts the final candidate momentary estimator, contact quality is not merely a nuisance; it is a rival.

In palliative contexts, care effects are especially sensitive. Comfort medication should never be delayed or adjusted for measurement clarity. The model must adapt to care; care must not adapt to the model. If medication makes the candidate momentary estimator uninterpretable, the result is abstention, not experimental pressure.

Treatment and hardware belong inside the observation model. A signal arrives through a body receiving care and through a device with its own response, calibration, failure, and version history; neither may be treated as invisible infrastructure.

9.4.6 — Channel Failure and Removal

A channel can fail analytically, technically, constructively, ethically, or contextually. Noise, saturation, missingness, medication, device drift, sign ambiguity, burden, privacy risk, or mismatch with the target may each make a channel unusable for one context of use. Removal should name the failure and the claims affected rather than treating the channel as generally bad.

Removal and down-weighting may not be selected by outcome. Dropping the witness that disrupts the preferred trajectory, or

reducing its weight until channels agree, turns model selection into result construction. Reliability, artifact, burden, and context rules must be frozen or evaluated in a separate development stage (American Educational Research Association et al., 2014; Nosek et al., 2018).

Channel composition is part of the estimator version. If one participant is estimated from five channels and another from two, their outputs are not automatically comparable; if firmware changes gain, pre- and post-update paths require a migration study or version split. Missing or removed channels must propagate into uncertainty and claim status.

Participant burden can independently justify removal. A sensor may disturb sleep, irritate skin, expose participation, interfere with care, or become intolerable during distress. Requiring unusual endurance changes the sample and observation process, so burden-triggered removal protects participants and validity.

Disagreement should be preserved long enough to diagnose. It may indicate wrong sign, different lags, dissociation, medication, illness, state change, or genuinely different constructs. Negative controls at channel, person, site, and time levels, plus leave-one-channel-out and leave-one-sensor-family-out analyses, show whether a result is robust or dominated by one witness.

The conflict patterns below illustrate why a composite should not override its components. Calm physiology beside reported suffering, a post-update shift across all participants, terminal variance compression as channels disappear, or one channel dominating the estimate each demands a different response.

Table 9.4. Cross-channel conflict patterns and required responses.

Conflict pattern	Possible source	Required response
Report says suffering, physiology looks calm	Dissociation, medication, learned suppression, wrong sign, sensor insensitivity.	Preserve discordance, examine context, block overriding participant report.
Physiology changes across all participants after update	Firmware, preprocessing, calibration, or device batch effect.	Version split, migration study, no silent pooling.
Terminal variance compresses as channels disappear	Observation shutdown or comfort-related device removal.	Model missingness and test against false compression.
One channel drives composite	Weight dominance, artifact, true mechanism, or poor fusion design.	Leave-one-channel-out analysis and component reporting.

Early, late, hierarchical, ensemble, and adjudicative fusion address different questions and hide different failures. The table states these commitments so performance is not mistaken for a validated phenomenal bridge. Comparisons among fusion strategies should use the same protected cases, revealing whether apparent improvement comes from better inference or more flexible adjudication.

Table 9.5. Fusion designs, failure modes, and diagnostics.

Fusion design	Strength	Main failure mode	Required diagnostic
Early fusion	Fuses standardized features before fitting, enabling interactions.	Feature scale, lag, and artifact differences are hidden inside one input space.	Preprocessing audit, feature ablation, negative-control dominance tests.
Late fusion	Keeps channel models separate before combining predictions.	Consensus may conceal systematic disagreement or shared confounds.	Channel-level posterior display and conflict report.
Hierarchical latent model	Models shared state, loadings, uncertainty, and missingness jointly.	A well-fitting factor may be arousal, illness, or device gain rather than valence.	Location, scale, sign, recovery, and rival-generation tests.
Ensemble model	Improves prediction across heterogeneous learners.	Performance can rise while interpretability and claim status fall.	Person-held-out, time-forward, site-held-out, and device-held-out validation.
Adjudicative fusion	Preserves discordance for expert review and context annotation.	Can become subjective rescue if rules are not prospectively specified.	Written adjudication criteria, blinded review, and audit trail.

Concrete discordant cases should remain visible. Grief may combine deep sorrow with love, opioid treatment may lower pain reports while altering respiration and arousal, and a wearable may disappear during anxiety because the device itself becomes aversive. These cases distinguish construct conflict, treatment

effect, observation loss, and burden rather than forcing them into one residual. Keeping these cases typed separately also lets model recovery test whether the pipeline can distinguish genuine latent disagreement from observation-system disagreement.

A disciplined model keeps uncertainty over channel state as well as over the latent state. When conflict cannot be resolved under protocol-fixed rules, the output may widen, split by channel, narrow to a local claim, or return No adequate estimate. The person does not become less credible because the pipeline has reached its identification limit. Channel-specific uncertainty can preserve useful evidence from one witness without forcing agreement with another whose meaning is temporarily unidentified.

The downstream consequence is versioned and auditable. Removing, delaying, or quarantining a channel changes the measurement map, estimator, calibration, and perhaps the estimand; every dependent interval, path, figure, and public statement must be recomputed or marked nontransportable. A version transition should record which past observations remain comparable, preventing a repaired channel from retroactively changing the status of earlier data.

9.5 — Measured-to-Latent Invariance

A measured signal becomes evidence about latent phenomenal value only through a bridge. That bridge includes representation, calibration, sign, scale, invariance, linking, transport, observation, and missingness assumptions. None is guaranteed by a stable instrument name or a high predictive score. The bridge must be specified, tested, and allowed to fail (Meredith, 1993; Putnick & Bornstein, 2016).

Invariance asks whether the measurement relation preserves enough structure for the intended comparison. Calibration asks how observed values relate to declared anchors and states. Linking asks whether versions or instruments can be placed on a common coordinate. Transport asks whether a relation learned in one context survives another. These are connected problems, not synonyms.

The measured-to-latent bridge is also noncompensatory. Strong prediction cannot repair an unidentified sign. A large sample cannot repair a missing neutral origin. Cross-site replication cannot repair a construct that changed across sites. Failure at an upstream bridge narrows the downstream claim before accumulation begins.

Chapter 10 will examine calibration and scale in greater depth. This section establishes the pipeline gate: what bridge strength licenses which type of claim, what uncertainty must travel with the output, and when the correct scientific response is a lower-tier result, an identified set, or abstention.

9.5.1 — Measurement Invariance as a Bridge Gate

Measurement invariance is a bridge gate, not a ceremonial fit statistic. It asks whether the same observed pattern corresponds to the same latent relation across time, people, languages, states, sites, devices, or versions. The answer may be full, partial, local, approximate, or absent, and each status licenses a different comparison (Meredith, 1993; Millsap, 2011; Putnick & Bornstein, 2016; Paap et al., 2025).

For within-stream tracking, the central question is often whether loadings, thresholds, sign, and response behavior remain stable enough to interpret change. Illness, medication, fatigue, learning, disability, and changing language can alter that relation. A stable score label does not make the ruler stable.

Cross-person and cross-context claims require stronger evidence. A channel may be reliable within each participant while differing in gain or meaning across participants. A translated item may preserve rank but not level. A device may preserve timing but not amplitude after a firmware change.

Partial invariance can support partial inference. If some anchors and channels remain stable, the study may retain within-person direction, local contrasts, or a subset of dimensions while withdrawing common-level claims. The surviving claim should be named rather than hidden inside a global score.

Time-varying measurement models may be necessary when change is expected. Flexibility should be bounded, prospectively specified where possible, and evaluated through recovery studies.

A model that allows every loading to move can fit almost anything while making the latent trajectory uninterpretable.

The bridge gate is claim specific. An invariance result identifies which comparisons the instrument supports and which require a revised model, additional calibration, or separate reporting.

9.5.2 — Local Calibration and Context of Use

Calibration links observed outputs to declared reference conditions inside a context of use. It may use repeated anchors, ethically available contrasts, known treatment or environmental changes, cognitive interviewing, and participant interpretation. The first defensible claim is usually local and within-stream; broader transport requires a separate linking argument with its own assumptions and uncertainty (American Educational Research Association et al., 2014; International Test Commission, 2018; Sprangers & Schwartz, 1999).

An anchor is not automatically a neutral origin. Rest after exertion, relief after treatment, ordinary baseline, or a familiar state may orient direction without defining zero. Calibration files should distinguish direction anchors, magnitude anchors, contextual anchors, and origin claims.

Context of use determines the evidence burden. A model intended for exploratory within-person tracking may tolerate wider uncertainty than a confirmatory terminal-window test. A rehabilitation context, pain clinic, ordinary ambulatory study, sleep study, and palliative setting may require different anchors and stop rules.

Calibration burden must be counted. Repeated prompts, challenge tasks, device wear, clinician time, and bridge sampling can change the person's experience or compete with care. A technically stronger calibration can be scientifically worse when the burden of obtaining it exceeds the value of the claim.

Local calibration should report failure and drift. If anchors change meaning, channels decouple, or participant reports contradict the model, the bridge may split into state-specific versions. Continuity is earned through evidence, not presumed because a longitudinal graph is convenient.

The output names the relation calibration supports: within-person direction, a local interval estimate, or a sensitivity range. Additional comparison levels enter the report as their own calibration evidence becomes available.

9.5.3 — Linking and Transport Across Versions and Settings

Linking places instruments, versions, languages, devices, sites, or models into a relation that permits a specified comparison. Common-item designs, common-person designs, bridge samples, anchor events, latent linking models, and historical replay answer different transport questions and require overlap across the range and states for which the link will be used. The method must be chosen for the claim it is expected to carry, and a link qualified for ranking cannot be promoted into common-origin or common-unit comparison (American Educational Research Association et al., 2014; Millsap, 2011).

Version changes are common. Hardware, firmware, preprocessing, prompts, item wording, model weights, and calibration samples may change over a long study. Old and new versions should run in parallel where feasible, or be compared through bridge data and synthetic fixtures.

Transport is stronger than linking. A model may link numerically across devices yet fail in a new clinical state, culture, language, or care context. Transport requires evidence that the relation between observables and the target remains sufficiently stable under the new conditions.

Bridge samples must cover the range that matters. A link built among healthy adults in low-burden states cannot silently support terminal, pediatric, disabled, or high-distress interpretation. Sparse overlap should produce wider uncertainty or separate versions, not confident extrapolation.

Backward compatibility may be partial. Rank order may survive while level comparison fails; timing may survive while amplitude changes; one channel may link while another must be retired. The migration record should state exactly which contrasts remain licensed.

When linking fails, the cumulative path may need to split. Historical estimates remain part of the scientific record, and later reanalysis should not erase what the earlier instrument reported. Version boundaries are evidence about the measurement system, not blemishes to be smoothed away.

9.5.4 — Measured-to-Latent Assumptions

Measured-to-latent assumptions define the inferential bridge between observed records and the phenomenal target. They include construct coverage, sign orientation, origin, unit, measurement-model form, channel response, invariance, missingness, state dependence, and the relation between the measured proxy and experienced exposure. These assumptions are not background prose. They determine which latent claim, if any, the data can support (Bollen, 1989; Borsboom, 2005).

A latent variable is not a hidden fact merely because a model estimates it. Location, scale, rotation, label switching, and model equivalence can leave multiple latent interpretations compatible with the same data. Constraints must be justified independently of the desired Law-facing result.

Measurement error has several layers. Sensor noise, report variability, preprocessing uncertainty, model misspecification, calibration error, and transport error are not interchangeable. A narrow posterior under one model can coexist with large uncertainty about whether the model represents valence at all.

Auxiliary evidence should test the bridge rather than decorate it. Known-groups contrasts, ethically permissible interventions, negative controls, participant interpretation, clinical events, and held-out prediction can support or challenge the proposed relation. None should be selected because it makes the terminal pattern cleaner.

Model recovery is indispensable. Synthetic data should include known states, lags, missingness, sign reversals, response shift,

device drift, and rival generators. The pipeline should recover the intended target when possible and widen or abstain when identification is removed.

The bridge should travel with every result as a compact dependency statement. Readers need to know which assumptions received empirical support, which were imposed, which remain uncertain, and what would force the claim to narrow. Without that statement, a measured line can impersonate a latent truth.

9.5.5 — Bridge Strength and Licensed Claims

Bridge strength should be stated as a ladder of licensed claims rather than one validity label. A channel may support artifact detection, broad state classification, within-person direction, local interval contrast, calibrated latent-state estimation, or measured-to-latent transport. Complete-stream accumulation and terminal adjudication require still stronger endpoint and domain bridges. Success on a lower rung cannot be promoted by rhetoric, and failure on a higher rung does not erase every lower-level use.

At the lowest tier, the pipeline may report observed or transformed channels with no latent interpretation. A stronger tier may support association with reports or context. A further tier may support time-forward within-person tracking under a declared state scope. Each achievement should remain visible.

Interval and path claims require additional gates: rate interpretation, temporal alignment, serial dependence, missingness, calibration, and version continuity. Cross-person or cross-cultural claims require origin, unit, linking, and invariance

evidence. Terminal-window claims require endpoint and observation architecture beyond the measurement bridge itself.

A bridge can support directional robustness without point identification. If all admissible calibrations imply improvement, the study may say so even when the magnitude is uncertain. If signs or levels differ across admissible bridges, the result should be an identified set, sensitivity statement, or abstention.

Measurement evidence can support compatibility, discriminate routes, identify the reference classes in which a bridge works, and guide interpretation of terminal results. The analysis connects these findings through the declared representation, endpoint, observation, and comparison criteria.

The licensed-claim ladder makes public communication easier because it replaces vague confidence with exact scope. A result can be scientifically valuable at a lower tier. The project need not inflate it into a stronger statement to justify the work.

9.5.6 — Bridge Failure, Narrowing, and Abstention

Bridge failure occurs when representation, origin, sign, scale, invariance, linking, observation, or recovery requirements are not met. Because these gates are noncompensatory, success downstream cannot repair failure upstream. A well-fitted cumulative curve cannot rescue an invalid bridge (Manski, 2003).

Failure should be localized by bridge layer and licensed output. Loss of cross-person linking may leave within-person direction intact; loss of scalar level may leave ordinal change; endpoint incompatibility may leave a bounded clinical-state model; and one failed channel need not invalidate another. Salvage is

legitimate only when the surviving object, population, state range, and inference tier are named separately from the failed bridge.

Identified sets show conclusions compatible with plausible origins, links, and calibrations. Incompatible signs or statuses indicate structural ambiguity rather than simply a large error bar.

Apply the canonical evidence states in §§24.2 and 27.4. Here, failed measured-to-latent identification narrows or blocks only the inference that depends on that bridge; collecting more observations does not repair nonidentification.

Later evidence of noninvariance, sign error, or invalid transport requires correction, narrowing, versioning, or withdrawal of affected figures, summaries, and verdicts. Preserve earlier outputs for traceability.

Bridge failure locates unsupported measured-to-latent transformations. Name the failed link, comparisons to narrow or stop, and lower-level claims still estimable. A more flexible fit to the same outcome does not repair the failure.

9.6 — Missingness, Provenance, Versions, and Uncertainty

A measurement is also a provenance chain. Sampling time, prompt version, device and firmware, preprocessing, missingness reason, analyst code, model version, and access history determine what the value means and whether it can be reproduced. Preserving those records is part of preserving the scientific object, not administrative overhead (Shiffman et al., 2008; Wilkinson et al., 2016; Center for Open Science, 2025).

This section treats the observation process as part of the evidence. Missingness can be caused by burden, care, sleep, refusal, device failure, low signal, staff unavailability, privacy, or model exclusion. Version changes can alter estimates. Provenance can determine whether a result is reproducible or merely remembered. The stack becomes more trustworthy when these histories are visible.

The public-risk issue is direct. A clean number without provenance can be quoted as truth. A number with provenance is harder to misuse because its conditions travel with it.

9.6.1 — Missingness Codes

Missingness codes should describe why, when, and at which layer a record is absent. No prompt, no response, refusal, sleep, device removal, low contact quality, care procedure, hospitalization, communication loss, privacy pause, technical failure, and endpoint-related observation shutdown are scientifically different events. Collapsing them into one missing flag destroys information about the observation process and can bias the

measured path (Little & Rubin, 2019; Tsiatis, 2006; Shiffman et al., 2008).

Refusal and withdrawal are not technical failures. They are participant acts within the consent structure. Sleep is not missing in the same way as battery failure. Care escalation is not missing in the same way as ambient noise. Low signal near severe illness is not missing in the same way as routine device charging. The code carries the rival explanation.

The codes should be applied as close to collection as possible and preserved through analysis. If all missingness is collapsed later, the model cannot distinguish a burden-related gap from a hardware-related gap. Apparent ledger smoothness may then reflect loss of evidence rather than change in experience.

Codes should also be auditable across groups and sites. If one site has high staff-unavailable gaps, the issue may be workflow rather than physiology. If one subgroup has high contact-quality gaps, the issue may be device design. If terminal windows show high privacy gaps, the study should respect them rather than impute over them without caution.

A missingness code does not need to shame the person or expose private detail. It needs enough specificity to govern the inference. The most privacy-preserving code that still protects science should be preferred.

Missingness is also where the human cost of measurement becomes visible. Fatigue, pain, fear, communication loss, device failure, and refusal can remove the very intervals most relevant to the estimand. The protocol should record that cost without

converting it into a permanent surveillance archive or treating absence as neutral evidence.

9.6.2 — Informative Observation

Informative observation means that whether a record exists depends on the latent state, observed history, participant burden, care context, device condition, or another variable related to the target. In experience-sampling research, prompt density, study duration, item burden, population, and protocol design can change compliance and therefore who and what remains observed. Observation cannot be treated as an independent window merely because the missing cells are numerous (Diggle & Kenward, 1994; Wrzus & Neubauer, 2023; Peeters et al., 2026).

A compact observation model can represent how burden, device condition, care events, or other state variables alter the probability that a channel is observed:

$$\begin{aligned} & \Pr(R_{kij} = 1 \mid F_{ij}, B_{ij}, D_{kij}) \\ &= \text{logit}^{-1}(\gamma_{0k} + \gamma_{1k}|F_{ij}| + \gamma_{2k}B_{ij} + \gamma_{3k}D_{kij}) \end{aligned}$$

R_{kij} indicates whether channel k is observed for person or stream i at time j ; B_{ij} can represent burden or observation burden; D_{kij} can represent device condition. This logistic form is illustrative rather than canonical. Its scientific purpose is to make observation causes explicit, because those causes can bias the measured path and may require selection models, sensitivity bounds, or abstention.

Informative observation can create false improvement. If high-burden intervals are less likely to be observed, the remaining data

look calmer. It can create false worsening when measurement intensifies during crisis. It can create false compression when terminal discomfort leads to device removal and only stable channels remain.

The stack should combine care logs, device-quality metrics, negative controls, and sensitivity analyses spanning plausible ignorable and informative observation mechanisms. Selection-model and pattern-mixture formulations reveal how conclusions move when unobserved intervals are treated differently, but neither creates identification from unsupported assumptions. If the scientific status changes across credible models, the result is model-dependent and public language must say so (Tsiatis, 2006; Little & Rubin, 2019).

Observation also burdens the participant. Increased measurement can alter behavior, sleep, anxiety, family attention, and clinician workflow. Informative observation therefore belongs both to measurement theory and research ethics. The data-generating process includes the act of data generation.

9.6.3 — Instrument and Model Version

Every candidate momentary estimator or candidate interval contribution estimate output should carry an instrument and model version. Hardware, firmware, sampling frequency, sensor placement, preprocessing, artifact rejection, transforms, signs, weights, priors, missingness model, calibration sample, and code release can all change the output. A value without version is not reproducible evidence (Munafò et al., 2017; Nosek et al., 2018).

Versioning should be granular enough to answer a challenge. Which sensor family produced the raw data? Which firmware processed it? Which preprocessing pipeline removed artifacts? Which composite weights were used? Which dynamic model version generated the posterior path? Which context-of-use statement governed the estimate? These questions are not optional when public claims are at stake.

A model version should include retirement status. Some versions are active for exploratory work only. Some are locked for confirmatory studies. Some are retired because of bias, sign failure, device shift, security issue, or burden. Old outputs from retired versions should not disappear, but their public status should change.

Version changes should be visible in figures and tables. A running ledger that crosses versions should show the version boundary. A sensitivity figure should distinguish historical replay under a new model from the original contemporaneous output. A public summary should not flatten these differences.

Versioning also prevents Artificial Intelligence drift. If an Artificial Intelligence support system changes prompts, models, embeddings, summarization templates, anomaly detectors, or feature flags, the change can affect outputs. The stack should version those support tools as carefully as physiological preprocessing.

Version change creates a new measurement relation unless equivalence is demonstrated. Revised wording, translation, firmware, feature extraction, imputation, and model weights can

all alter the construct or observation process. Earlier and later outputs should carry version labels and bridge uncertainty rather than being joined because their column names match.

9.6.4 — Data and Model Provenance

Provenance records where data came from, how they were transformed, who or what accessed them, which model acted on them, which outputs were generated, and which versions were released. It is the chain of custody for a scientific estimate and the route by which a correction can find every dependent result. Provenance makes that audit reproducible (Wilkinson et al., 2016; Center for Open Science, 2025; National Institute of Standards and Technology, 2020).

A provenance record should include source identifiers, collection time, device and model version, preprocessing steps, excluded intervals, missingness codes, auxiliary sources used, consent permissions, access events, derived outputs, publication labels, and deletion or retirement status. It should be detailed enough for reproduction and limited enough to avoid creating a cross-life dossier.

The stack should distinguish raw data, transformed data, features, posterior paths, candidate interval estimates, running ledgers, summaries, and public figures. Each layer has different sensitivity and different reuse rules. Model-training permission for one layer should not imply permission for every layer.

Provenance also helps participants contest outputs. A participant who sees a summary should be able to ask what data produced it, what context was used, whether a missingness code was wrong,

whether medication was recorded, whether a device failed, and whether an auxiliary witness was included. Contestability depends on records that can answer.

In public science, provenance protects against attractive diagrams. A curve can look definitive after many transformations. A provenance trail reminds the reader that the curve is the endpoint of choices. Some choices are justified; some are uncertain; some may be wrong. The trail is where correction enters.

9.6.5 — Migration and Backward Compatibility

Migration is the controlled relation between one instrument or model version and another. Backward compatibility is the stronger claim that old and new outputs can be compared, pooled, or translated under a documented bridge. Neither follows from improved fit. A new model may be preferable for future work while making historical estimates noncomparable (American Educational Research Association et al., 2014; Wilkinson et al., 2016; Center for Open Science, 2025).

A migration study should use overlapping data where possible, replay old raw data through the new pipeline, simulate known states, test subgroup effects, examine sign stability, compare missingness behavior, and estimate version-specific shifts. It should also ask whether the new model changes historical conclusions. If it does, the change should be reported, not hidden.

Backward compatibility may be partial. A new version may preserve rank ordering but change scale. It may preserve within-person direction but change between-person comparison. It may

work in ordinary settings but not terminal settings. It may link some channels and retire others. The compatibility statement should name the exact claim.

Historical rescoring is especially risky. Reprocessing older data with a new model can be useful for sensitivity, but it should not erase what the old model said at the time. The original output, the rescored output, and the migration method should coexist. A scientific field that rewrites its past silently cannot learn from failure.

The momentary-to-interval estimation pipeline should also define version-spanning public language. A claim supported under version 2 but not version 1 should say so. A result that disappears after migration should narrow. A result that survives migration gains robustness, but only for the claim that actually survived.

9.6.6 — Audit and Reproducibility

Audit begins with a reconstructable measurement dossier: construct, measure and channel selection, administration, scoring, transformations, context of use, validity evidence, versions, code, and data provenance. Reproducing an analysis is insufficient when the measure itself cannot be reconstructed or evaluated (Flake & Fried, 2020; Gagnier et al., 2025; Wilkinson et al., 2016).

The pipeline records dictionaries, units, timestamps, missingness codes, hardware and firmware, preprocessing, features, calibration objects, estimands, models, regularization, uncertainty, and thresholds. Synthetic fixtures and unit tests should detect sign reversal, time misalignment, version drift,

dropout, leakage, and failed abstention without exposing participants. Test fixtures should be versioned with the pipeline, because a check that no longer exercises the current transformation can create false confidence.

Audit also governs access and burden. It identifies who may see raw signals, features, posterior paths, summaries, and public results, and whether reproducibility requirements create disclosure or reidentification risk. Controlled access and secure enclaves can be more scientific than maximal release (National Institute of Standards and Technology, 2020; U.S. Food and Drug Administration, 2023). The release boundary should therefore be part of the reproducibility design, specifying what can be independently checked without exposing information the study never needed to disclose.

Independent review should combine psychometrics, signal processing, missing-data methods, clinical context, privacy engineering, and participant perspectives. Plausible detectors can flag different records, so flags need validation and uncertainty rather than becoming credibility scores (Vogelsmeier et al., 2026). Disagreement among detectors is itself diagnostic and should prompt examination of the error model rather than automatic escalation against the participant or site.

Correction must be executable. Provenance should identify every affected date, device, participant, figure, summary, and downstream model after a firmware or estimator failure, and distinguish public methods and fixtures, controlled features, and records that never leave the protected setting. Executable correction is strongest when provenance reaches machine-

readable identifiers, allowing a defect to be traced through derived datasets without depending on institutional memory.

Table 9.6. Provenance fields and minimum public labels.

Record field	Why it matters	Minimal public label
Missingness code	Distinguishes burden, refusal, sleep, care, device, and staff causes.	Observed, missing, abstained, or modeled.
Instrument version	Prevents hardware or preprocessing drift from masquerading as experience.	Device and pipeline version.
Model version	Tracks weights, priors, architecture, and code release.	Exploratory, locked, retired, or sensitivity.
Provenance chain	Allows audit, contestability, and reproduction.	Source-to-output lineage retained.
Migration status	Governs comparison across versions.	Linked, partially linked, unlinked, or split.

9.7 — Anti-Score, Privacy, and Non-Deployment Governance

The momentary-to-interval estimation pipeline becomes dangerous when people forget why it exists. It exists to test bounded scientific claims about measured consequence structures, not to evaluate persons. Governance is implemented through context-of-use limits, access rules, model permissions, participant rights, deletion routes, and retirement criteria (Shiffman et al., 2008; Stone et al., 2007; National Commission, 1979).

Anti-score rules are part of measurement validity. Fear that an output could affect employment, insurance, care, family standing, or public reputation changes participation, response, and missingness. Purpose limitation and nondeployment therefore protect both dignity and the data-generating process; they are not ethics added after the model has finished (National Commission, 1979; Council for International Organizations of Medical Sciences, 2016; National Institute of Standards and Technology, 2020).

The mechanism is direct. When participants anticipate ranking or surveillance, they may withhold, perform, disengage, or leave, and the resulting sample ceases to represent the context the instrument claims to study. A pipeline that cannot prevent those uses may be scientifically unqualified even if its internal fit is excellent.

9.7.1 — No Human-Worth Score

Candidate momentary, interval, and cumulative estimates may never be used as scores of human worth. They do not rank moral value, civic value, spiritual status, trustworthiness, loyalty, eligibility, productivity, deserved care, deserved privacy, or future potential. Chapter 9 states the prohibition here because the measurement stack is where a bounded research output is most likely to be mistaken for a verdict on a person (National Commission, 1979; Council for International Organizations of Medical Sciences, 2016).

The rule should be embedded in outputs. A report should display context of use, uncertainty, abstention status, version, and prohibited interpretations. It should not display leaderboard aesthetics, rank colors, badges, moral labels, achievement language, danger labels, or public comparison. The visual design should communicate the same research purpose and context as the accompanying text.

The no-score rule does not prevent participants from receiving understandable information about research outputs when appropriate. It requires that outputs be explained as estimates under uncertainty, not as verdicts on the person. Participant-facing summaries should say what the estimate can and cannot mean, and how to challenge it.

The rule also applies to aggregate public communication. A site, group, country, community, or clinical program should not be ranked by average candidate momentary estimator or cumulative candidate interval contribution estimate unless a specific, ethical,

and scientifically qualified comparative study has been designed for that purpose and stripped of person-evaluation meaning. Even then, the target is measurement behavior or burden conditions, not human worth.

9.7.2 — No Hidden Continuous Monitoring

Continuous monitoring can look scientifically attractive because dense data improve temporal models. It can also become the most invasive form of measurement and change the behavior it is meant to observe. The protocol should use the least intrusive cadence sufficient for the declared question, define off-periods and deletion rules, and require renewed consent when monitoring purpose or intensity changes (Council for International Organizations of Medical Sciences, 2016; National Institute of Standards and Technology, 2020; Shiffman et al., 2008).

Hidden monitoring is prohibited. Participants should know what is collected, when, by which devices, for which research purpose, who can access it, what derived outputs may be created, whether model training is permitted, how withdrawal works, and which outputs can be deleted or retired. Consent to wear a device is not consent to every inference the device might later support.

The least-intrusive-cadence rule is technical. Oversampling can increase burden, alter sleep, change behavior, increase anxiety, and generate missingness. Undersampling can miss relevant dynamics. The cadence should be justified by the channel's response time, the scientific question, and the participant burden. More data are not automatically more fairness.

Private settings require special limits. Home, sleep, intimacy, family conflict, prayer, grief, bathing, caregiving, and ordinary rest can all be affected by sensors. A research stack should use collection windows, privacy pauses, local processing, feature minimization, or participant-controlled modes where possible. The full life is not the data source simply because the Law concerns life.

Continuous monitoring also creates security risk. Raw physiological streams, context annotations, and derived paths can reveal health, habits, relationships, disability, medication, stress, sleep, and location-like routines. Security, access separation, retention limits, and deletion routes are therefore measurement requirements.

The stack should collect the minimum data needed to answer the declared question, not the maximum data that a future model might find interesting.

9.7.3 — Participant Access and Contestability

Participants should receive understandable explanations of outputs returned under the protocol. Access does not mean releasing raw telemetry or posterior draws without support. It means giving the construct, context, uncertainty, limits, and a route to challenge the data or interpretation, while preserving the option not to receive a result that lacks clinical or personal meaning (American Educational Research Association et al., 2014; Council for International Organizations of Medical Sciences, 2016; World Medical Association, 2024).

Contestability is a validity tool. A participant may know that a device was loose, a medication was taken, a report was misunderstood, a family event occurred, a sensor was removed for privacy, or a state was mixed in a way the model missed. Their challenge can correct the record, trigger a missingness code, change an exclusion rule, or reveal construct failure.

Contestability should be designed before collection begins. The protocol should specify which outputs participants can view, how they can challenge them, who reviews the challenge, what corrections are possible, whether downstream derived results can be updated, and when a challenge results in abstention rather than revision.

The system should also protect participants from overinterpretation. Return-of-results language should avoid diagnosis, moral interpretation, endpoint prediction, and claims about the whole life. It should say that the output is a research estimate under a declared context. If the estimate is not clinically actionable, that must be clear.

Family and surrogate contexts require careful separation. A participant's access does not automatically grant relatives access. A surrogate role does not create general permission to inspect private affective data. Contestability should respect capacity, consent, privacy, and the dignity of the person whose stream is being studied.

Contestability prevents a research output from becoming a one-way description of a person. When the stack can speak about someone, that person must have a route to correct context,

challenge interpretation, refuse unsupported return, and trigger review without carrying the burden of proving the model wrong.

9.7.4 — No Cross-Architecture Dossier

The privacy architecture should be designed around separation rather than one supposedly perfect vault. Identity, raw signals, derived features, context, calibration files, model outputs, and public summaries have different purposes and retention needs. Linking them by default creates a dossier even when each component was collected for a defensible reason.

This rule is not merely privacy preference. It protects the book series from a structural inversion. The science volume studies how a hypothesis could be tested. It does not authorize public transparency of ordinary persons. The City book may make public power answerable; it does not make private life measurable. The religion book may define optional practice; it does not receive candidate momentary estimator data as devotion. The transition book may sequence institutions; it does not import inner-life metrics.

A dossier would also poison participation. People would reasonably fear that research data could follow them into civic, religious, economic, clinical, or social contexts. The result would be selection bias, concealment, withdrawal, and public mistrust. The science would become less true because the data architecture became threatening.

Aggregated research outputs need caution too. Even deidentified data can be vulnerable when combined with rare conditions, time stamps, location-like routines, or clinical events. The stack should

use minimization, aggregation thresholds, differential privacy where appropriate, or nonrelease when reidentification risk is too high.

The no-dossier rule tells the reader what kind of civilization this science is not building. It is not building a registry of souls. It is building a testable research program whose outputs must remain smaller than the lives that made them possible.

9.7.5 — Artificial Intelligence as Bounded Support

Artificial Intelligence may assist artifact detection, provenance checks, anomaly flags, code tests, model comparison, and documentation under §3.6.4's authority limits and §20.7.4's analysis rules. It may not infer inner truth, assign a human score, decide care, adjudicate disputes, or issue a Law-facing verdict (World Medical Association, 2024). Patterns alone can miss sign, context, missingness, and causation; every output remains auxiliary within its declared context of use.

Version each component by model, release, configuration, input, output, review step, known errors, prohibited uses, and retirement status. A changed component changes provenance and may change the result. Participant and public materials must state when AI assisted, what it did, what it could not do, and who remains responsible; no output may imply direct access to experience.

Negative-control monitoring can flag device failure, site drift, missingness clusters, or version mismatch to inform the instrument's declared abstention rules. AI cannot replace the

participant, clinician, statistician, ethics board, stated hypothesis, or verdict architecture.

9.7.6 — Retirement and Deletion

Each instrument carries versioned, scoped retirement criteria: persistent sign error, subgroup noninvariance, device dependence, excessive burden, broken provenance, unsafe disclosure, security failure, or repeated prohibited use.

Separately map deletion of raw signals, features, embeddings, checkpoints, logs, backups, exports, and identifiers. Explain deletion options, retention periods, and residual-copy records to participants (National Commission, 1979; Council for International Organizations of Medical Sciences, 2016).

Pull, correct, or relabel dashboards, summaries, model cards, figures, and excerpts that invite scoring, hidden monitoring, eligibility decisions, or claims of inner access.

Purpose separation is architectural. Identifiers, permissions, raw data, summaries, model-training rights, and public artifacts share no universal key or default export path. None transfers automatically into civic, religious, employment, insurance, clinical, donor, or unrelated Artificial Intelligence systems.

Participant and public materials explain collection, uncertainty, context, contestability, and withdrawal without badges, destiny language, moral colors, rankings, or claims of revelation or proof.

The governance table converts no-score, no-surveillance, no-dossier, bounded Artificial Intelligence, and version retirement into enforceable technical and public-language controls.

Table 9.7. Anti-score governance risks and controls.

Governance risk	Technical control	Public-language control
Human-worth scoring	No rank outputs, no eligibility fields, no comparison dashboards.	Research estimate only, never person value.
Hidden monitoring	Purpose-limited collection, privacy pauses, minimization, consent logs.	No surveillance and no implied duty to be measured.
Cross-dossier linkage	Separated identifiers, no shared keys, no secondary model-training use.	No City, government, religious-community, Workgame, archive, donor, or voting linkage.
Artificial Intelligence overreach	Bounded support, versioning, human review, audit trail.	No autonomous valence authority.
Unsafe versions	Retirement criteria, deletion routes, release records.	Corrected, narrowed, or withdrawn outputs.

All releases, including donor and institutional materials, label outputs as observed, filtered, smoothed, forecast, simulated, or sensitivity-based and state their context and uncertainty. Those status labels should remain attached when an output is excerpted, reformatted, or exported, because a forecast or smoothed estimate stripped of its status can be mistaken for an observation.

Visible correction tests credibility. Stop, narrow, retire, or, where authorized, delete unsafe versions; notify affected users. Preserve methods, synthetic fixtures, aggregate performance, incidents, and correction history without unnecessary dossiers (National Institute of Standards and Technology, 2020; National Institute of

Standards and Technology, 2024). The trigger for each corrective action should be tied to the qualification or governance condition that failed, keeping correction proportional to the defect and independent of whether the result was favorable.

The pipeline ends with revocable authority: it estimates only in its declared context, abstains when its bridge fails, and loses its role when evidence or governance no longer supports it. Revocation should remain scoped to the authority actually lost, so failure in one context of use does not automatically invalidate a separately qualified use that still satisfies its own evidence and governance requirements.

Chapter 10 — Calibration, Scale, and Uncertainty

A scale is a promise about comparison. It promises that an order, interval, sign, or zero has the meaning the analysis assigns to it, and that change in the number can be separated from change in the instrument. For a cumulative phenomenal claim, that promise becomes especially demanding. Small errors in origin or unit can accumulate across long exposure, and a stable score can conceal a changed response process. Chapter 10 asks what must be calibrated, what must remain invariant, and what conclusions survive when a common scale cannot be earned.

The narrowest defensible starting point is calibration within one stream. Repeated anchors and contrasts can test whether the same person's responses preserve direction and magnitude across ordinary variation in a declared context. That local success may support a within-person trajectory without supplying a universal zero or common unit. Beginning locally preserves the intrastream structure of PTVC and prevents a convenient between-person scale from being assumed before its bridge exists.

Neutral origin deserves special scrutiny because translation moves zero while positive rescaling preserves it. A tiny origin error can create a large cumulative residual when exposure is long. Midpoint labeling, within-person centering, retrospective mean subtraction, or completed-record normalization can therefore manufacture apparent neutrality. The origin rule must be fixed independently of the terminal outcome, supported by response-process and anchor evidence, and propagated as uncertainty whenever more than one origin remains defensible (American Educational Research Association et al., 2014).

Longitudinal invariance asks whether repeated observations continue to measure the same construct in the same way. Configural, metric, and scalar invariance answer different questions, and partial invariance may license some comparisons while blocking others. Reliability alone cannot establish transport through time. A model can reproduce scores consistently while thresholds, loadings, meanings, or channel relations change. The chapter therefore treats invariance as a claim-specific bridge rather than a badge attached permanently to an instrument (Meredith, 1993; Putnick & Bornstein, 2016).

Response shift turns apparent stability into a scientific question. Illness, treatment, adaptation, grief, recovery, aging, or approaching death can change internal standards, the importance of dimensions, or the meaning of the construct itself. Stable scores can then coexist with changed experience, and changed scores can coexist with stable experience. Current longitudinal psychometric work illustrates how partial invariance and item-level changes can be detected in clinical populations, while leaving transport to other measures and settings open (Sprangers & Schwartz, 1999; Paap et al., 2025).

Language and culture affect more than wording. Translation can change thresholds, connotation, response style, social desirability, emotional categories, and what neutral or severe means in use. Cultural scripts can alter which states are named, hidden, tolerated, or expressed. Cross-cultural linking therefore requires translation procedures, participant interpretation, differential item functioning, anchor review, and evidence that the same comparison survives. When it does not, group-specific models or

noncomparability can preserve more truth than a falsely universal coordinate (International Test Commission, 2018; Henrich et al., 2005).

Consider a hypothetical longitudinal calibration record. The same participant completes one instrument in two languages before and after a medication change, then later uses supported communication after aphasia. The total score remains nearly flat, yet cognitive interviews show that the neutral anchor shifted in translation, one item's threshold changed after medication, and the new interface altered which states could be expressed. A flat trajectory is therefore compatible with stable experience, response shift, translation drift, or changed observability. The study must test those alternatives before it calls either the person or the ruler stable (Sprangers & Schwartz, 1999; International Test Commission, 2018; Paap et al., 2025).

Development, disability, and neurodiversity also change access and expression. Communication form, sensory processing, motor control, interoception, fatigue, cognitive load, dependence on supporters, and device accessibility can alter both the target's expression and the observation process. Inclusive calibration is not achieved by forcing every person through the same interface. It is achieved by testing alternative channels, preserving response rights, and narrowing claims when a bridge cannot travel without erasing the person's mode of communication.

Uncertainty must remain decomposable. Sampling variation, measurement error, calibration uncertainty, origin uncertainty, response shift, missingness, model selection, version migration, and transport each enter through different routes. One total

standard error can hide the source that actually limits interpretation. The chapter therefore favors uncertainty budgets and sensitivity envelopes that show what would need to improve before a stronger claim becomes available.

Calibration authority must remain current; §10.7 governs drift, requalification, correction, and retirement.

Correction can change earlier conclusions, and the system must be designed to carry that change downstream. Reanalysis identifies affected estimates, figures, public summaries, and claims. Superseded versions remain traceable rather than disappearing. A scale may retain within-person use while losing cross-site or terminal authority. Retirement can be local, versioned, and informative. This is how the book turns fallibility into a reproducible scientific process rather than a reason for quiet inconsistency.

Public language is part of calibration. A sentence such as ‘this instrument tracked directional change for this person in this state, language, device version, and treatment period within the stated uncertainty’ can be both precise and useful. The sentence becomes misleading when its context and bridge disappear and the output is described as the person’s true burden. Every public claim must therefore preserve the comparison tier, population, state, version, uncertainty, and prohibited uses that materially define it.

These requirements make a future PTVC test more informative because they identify the work the test must accomplish. A valid within-stream coordinate, independently calibrated origin, stable

sign, justified unit, transparent observation process, and endpoint-appropriate bridge would give cumulative evidence a defensible meaning. A failed protocol or implementation gate narrows any permitted use and makes the evidence Unusable for the affected estimand; a target that is undefined or cannot be identified or validly bounded yields No adequate estimate. Neither status counts for or against a stronger object the study never reached.

The chapter is optimistic about bounded comparability. Full common-scale cardinality is not the only valuable outcome. Local trajectories, stable orderings, identified sets, state-specific calibrations, and transparent noncomparability can each advance affective, psychometric, clinical, and longitudinal science. The program becomes more credible when it can distinguish what travels from what merely looks standardized.

Chapter 10 moves from within-stream calibration through origin, sign, unit, linking, longitudinal invariance, response shift, culture, language, disability, clinical edge states, identified sets, audit, correction, and retirement. Its final product is a maintained contract of comparability with visible limits and challenge routes. Part IV can then take up the next dependency in the chain: which conscious stream owns the experience, how continuity and routing are adjudicated, and where the truth-relevant endpoint lies.

10.1 — Calibration Within the Stream

Within-stream calibration asks whether repeated measurements preserve meaning for one unfolding stream. It must distinguish familiar item use from genuine validity, group-level discrimination from person-level tracking, and stable averages from state-dependent response processes. Reliability must also be attached to the level and purpose of inference: between-person consistency, within-person sensitivity, person-specific precision, and temporal stability are different properties. Only after those tests may the instrument support accumulation or a bridge to broader comparison (Molenaar, 2004; Hamaker, 2012; Vogelsmeier et al., 2024; Castro-Alvarez et al., 2026).

This order is required because the target is not an external commodity. A local baseline, repeated anchor, or stable channel relation can help study change within one stream, but none of them creates an instrument-fixed origin. A person's mean, median, or familiar resting state is not automatically phenomenal neutrality.

Within-person calibration supports time-forward prediction, drift detection, and early diagnosis of measurement problems. Repeated validation can show how the local reference changes with adaptation, illness, disability, culture, medication, sleep, and memory.

The comparison tier matrix below is the chapter's first calibration map. It shows how each step outward from one stream increases the burden of proof. It also prevents a common public error:

treating a strong within-person result as if it already licensed interpersonal comparison.

Table 10.1. Within-stream comparison tiers and calibration burdens.

Comparison tier	What it may support	Minimum calibration burden	Stop rule
Within episode	Short-window direction or responsiveness	State label, sign anchor, artifact rule	Stop when state or artifact cannot be separated
Within person over time	Trajectory and change under declared conditions	Longitudinal invariance, drift checks, response-shift review	Stop or split when bridge changes
Across states	Sleep, illness, medication, or clinical state comparison	State-specific calibration and error costs	Stop when state changes sign, origin, or unit
Across persons or groups	Common-level or same-scale claims	Origin, sign, unit, linking, invariance, transport	Stop when scalar or common-origin claims fail
Clinical or terminal context	High-burden and endpoint-adjacent inference	Treatment, symptom, burden, and observation model	Stop when care or physiology dominates the bridge

A concrete within-stream example helps fix the scope. Imagine a participant whose ordinary afternoon estimates have been stable for three weeks, whose self-reports and physiological channels both move during ethically available pain-relief anchors, and whose device diagnostics remain clean. The study has built a local measurement bridge for that participant under those conditions.

Now the person develops an infection and begins a new medication. Heart rate, sleep, temperature, and fatigue shift at once. Simply appending the new points to the old path would assume that the earlier calibration still applies. A calibrated analysis asks whether the state label has changed, whether the anchor relation still holds, and whether the bridge should split into pre-infection and post-infection segments.

The same example shows why local calibration can still be valuable. Even if the bridge splits, the earlier segment may support within-person estimates, the later segment may support a new development period, and the break itself may teach the instrument how illness changes its relation to burden. Scientific loss at one tier can become scientific information at another.

The interpretive burden in this example is created by a model that values continuity more than accuracy. Refusing to mark the infection and medication break produces a smoother curve, but it also hands later readers a less truthful history and makes every downstream integral look more certain than the bridge permits.

A within-stream calibration file should therefore remain a living, versioned object. Raw context, anchor episodes, state labels, missingness, device and software versions, and model changes

are what allow later investigators to locate where the bridge held, weakened, or failed.

A local calibration dossier should include an explicit nontransfer statement. That statement is not a weakness; it is the exact boundary that lets later researchers decide what additional evidence is needed for travel.

Strong local evidence should produce sharper labels rather than automatically larger claims. The better a bridge performs within one stream, the more precisely the report can state its population, state, version, and time bounds before asking whether any part of it transports.

The final local question is always practical: what next observation would break this bridge? If no answer can be named, the bridge has become a story rather than a measurement relation.

10.1.1 — Personal Baselines and Their Limits

A personal baseline describes a participant's channels in a familiar state, variation in self-report across ordinary days, or physiological changes after rest, pain relief, social contact, sleep, or exertion. It provides a local reference for detecting change (Borsboom, 2005; Cronbach & Meehl, 1955).

Personal baselines and the target origin serve different analytical purposes. A usual level describes a participant's recent experience; independent origin anchors provide the reference for signed accumulation. Keeping both visible helps the analysis detect persistent burden as well as change.

A baseline is therefore useful only when its scope is named. A quiet morning baseline may not travel to fever, grief, opioid medication, delirium, panic, or terminal weakness. A device baseline may shift with skin contact, hydration, posture, arrhythmia, sensor gain, or environmental temperature. A report baseline may shift with language, expectation, or what the person has learned to tolerate.

The calibration file for a stream should record the baseline context: time of day, wake state, medication timing, activity, symptom level, device version, sampling cadence, and the person's own description of what was happening. Without that record, later investigators cannot tell whether change reflects experience, measurement, or context.

The calibration question is which burden disappears when a personal baseline is treated as neutral. Chronic pain, fatigue, fear, isolation, or learned endurance can become the background against which later states are measured, so a local baseline must be described as a reference condition rather than an independently established neutral origin.

The safe language is therefore narrow. A baseline may support within-stream deviations under declared conditions. It may help detect change. It may inform person-specific prediction. It may not be used as a common zero, a proof of adaptation, a rank of persons, or a way to say that a long-carried burden has ceased to count.

10.1.2 — Repeated Anchor Events

Anchor events are moments whose direction is known well enough to test whether the measurement relation behaves as expected. The ethical word is crucial: anchors must be available without inducing harm. Relief after ordinary care, increased discomfort during naturally occurring pain, recovery after rest, dyspnea during documented exertion, or calm after a chosen calming practice can become calibration evidence only when the event would occur without the study manufacturing it (Shiffman et al., 2008; Stone et al., 2007).

An anchor is stronger when it is repeated across time and context. One pain-relief episode can orient a channel; several episodes across days can test whether the relation is stable. If the physiological estimate moves in the expected direction only once, the result may be coincidence, medication artifact, reporting delay, or care-context confounding. Repetition lets calibration become more than an anecdote.

The anchor design should separate sign, magnitude, and timing. A person may report relief before autonomic change settles. Movement may precede dyspnea. Analgesia may reduce distress while altering respiration or heart-rate variability in ways that mimic calm. The anchor therefore needs a time window, lag plan, negative controls, and a record of co-occurring care.

A repeated-anchor file should name the anticipated direction before the data are examined. If the study waits to see which channel changed and then declares that channel the anchor, it has

calibrated to the outcome. That is not anchor validation. It is post hoc fitting in clinical clothing.

Anchors also protect against false universality. A pain-relief anchor for one person may not orient the same channel in another person with neuropathy, disability, medication tolerance, or different expression norms. Even within one stream, the same anchor can change meaning after illness or adaptation. Anchors require requalification when the life context changes.

Repeated anchors can establish a practical measurement foothold in ordinary life. They test whether an instrument reliably tracks the direction of burden under its stated conditions. Passing that qualification supports the next measurement stage; a failed result identifies what must be repaired before larger claims are made.

10.1.3 — State-Dependent Calibration

State dependence is expected, not exceptional. Pain, arousal, sleep, medication, illness, posture, fatigue, fever, social setting, and attentional demand can alter both experience and the channel that witnesses it. Calibration should model those state-conditioned relations or narrow the context, rather than assume one observation law across every body and circumstance (Khalsa et al., 2018; Feldman et al., 2024; Shiffman et al., 2008).

A useful first model lets the measurement relation depend on an observed or independently adjudicated state. In prose, the signal observed from channel j at time t depends on a state-specific intercept, a state-specific loading on the latent target, and residual error. This model is deliberately simple. Its job is to turn presumed stability into a testable claim and to expose where state

uncertainty, parameter flexibility, or weak anchors make calibration unidentified.

If loadings change by state, the same latent change can produce different observed changes. If intercepts change by state, the same observed score can correspond to different latent levels. If residual variance changes by state, confidence can be narrower in some conditions and dangerously overconfident in others. Each difference has a different consequence for the measured cumulative estimate.

The state categories and their observation parameters should be specified before confirmatory analysis. Calibration must then be demonstrated across the clinical, behavioral, and device states in which the resulting estimate will be interpreted.

State-dependent models also prevent a common fairness error. A person whose body responds differently should not be treated as less measurable, less credible, or less available to science. The model's job is to ask what relationship can be defended in that state. When it cannot be defended, the instrument abstains; the person is not discounted.

The practical requirement is a state label with uncertainty. Every record should carry wake state, medication exposure, symptom context, device context, and clinical state when available. Where labels are uncertain, the analysis should propagate that uncertainty rather than assigning a crisp state because the model needs one.

10.1.4 — Calibration Drift

Calibration drift is a change in the measurement relation that may develop gradually. Monitoring can help detect that change before it causes a major inferential error. The device may age, the skin contact may change, the person may learn the prompts, the clinical routine may shift, the illness may progress, or the meaning of a response option may evolve. The scale still produces numbers, but the numbers no longer carry the same relation to the target (Russell, 1980; Cacioppo & Berntson, 1994).

Drift can be technical, physiological, interpretive, or contextual. Technical drift includes sensor gain, software preprocessing, battery behavior, firmware changes, and replacement devices. Physiological drift includes medication adaptation, autonomic neuropathy, weight loss, inflammation, fever, sleep disruption, and disease progression. Interpretive drift includes changes in how a person understands pain, fatigue, dignity, relief, or endurance.

A calibration system should therefore include drift monitors before it is used for confirmatory inference. Anchor-response stability, negative-control channels, device diagnostics, residual patterns, missingness changes, and self-report discordance can all signal that the measurement relation has moved. Drift is not a nuisance parameter after the fact. It is a reason to pause comparison.

The drift threshold and its action rule must be declared before confirmatory outcome inspection. Changing either to retain a favorable result or exclude an unfavorable one makes calibration

outcome-dependent. A justified revision belongs to a new version and is evaluated on independent data.

Drift also complicates accumulated ledgers. A small calibration shift repeated over many intervals can create a large apparent cumulative difference. The longer the integration window, the more dangerous drift becomes. A ledger that spans months or years without drift handling may look precise because errors have been averaged, while actually being biased by a slowly moving scale.

The right response to drift is not panic. It is provenance, correction, and narrowed language. A drifting scale may still support local comparisons before the drift point, or within a stable segment, or under a reestimated bridge. It may not silently support a single continuous conclusion across the break.

10.1.5 — Within-Person Validity

Within-person validity asks whether estimate changes track the intended experience for that person. A measure can separate diagnostic groups or correlate with average burden yet fail to follow one person's trajectory. Because the downstream object is path-based, between-person evidence cannot substitute for within-person sensitivity (Molenaar, 2004; Hamaker, 2012; American Educational Research Association et al., 2014).

A serious within-person design uses repeated observations, time-forward prediction, lag sensitivity, and negative controls. The estimate should track known changes in experience at the time relation justified by its validated response model, without using later data to manufacture an earlier prospective signal. It should

fail to move with irrelevant device artifacts. It should be sensitive to direction, not merely magnitude.

The analysis should separate within- and between-person effects. A channel can be higher among more distressed people on average yet fall within one person during acute distress as medication, withdrawal, or fatigue changes the signal. Such reversals are common in longitudinal science and should be expected calibration hazards, not surprises.

Validity must be tested against competing explanations. If an estimate rises during pain but also rises with motion artifact, fever, battery heating, family visits, or clinical procedures, the interpretation is not secure. The relevant question is not merely whether the signal changes, but which causal and observation processes could have produced that change.

A within-person validity file should preserve raw channels, preprocessing version, state labels, prompts, anchor events, missingness codes, and model version. Without it, later claims cannot be audited. A beautiful curve without provenance is not a measurement result; it is a picture with hidden conditions.

The payoff is worth the discipline. Strong within-person validity gives the program a credible way to study ordinary and clinical dynamics without overclaiming interpersonal comparability. Failure is informative: the instrument may need a different state model, narrower context, or retirement for that use.

10.1.6 — No Automatic Between-Person Transfer

The hardest calibration error is the leap from one stream to many. An instrument may track one person's directional change while

sharing neither origin, unit, response process, nor channel gain with another; within-person success therefore does not establish interpersonal comparability, population rank, or a common measure of burden (Molenaar, 2004; Hamaker, 2012).

Comparison should advance through explicit tiers: within episode, within person over time, across states, instruments, groups, and persons. Each tier adds anchors, linking, invariance, and transport assumptions. Between-person transfer further requires comparable anchor function and preserved sign and interval meaning across physiology, disability, language, culture, development, treatment, and response style; identical wording or standardized scores are insufficient (Putnick & Bornstein, 2016; American Educational Research Association et al., 2014).

A calibration sheet records state, medication, device version, anchors, response process, missingness, burden, and permitted comparison. If anchors move or reporting changes, split the series, widen the identified set, or withdraw the estimate. Person-specific and population models answer different questions; pooling requires tested shared structure.

Partial transfer may support rank without level, direction without interval magnitude, or some anchors without a common zero. No person carries another person's scale: every comparison must name the tier, population, state, instrument, bridge, and uncertainty earned, and broader use requires new calibration.

10.2 — Origin, Sign, Unit, and Linking

Every common-scale claim rests on coordinate choices. Origin, sign, unit, and linking are not clerical details; they determine which mathematical statements are meaningful. If origin fails, terminal neutrality cannot be stated as a common-zero result. If sign fails, burden and relief cannot be distinguished. If unit fails, integration has no stable cardinal meaning. If linking fails, instruments or persons do not share one coordinate (Krantz et al., 1971; Borsboom, 2005).

Coordinate honesty is more useful than generic skepticism. A scale may support order without distance, change without a common origin, or bounded sets without a point estimate. Each achievement should be stated at its actual level. Standardization changes a coordinate; it does not independently identify the zero or unit the hypothesis requires.

Origin, sign, unit, and linking receive separate rules because each can fail independently. Keeping them distinct prevents convenient rescaling of the formal target and protects participants from being interpreted through a coordinate system that has not earned its authority.

$$y^* = a + by, \quad b > 0$$

This transformation is the chapter's simplest warning. Positive rescaling can preserve direction, but translation moves the origin. Any claim that depends on a shared zero must therefore defend the origin independently of the result it hopes to support.

A coordinate example makes the danger visible. Suppose two instruments are both transformed to have mean zero and standard deviation one in their own development samples. The resulting scores look commensurable, and their graphs share a horizontal zero line. But one zero is a development-sample average, the other is a translated instrument mean, and neither is an independently defended neutral origin.

These data can establish useful relations between instruments. Consistent movement after burden and relief anchors can orient sign locally. A bridge sample that aligns slopes under ordinary conditions can support comparison of direction or relative change.

A professional calibration report would therefore mark three statements separately: sign evidence obtained, relative linking estimated with uncertainty, common-zero claim unavailable. That triad states exactly what the linking evidence has established and what remains to be learned.

Label each reported zero by its reference: personal baseline, sample mean, instrument origin, or independently calibrated neutral origin. That label makes the displayed coordinate interpretable.

This is why the affine transformation is central rather than decorative. Translation can move zero without changing many patterns the eye finds persuasive. If the origin is not anchored independently, a terminal-zero statement can be made or erased by coordinate choice.

The coordinate rule therefore travels forward: figures, tables, and verdicts must say which zero is being used, what sign means, what unit is defensible, and whether linking uncertainty changes the claim.

A professional result can carry several coordinate statuses at once. It may have sign, lack common origin, preserve rank, and fail interval meaning. The analysis should let those statuses coexist instead of compressing them into a single verdict.

Coordinate discipline is therefore a way of protecting the positive case. If a pattern still matters after origin, sign, unit, and linking have been separated, it is worth the reader's attention.

10.2.1 — Neutral-Origin Rule

A neutral origin is not a place where the investigator decides to put zero. It is a reference point whose neutrality is justified independently of the outcome being tested. In the Law's scientific program, that independence is essential. If the endpoint pattern itself is used to choose the origin, the test has been wired to favor neutrality (Krantz et al., 1971; Russell, 1980).

Questionnaire centering, person-mean centering, z-scoring, baseline subtraction, and regression residualization can improve numerical stability, remove nuisance variation, or support within-person change analysis. Their reference points and units belong in the measurement specification alongside any separately justified neutral origin.

The neutral-origin rule therefore has three parts. The reference must be specified before confirmatory analysis. It must be justified through anchors, construct theory, or external calibration

not chosen because it makes terminal results look favorable. It must carry an uncertainty interval or failure condition, because an origin with unknown error cannot support exact zero language.

A complementary task in the Cloos et al. (2025) follow-up isolated interface precision: 87.0% of respondents placed a requested value of 31 between 30 and 32 on a digital 0–100 slider. Including such a task alongside affective judgments separates use of the interface from interpretation of the feeling scale. Repeating it across devices and assessment periods provides a direct check on measurement consistency.

Suppose two terminal estimates approach zero after each is centred on its own preterminal mean. The observed pattern is a return toward personal recent baselines. An analysis using a separately calibrated neutral origin asks a different question.

When the origin remains unresolved, the study can examine origin-invariant dynamics, within-person directional change, or rival discrimination. It can also report endpoint proximity to a declared analytic baseline. These analyses preserve the information available while origin calibration develops.

Independent origin calibration keeps persistent burden visible even when personal baselines or reporting conventions change. Record the reference used and show how alternative plausible origins affect the result.

10.2.2 — Sign Orientation

Sign orientation asks which direction means burden increasing and which direction means relief, restoration, or positive valence. This sounds obvious only when the channel is already interpreted.

Physiological channels are rarely so obedient. Increased heart rate can signal fear, effort, fever, joy, pain, medication, or movement. Reduced expression can signal calm, fatigue, sedation, inhibition, or disconnection (Bollen, 1989; Borsboom, 2005).

A sign-bearing anchor must therefore be declared. The study should name which events, reports, or external criteria are allowed to orient sign and which are only auxiliary. A channel that changes during pain relief and during motion artifact cannot be signed by inspection. A report channel may orient sign in one context while becoming unreliable in another.

The sign gate also prevents magnitude-only evidence from masquerading as signed evidence. A model may detect arousal, disequilibrium, effort, or physiological instability. Those can be important constructs, but they are not signed valence. If the observation model cannot tell whether a state is burdensome or restorative, the result must be reported as magnitude, arousal, uncertainty, or abstention.

Sign orientation should be tested for independence from the outcome. If the same terminal pattern that the study hopes to test is used to orient sign, the bridge is circular. Sign anchors should come from ordinary and ethically available events, cross-fitted data, earlier development samples, or independent validation streams. Confirmatory sign should not be learned from the terminal result it is meant to evaluate.

Sign can also vary by person and state. A signal that means relief for one person after medication may mean sedation, fatigue, or withdrawal for another. A sign rule that travels without testing

may turn atypical physiology into apparent contradiction. When sign differs, the model should allow separate sign structures or stop common-scale claims.

Sign is technically indispensable because the proposed ledger is signed. Burden and relief cannot be treated as interchangeable magnitudes, and every integration or comparison must preserve a prospectively defended orientation. When sign is uncertain, the output must remain mixed, set-valued, magnitude-only, or abstaining rather than being assigned the direction the theory needs.

10.2.3 — Unit and Interval Meaning

A unit is a contract about equal differences. If one candidate interval contribution estimate is to represent an interval contribution, then the scale must say where equal numerical changes correspond to comparable changes in the intended construct. Standardized scores do not supply that meaning by themselves. A standard deviation is a distribution fact, not a unit of lived burden (Cronbach & Meehl, 1955; Campbell & Fiske, 1959).

Interval meaning can be local. It may hold across a narrow range of a person's ordinary states while failing at extremes. It may hold for mild to moderate fatigue and fail in severe dyspnea. It may hold across one instrument version and fail after item wording or sensor preprocessing changes. Unit claims should therefore name range, context, and version.

The interval problem also matters for integration. Multiplying a score by time produces an area, but not necessarily a meaningful

contribution. The score must estimate a rate or a declared proportional rate proxy before time integration is scientifically interpretable. Otherwise the ledger becomes arithmetic performed on a label.

A useful unit file should name raw units, transforms, anchors, scaling constants, uncertainty, and the conditions under which equal differences are defensible. If a model uses nonlinear links, ordinal categories, thresholds, or bounded scales, the unit claim must reflect that. Equal category steps on a questionnaire need not represent equal changes in latent experience.

The same caution applies to cross-version and cross-language work. If one version has different item difficulty, different response style, or different sensor preprocessing, unit continuity must be revalidated even if the label remains the same. Historical continuity cannot be asserted because the name of the scale survived.

A unit that cannot be defended does not end all science. It may narrow the analysis to ordinal ordering, monotone change, bounded sets, or within-person rank. The error would be to force interval language because later chapters need a total. The burden of a total must be earned before the total is used.

10.2.4 — Linking Across Instruments

Linking places instruments, versions, languages, devices, or model outputs onto a shared coordinate. It is not the same as correlation. Two measures can correlate strongly and still differ in origin, unit, sign, sensitivity, or state behavior. For the Law, linking must support the exact comparison being made, not

merely show that two instruments are related (Manski, 2003; American Educational Research Association et al., 2014).

A linking design needs overlap that genuinely spans the intended use. Common items, common persons, bridge samples, anchor events, or latent calibration models must cover the relevant range, languages, devices, states, and clinical conditions. A bridge estimated in healthy adults cannot silently connect an instrument used during aphasia, autonomic neuropathy, delirium, or terminal sedation (American Educational Research Association et al., 2014; International Test Commission, 2018; Putnick & Bornstein, 2016).

Linking should be versioned. A device update, questionnaire translation, changed preprocessing pipeline, or new weighting rule creates a new instrument for scientific purposes. During migration, dual scoring should be preserved long enough to estimate the relation between old and new outputs. Without a bridge period, historical comparison becomes a guess.

The linking equation may look simple, but the assumptions behind it are not. A slope and intercept can align means and variances while leaving differential item functioning, response shift, heteroscedastic error, or state-specific bias. A linked score should therefore carry uncertainty and sensitivity results into the measured cumulative estimate, not only into a methods appendix.

The chapter treats linking as a permission with scope. It may link within one language but not another, one age range but not another, one care site but not another, one clinical state but not

another. When the link fails outside scope, the output is not a bad person or a bad population. It is a nontransportable instrument.

The Law's scientific credibility depends on refusing silent backward rescoring. If a new calibration makes old data look more favorable, that is exactly when provenance matters most. The old version, new version, bridge model, uncertainty, and public claim change must all remain visible.

10.2.5 — Affine Freedom and Residual Ambiguity

Affective measures can retain uncertainty in origin and unit. Positive rescaling preserves an identified zero; translation generally does not. Person-specific positive rescalings can therefore preserve each stream's zero while leaving magnitudes incomparable across streams. When the bridge identifies only a family of affine coordinates, propagate the unresolved translations and scales rather than selecting them for favorable closure (Luce & Tukey, 1964; Krantz et al., 1971).

The simplest transformation makes the problem plain. If a measured coordinate is transformed by shifting and rescaling, changes in direction may survive, but the location of zero may not. A positive rescaling leaves zero in place only when there is no translation. A translation can turn an apparent neutral endpoint into a nonneutral endpoint, or the reverse, without changing relative patterns.

Residual ambiguity can remain after linking. Bridge samples may identify slope and intercept with uncertainty. Anchor events may orient sign but leave origin broad. Cultural adaptation may preserve rank but not level. Response shift may allow within-

person direction but not cross-time level comparison. A responsible claim names what remains unidentified.

This is where identified sets become more honest than point estimates. Instead of forcing one calibration, the analysis can report the range of terminal estimates, drift estimates, or cumulative contributions compatible with admissible transformations. If all admissible calibrations support the same qualitative conclusion, confidence rises. If conclusions change across admissible calibrations, the result is representation-sensitive.

The public version should not say that ambiguity means nothing can be known. It should say what can be known under the available bridge. A pattern may be robust to positive rescaling, sensitive to origin, stable within person, unstable between persons, or valid only as a direction. Those are different scientific results.

The Law becomes stronger when it accepts this ambiguity rather than hiding it. A claim that survives known transformation freedom is more valuable than a larger claim propped up by an arbitrary coordinate.

10.2.6 — Withdrawal of Common-Zero Claims

The origin must come from an independently justified response or state relation, not from sample centering, an instrument midpoint, a population mean, a fitted terminal value, or a transformation chosen because it improves closure. Different anchors may support local zeros while failing to establish one shared origin.

Withdrawal is required when anchors conflict, response processes change, linking leaves an additive constant unidentified, or plausible origins produce incompatible sign or terminal status. The correct output may be origin-specific results, an identified set over admissible origins, or an origin-free feature such as ordering or shape.

Failure of common zero need not destroy all calibration. Within-person direction, thresholds, ranks, local responsiveness, and some contrastive effects may remain interpretable. The report should state exactly which relations survive and which claims, especially exact-zero and cross-person level claims, are unavailable.

Z-scores, centering, and norm-referencing express values relative to a specified sample. Analyses using them should record that reference and use independent calibration when the target requires a different origin.

Restoration requires new anchor evidence and a prospectively specified linking test on data independent of the failure that motivated redesign. The program may not search across origins until one produces the preferred terminal result. Development and confirmatory status must remain separate (American Educational Research Association et al., 2014; Nosek et al., 2018).

10.3 — Longitudinal Invariance and Response Shift

Longitudinal calibration asks whether the same instrument is still measuring the same construct in the same way after time has passed. A person who becomes ill may change what fatigue means. A person who survives pain may change what counts as severe. A person who nears death may change the relation among dignity, fear, comfort, and report. Intensive longitudinal measurement therefore requires tests of temporal measurement structure, not merely more observations from the same items (Bollen, 1989; Borsboom, 2005; Vogelsmeier et al., 2024; Paap et al., 2025).

If the measurement relation changes, a numeric change can be ambiguous. It may reflect a change in experience, a change in response scale, a change in physiology, a change in meaning, or some mixture of all four. The Law's measured cumulative estimate cannot afford to pretend that these are the same.

Longitudinal invariance and response shift belong at the center of the science because apparent stability can arise in two different ways: experience may remain stable, or the ruler may change with the person. The task is to distinguish adaptation in the lived construct from adaptation in standards, interpretation, or measurement behavior (Sprangers & Schwartz, 1999).

$$X_{j,t} = \tau_j(t) + \lambda_j(t)\eta(t) + \varepsilon_{j,t}.$$

This displayed relation is deliberately modest. It does not announce the true model of experience. It shows how a stable-looking score can change because the latent state changed,

because the loading changed, because the intercept changed, or because residual error changed.

Longitudinal invariance can be tested directly through item parameters and factor relations. Recent clinical work illustrates how a population may support partial invariance, with uncertainty carried for the changing portions of the measurement structure (Paap et al., 2025; Meredith, 1993; Putnick & Bornstein, 2016).

A response-shift example shows why longitudinal measurement is not simply repeated measurement. A person recovering from a long illness may report the same fatigue score before and after adaptation, yet the meaning of that score may have changed. The first score may mean alarm and disruption; the second may mean a familiar limitation folded into a changed life.

The opposite can also happen. A person may report lower distress after a diagnosis because their standards changed, while qualitative evidence and physiological strain suggest continuing burden. That report is not false. It is evidence that the person's evaluative frame has shifted, which means the measurement bridge must be updated before the ledger uses it as a level change.

A serious design does not ask the person to freeze their meanings so a scale can remain stable. It lets meanings change and then asks what that change does to the inference. Time-varying loadings, anchors, qualitative context, and partial invariance become ways to respect the life rather than overwrite it.

This distinction supports both compassionate care and accurate measurement. Adaptation can be real relief, real strength, or real meaning. It can also be a change in standards that hides

continuing burden. Measurement earns trust by keeping both possibilities alive until the evidence narrows them.

The public consequence is that a stable score across illness is not automatically stable experience, and a changing score is not automatically changed experience. The bridge, not the graph, decides what can be said.

Longitudinal calibration therefore gives later terminal chapters a rule of restraint. Terminal calm, distress, narrowing, or compression must be interpreted through state and response-shift gates before it becomes evidence about the Law.

The same rule applies to every long-run graph in the science book. A curve that crosses months or years should carry the history of its bridge: what remained stable, what changed, and which parts of the conclusion were relabeled after change.

10.3.1 — Configural, Metric, and Scalar Invariance

Configural invariance asks whether the same pattern of indicators relates to the same construct across time. If the factor structure changes, the instrument may be measuring a different object. For the Law, this is the minimum condition for treating repeated measures as part of one trajectory rather than a sequence of different constructs with the same label (Sprangers & Schwartz, 1999; Paap et al., 2025).

Metric invariance asks whether the loadings are comparable. If loadings change, then the same latent difference produces different observed differences at different times. A channel may become more sensitive during illness, less sensitive during

sedation, or differently related to burden after adaptation. Without metric invariance, slope and change claims must narrow.

Scalar invariance asks whether intercepts or thresholds are comparable. Without it, level comparison becomes unsafe. A person may endorse the same response category at two times while meaning different latent levels, or produce the same physiological level under different clinical states. Scalar failure bars common level claims even when direction may remain usable.

Residual invariance is stronger still. It asks whether residual variances are comparable. This may matter when uncertainty is carried into cumulative ledgers. If residual variance increases near terminal states or under device burden, confidence intervals must widen. A chapter on fairness cannot let fragile states produce the narrowest public claims merely because the model forgot heteroscedasticity.

The invariance ladder should be treated as a permission ladder. Passing configural invariance may allow structural similarity. Passing metric invariance may allow some change comparisons. Passing scalar invariance may allow level comparisons. Passing residual invariance may support stronger uncertainty claims. Each rung licenses only what it actually earns.

In the Law's vocabulary, invariance failure narrows measurement, not dignity. A person whose measurement relation changes is not less real, less coherent, or less worthy of attention. The scale has met its boundary.

10.3.2 — Response Shift

Response shift occurs when a person's internal standards, values, or conceptualization of the construct change. In health measurement, it is often described through recalibration, reprioritization, and reconceptualization. These three processes describe how changes in a person's life can alter the meaning of their measurements (Putnick & Bornstein, 2016; Bollen, 1989).

Recalibration changes internal standards. A pain level once rated severe may later be rated moderate after prolonged illness, not because the sensation is smaller, but because the person's scale has changed. Reprioritization changes what matters within an evaluation. Fear, dignity, fatigue, social connection, and autonomy may carry different weight after diagnosis. Reconceptualization changes what the person means by the construct itself.

A response-shift example can break a naïve ledger. Suppose a person reports lower distress after months of illness while physiological burden and qualitative accounts show continued suffering. The report may indicate genuine adaptation, altered standards, resignation, meaning-making, medication, or a changed interpretation of the response categories. The number alone cannot decide.

The correct design uses multiple evidence streams, then-tests or individualized appraisal where appropriate, anchor events, qualitative context, and longitudinal models with time-varying measurement parameters. None of these makes response shift disappear. They make it observable enough to affect the claim.

Response shift can be part of meaningful change. A person may find relief, courage, or purpose in conditions that previously seemed unbearable. Measurement can help distinguish that lived transformation from changes in reporting scale and describe how the two interact.

Reported calm near an endpoint may reflect adaptation, care, reconciliation, sedation, altered standards, or a change in the meaning of the reported construct. Modeling these pathways helps identify which aspects of the latent trajectory each observation informs.

10.3.3 — Time-Varying Loadings and Intercepts

Time-varying loadings, thresholds, and intercepts turn response shift into a testable measurement structure. Allowing parameters to move is not a license for unrestricted flexibility; the model needs constraints, external anchors, prospective checks, and comparison with simpler invariant alternatives. Its purpose is to discover whether stability is present before stability is used (Bollen, 1989; Meredith, 1993; Paap et al., 2025).

A time-varying loading can show that one channel becomes more or less connected to the latent target. For example, respiration may become a stronger indicator of distress during dyspnea, while facial expression may become weaker under fatigue. A time-varying intercept can show that the observed level shifts even when the latent target is held constant.

Such models require discipline because flexibility can rescue too much. The calibration plan should specify which parameters may vary, what covariates justify variation, what smoothing is

permitted, and what failure thresholds trigger withdrawal. Otherwise every discrepancy can be explained away by a moving parameter, and the model loses empirical content.

The observed covariates matter. Medication, sleep state, disease stage, device version, language, age, care setting, and symptom clusters can all justify time-varying relations. If these variables are unobserved, the model should not pretend to have solved the problem. It may report wider uncertainty or an identified set over plausible parameter paths.

A time-varying model can also protect participants from false stability. If the instrument admits that sedation changes expression, it need not interpret silence as relief. If it admits that delirium changes report, it need not rank confusion as low burden. Flexibility, when constrained, can be more humane than a rigid scale.

The final rule is change-control: changing the measurement bridge changes the claim version. A result obtained under time-varying calibration is not the same claim as a result obtained under a fixed bridge. Public language must say which bridge was used.

10.3.4 — Partial Invariance

Partial invariance permits only the comparisons supported by the structure that remains stable. Stable loadings may preserve selected associations or within-person dynamics, while failed intercepts or thresholds can block latent-level comparisons; a subset of stable anchors supports only the construct range those

anchors still represent (Meredith, 1993; Millsap, 2011; Putnick & Bornstein, 2016).

Partial-invariance decisions must be prospective and auditable. The analysis should define how indicators are tested, which departures trigger review, whether modifications were anticipated, how multiplicity and model search are handled, and whether the retained indicators still cover the intended construct. Dropping inconvenient items after seeing the result is not evidence of invariance.

Construct coverage is the noncompensatory gate. If indicators of dignity, fear, agency, or social connection fail while only autonomic channels remain, the reduced model may no longer represent the intended valence construct even if its fit improves. A numerically stable remnant cannot inherit the name or authority of the larger construct without an explicit bridge.

The correct output may therefore be a narrower trajectory, a relation supported only within persons, a version-specific estimate, a set-valued comparison, or abstention from common-scale language. Partial invariance licenses partial inference and a named loss of scope; it does not license full-scale rhetoric with a smaller item set.

10.3.5 — Change Versus Measurement Change

A measurement system must distinguish change in experience from change in the instrument's relation to experience. This is the heart of longitudinal calibration. A rising score could mean rising burden, greater sensor sensitivity, changed response standards, a new medication effect, an altered clinical state, or a software

update. The same graph can carry many stories (Cronbach & Meehl, 1955; American Educational Research Association et al., 2014).

The first strategy is design. Repeated anchors, negative controls, bridge periods, dual scoring, time-forward prediction, and contextual annotation make the distinction more visible. A study that collects only one composite score at each time point has very little ability to separate experience from measurement change after the fact.

The second strategy is modeling. Joint models can include latent experience, measurement parameters, state variables, and drift terms. They can ask whether observed change is better explained by the latent state or by a changing bridge. They can produce posterior uncertainty over both, rather than giving the reader one falsely clean curve.

The third strategy is precise reporting. State how the measurement bridge connects a decrease, increase, or stable score with the underlying experience, and report the remaining alternatives when that connection is unresolved.

Measurement change is especially plausible during major life events. Illness, bereavement, disability adjustment, aging, terminal transition, treatment, and social disruption can change both the person and the way evidence is expressed. The more consequential the state change, the less safe it is to assume measurement stability.

This distinction is a falsifiability condition. If favorable movement is always attributed to experience while unfavorable

movement is assigned to measurement change, the program can absorb every result. The rules that distinguish latent change from bridge change must therefore be frozen before the trajectory is inspected and must allow either explanation, or unresolved ambiguity, to win.

10.3.6 — Longitudinal Withdrawal Rule

The longitudinal withdrawal rule marks the point at which a trajectory no longer has one defensible scale. Failed invariance, response shift, state-dependent calibration, changed channel gain, or unrecoverable version breaks can make before-and-after values incomparable even when the printed score is stable (Meredith, 1993; Sprangers & Schwartz, 1999). The withdrawal point should be reported as part of the data structure so later models cannot bridge across it without an explicit linking study.

Partial invariance provides a middle path. Indicators or channels that remain stable may support a narrower longitudinal claim while unstable components are modeled separately, removed under prespecified rules, or placed in an identified set. Partial invariance licenses partial inference, not full-scale rhetoric (Putnick & Bornstein, 2016). The retained indicators should still cover the construct region required by the estimand; statistical stability alone does not guarantee substantive coverage.

Withdrawal rules should be fixed before the target trajectory is examined. They name the tests, tolerances, affected comparison tiers, and successor outputs, such as split phases, state-specific models, bounded direction, or no common trajectory. This prevents post hoc preservation of an attractive path. The successor

output should be chosen by the failed invariance property, so a threshold failure and a loading failure do not trigger the same fallback automatically.

When a common longitudinal scale withdraws, the study may still report symptom-specific change, local direction, origin-free shape, or separate pre- and post-shift trajectories with explicit contexts and versions. Restoration requires requalification and external replication; changed anchors, parameters, or items define a new measurement version rather than silently repairing the old one. Cross-version linking can later restore some continuity, but only through data that directly span both measurement versions rather than by assuming semantic equivalence.

10.4 — Culture, Language, Development, and Disability

A scale that travels across populations carries moral weight even when it pretends to carry only numbers. If one language, body, age, or culture becomes the silent template, the measurement system can mistake difference for absence, restraint for calm, atypical physiology for neutrality, or unfamiliar expression for noise (Borsboom, 2005; Campbell & Fiske, 1959; Henrich et al., 2005).

The Law's burden lens makes that error acute. Hidden burden often stays hidden because institutions expect pain, distress, relief, and dignity to appear in familiar forms. Calibration must resist that expectation. It must ask whether the construct, sign, unit, and response relation actually travel.

Culture, language, development, disability, and neurodiversity are not sensitivity checks added after a main analysis. They determine how items are understood, which channels are available, what anchors mean, and whether the construct itself is comparable. They therefore help define the main estimand rather than merely qualifying it later.

$$Pr(X_j = 1|\eta, g) = \text{logit}^{-1}(\alpha_{jg} + \beta_{jg}\eta)$$

The group index in this item-functioning relation is not a ranking device. It is a warning that an item or channel may behave differently across language, culture, disability, development, or clinical state even at the same proposed latent level.

A cross-language example shows why fairness needs calibration rather than good intentions. An item translated as ‘I feel at peace’ may evoke emotional calm in one language, spiritual reconciliation in another, absence of conflict in another, and social acceptability in another. The same words can cross a border while the construct does not.

A disability example sharpens the point. A participant with limited facial expression may be scored as affectively flat by a model trained on expressive movement. The model may be technically consistent and still wrong. The problem is not the participant’s body. The problem is a calibration bridge that confused one form of expression with experience itself.

Developmental context adds a third pressure. A child, an adolescent, an adult, and an older person may all answer a question about tiredness, but the construct could involve play, school, social withdrawal, work, autonomy, frailty, or medication in different proportions. The word travels more easily than the meaning.

Group-specific models are often the most accurate statement of where a bridge has been earned. A common model deserves wider authority only after it survives transport across the relevant languages, developmental stages, disabilities, clinical states, and communication modes. When it does not, local models prevent one group’s evidence ecology from becoming the hidden norm for everyone else.

Where comparability remains unresolved, preserve the local result and identify the evidence needed to extend it. Separate

models can retain useful information while a wider measurement bridge is developed.

This is also a source-design rule. Recruitment cannot include only the populations easiest to link and then let the resulting scale describe humanity. The chapter requires the limits of the recruitment frame to remain visible in the claim.

When a group-specific model is necessary, it should be presented as the valid model for its qualified context, not as a deviation from a supposedly real universal scale. That wording matters because measurement language can turn a transport failure into an unjustified claim that the population itself is anomalous.

10.4.1 — Language and Translation

Translation is not word substitution. It is construct transport. A response option may carry the same dictionary meaning while changing intensity, dignity, social acceptability, or clinical implication. Words for pain, anxiety, peace, exhaustion, shame, relief, and meaning can carry different histories across languages and care settings (Henrich et al., 2005; Henrich et al., 2010).

Translation is a measurement study, not a clerical step. Forward translation, reconciliation, back translation, expert review, cognitive interviewing, harmonization, and field testing examine whether an item elicits the intended construct in the new language and context. Statistical fit cannot replace response-process evidence when words, norms, disclosure risks, or communication routes have changed (International Test Commission, 2018; Putnick & Bornstein, 2016; American Educational Research Association et al., 2014).

Conceptual equivalence matters more than lexical equivalence. A culture may distinguish forms of suffering that another language folds together. A phrase about feeling down may imply sadness in one context, fatigue in another, spiritual burden in another, and social shame in another. The Law's scalar target cannot absorb such differences by pretending the translated words are identical.

Cross-language linking requires bridge samples and uncertainty. If bilingual or multilingual participants, common anchors, or parallel validation data are unavailable, the claim may narrow to language-specific models. A language-specific model is not a second-class result. It may be the only honest result.

Translation also interacts with state. Terminal weakness, delirium, sedation, cognitive impairment, and low literacy can make even a conceptually good translation unusable in a given context. The calibration plan should specify when proxy report, clinician observation, or physiological channels may serve as auxiliary evidence and when they cannot replace report.

Public language should say translated and calibrated, not merely translated. The difference is the difference between words on a page and a measurement bridge that has survived contact with lived meaning.

10.4.2 — Cultural Display and Meaning

Culture changes expression, interpretation, suppression, and the social consequences of disclosure. Understatement, somatic language, relational description, strategic emphasis, or avoidance may each be locally intelligible responses rather than evidence of lesser or greater experience. These differences belong in the

observation model and in the design of anchors, not in stereotypes about a group (Henrich et al., 2005; Henrich et al., 2010; International Test Commission, 2018).

A calibration system should model display and meaning rather than moralize them. If a person does not cry, does not complain, does not use the expected affect words, or does not show the expected autonomic pattern, the instrument should not treat the absence of the expected signal as absence of burden. It should ask which channels are valid in that context.

Cultural display also affects anchors. A self-report anchor may be stronger in one setting and weaker in another. A behavioral anchor may be interpreted differently across care practices. Family presence, clinician authority, privacy, stigma, and spiritual interpretation can all change what is said or shown. Calibration needs those variables in the design, not only in the discussion.

Meaning can alter unit claims. A one-category change in a response scale may not represent the same experiential difference across cultural contexts. The same word for moderate may be used conservatively in one setting and expansively in another. Scalar invariance is therefore a substantive cultural question, not just a model-fit statistic.

The project should avoid both stereotypes and erasure. Culture should not be used to explain away every discrepancy, but neither should discrepancies be forced into one universal expression template. The correct response is measured: test, model, bound, and withdraw when the bridge fails.

A fair calibration system leaves room for separate models. If common comparison cannot be defended, the result is noncomparability, not failure of the people being measured.

10.4.3 — Developmental Change

Development changes construct meaning, communication, physiology, autonomy, memory, and reporting. A child's distress, an adolescent's shame, an adult's endurance, and an older person's fatigue may not relate to the same channels in the same way. Calibration across development must therefore be developmental science, not adult measurement stretched across age (Sosa-Hernandez et al., 2024; Shiffman et al., 2008).

For younger children, self-report may be limited by language, temporal understanding, scale comprehension, and dependence on caregivers. For adolescents, privacy, identity, peer context, and risk sensitivity can alter disclosure. For older adults, sensory impairment, cognitive change, medication, frailty, and social expectation can alter both channels and reports.

Developmental calibration should use age-appropriate anchors and accessible response methods. Visual scales, behavioral tasks, caregiver context, clinician observation, and physiological channels can all help, but each carries its own bias. A caregiver's concern is not the child's experience. A child's silence is not neutrality. A sensor's stability is not well-being.

Development also affects the unity and endpoint chapters downstream, but this chapter owns comparability. Even if later chapters ask whether a bearer exists or how a stream is adjudicated, calibration must ask what a score means at that

developmental stage. The same number cannot travel across age without evidence.

Longitudinal development is especially challenging because response shift and maturation occur together. The person may change, the construct may change, and the instrument relation may change. A developmental trajectory therefore often supports within-stage or transition-specific claims rather than one lifetime common scale.

The humane rule is to make development a reason for better measurement, not exclusion. Children, aging persons, and those whose communication changes should not disappear from the research program because adult scales are convenient.

10.4.4 — Disability and Neurodiversity

Disability and neurodiversity require calibration to stop mistaking familiar expression for experience itself. A person may communicate nonverbally, use assistive technology, show atypical facial or autonomic patterns, mask distress, or encounter sensory and social conditions a standard model was never designed to represent. Accessible response routes and local response-process evidence are therefore part of validity, not accommodations outside it (American Educational Research Association et al., 2014; International Test Commission, 2018).

Access is a prerequisite to interpretation. Prompt wording, response mode, timing, device design, sensory demands, motor demands, communication supports, and consent procedures must be usable before a missing or unusual response is treated as

evidence about the construct. When the interface excludes a participant, the failure belongs first to the instrument.

The second duty is construct respect. Atypical physiology does not mean absent feeling. Reduced expression does not mean reduced burden. Different social communication does not mean lower relational depth. The chapter's calibration rule is that deviation from the development sample must trigger context-of-use review, not automatic deficit interpretation.

Neurodiversity can also alter sensory burden. A device, prompt frequency, clinical context, or social demand may itself create distress. A calibration design that ignores measurement burden can alter the very state it hopes to estimate. The instrument then measures the consequences of being measured.

Disability-specific or neurodiversity-informed models may be necessary. They should not be treated as inferior to a universal model. A universal model that misreads people is not more scientific because it is universal. It is less scientific because it hides failed transport behind a single score.

The no-score rule has local force here. Calibration may qualify claims about an instrument. It may not rank communicative forms, bodies, cognitive styles, or lives. When the instrument cannot travel, the scale withdraws. The person remains fully present.

10.4.5 — Differential Item and Channel Functioning

Differential item functioning occurs when people with the same underlying construct level respond differently to an item because of group, language, culture, state, disability, or method.

Differential channel functioning is the physiological analogue: the same latent target produces different channel behavior across contexts. Both threaten comparability (Borsboom, 2005; Russell, 1980).

DIF is not automatically bias, but it is always a warning. An item may function differently because it captures a real contextual difference, because translation shifted meaning, because response style differs, because a symptom overlaps with the construct, or because the model is misspecified. The analysis must decide whether to retain, adjust, isolate, or remove the item.

A worked example clarifies the problem. Suppose two groups have the same latent distress level, but one group endorses a fatigue item more often because a medication produces physical tiredness unrelated to valence. If the item is retained as pure distress, the group appears more burdened. If the item is removed without noting medication burden, the model may erase real experience. Calibration must separate symptom overlap from construct bias.

Channel DIF can be more hidden. Skin conductance, heart-rate variability, respiration, voice, facial movement, sleep, movement, and temperature can all vary with physiology, medication, environment, disability, device placement, and care practices. A channel that is reliable in one group may be artifact-dominated in another.

Testing should include group comparisons, item or channel response functions, residual diagnostics, anchor stability, multiple-group models, and sensitivity analyses. More

importantly, it should include construct review. Statistical detection without construct interpretation can remove the very features that matter.

When DIF or channel functioning cannot be corrected, common comparison should narrow. Separate models, bounded comparisons, or abstention are better than a single score that silently taxes one group with another group's measurement assumptions.

10.4.6 — Group-Specific or Noncomparable Results

Group-specific results can be the most honest scientific outcome. If a scale is calibrated within one language, culture, developmental stage, disability context, or communication mode but fails a common link, local models preserve valid information without forcing one group's expression to become the hidden norm for everyone else (International Test Commission, 2018; Putnick & Bornstein, 2016).

Noncomparability can arise from item wording, response style, cultural display, reference groups, developmental change, disability, device access, or the construct itself. The analysis should separate these possibilities because an item-level failure calls for a different remedy from a channel failure or genuinely different construct expression.

Differential item and channel functioning should be tested at the level of the intended comparison. A translated item may shift thresholds, a wearable may change gain with skin or mobility, and a communication channel may carry different effort or risk.

Equality constraints and standardized scores cannot create common meaning when these relations fail.

A transport dossier should combine statistical invariance tests with response-process evidence, expert review, participant challenge, and context information. Psychometric fit is important, but a common factor can still reflect a shared method or institutional script rather than a common phenomenal coordinate (American Educational Research Association et al., 2014; Mokkink et al., 2024).

When full comparison fails, several outputs remain possible: separate group models, within-group trajectories, rank-only relations, bounded links, partially invariant composites, or explicit noncomparability. The chosen output should identify which transformation and inference survive rather than reporting that the population failed the scale. Choosing among these outputs should follow the scientific question and surviving invariance structure, not a preference for whichever result looks most comparable.

A universal template is especially risky in developmental and disability contexts. Familiar speech, facial expression, movement, and response speed are not privileged evidence of experience, and nonparticipation or alternative communication cannot be interpreted as low burden or low validity. The no-score and dignity rules apply to the measurement system, not to the person. Accessibility adaptations should be treated as measurement conditions to validate, not as deviations from a supposedly standard participant.

Transport should be earned cell by cell. A matrix across groups, languages, states, items, channels, anchors, lags, and devices can record supported, partial, unsupported, or prohibited relations, making the exact boundary of comparison visible and correctable (Gagnier et al., 2025). Sparse cells should remain explicitly unresolved rather than borrowing certainty from a neighboring group whose response process may differ.

The result prepares the clinical edge-state problem. If ordinary cross-group calibration already requires this discipline, illness, sedation, delirium, terminal physiology, sleep, anesthesia, and communication loss demand even more explicit state-specific bridges and abstention rules. Those edge-state bridges should also distinguish changes in experience from changes in expressibility, because the same observed silence can arise through very different mechanisms.

10.5 — Clinical, Terminal, and Edge-State Calibration

Clinical and terminal contexts change the observation model. Pain, dyspnea, delirium, fatigue, medication, sedation, fever, cachexia, anxiety, family presence, clinician workflow, and limited communication can alter expression, physiology, report, and missingness. Context-specific calibration is required; No adequate estimate may be the only defensible inference (Giacino et al., 2018; Surges et al., 2024; World Health Organization, 2020; World Medical Association, 2024).

Many consequential empirical questions arise near endpoints and high-burden states, where calibration demands increase. As science approaches vulnerability, it must more carefully separate experience, treatment, physiology, observation burden, and loss of communication.

Table 10.2. Clinical and edge-state calibration hazards and safe outputs.

Clinical condition	Calibration hazard	Required distinction	Likely safe output
Pain crisis	Symptom intensity overlaps with valence	Pain signal versus total burden	Symptom-specific direction or abstention
Dyspnea	Respiration carries panic, exertion, and physiology	Breathlessness versus affective distress	State-specific model
Delirium	Report and expression may change meaning	Experience versus observation reliability	Uncertainty expansion or no level claim

Clinical condition	Calibration hazard	Required distinction	Likely safe output
Sedation	Signal suppression may mimic relief	Treatment effect versus measured calm	Treatment-labeled sensitivity analysis
Terminal decline	Physiology may compress channels	Reserve and care effects versus Law-specific dynamics	Rival comparison only after bridge passes

A terminal-clinical example makes the stress test concrete. A patient receiving opioids for severe dyspnea shows reduced movement, slower respiration, fewer reports, and lower measured agitation. That pattern may reflect genuine relief, sedation, exhaustion, disease progression, family quieting, sensor attenuation, or several of these at once.

A weak calibration labels the graph as calming and moves on. A strong calibration asks which channels were changed by treatment, which symptoms and care events were present, whether communication or device contact deteriorated, and whether the previously qualified bridge still applies. Movement is observable; its permitted meaning is the calibration question.

Clinical calibration also has to preserve care. If asking for more reports burdens the patient or family, the protocol should stop or reduce contact. Scientific uncertainty is preferable to measurement that worsens the state being measured.

Terminal physiology provides specific mechanisms to investigate. Changes in perfusion, medication, movement, and signal quality can produce compression or reduced amplitude.

Including these processes in the model makes the comparison with a proposed signature more informative.

Vulnerable contexts can teach the science only when the bridge is strong enough, participant burden is low enough, and rival explanations are specified well enough for the preferred interpretation to fail. This is not opposition to terminal research. It is the standard that prevents urgency and symbolic importance from substituting for measurement validity.

A clinical-context file should therefore travel with every estimate produced in serious illness. It should tell later readers what the patient was receiving, what the care team was doing, what signal was feasible, and what the instrument was not allowed to infer.

The appropriate posture near vulnerability is disciplined scarcity: collect only what can be obtained without compromising care, interpret only what the qualified bridge supports, preserve clinical and observation context, and leave the remainder unforced.

10.5.1 — Pain, Dyspnea, Delirium, and Fatigue

Pain, dyspnea, delirium, and fatigue are not interchangeable burdens. They can overlap in physiology and report while differing in experiential structure. Pain can be sharp, dull, meaningful, terrifying, manageable, or dignity-threatening. Dyspnea can carry panic beyond its oxygen metrics. Fatigue can flatten expression while increasing burden. Delirium can disrupt report and amplify distress (Giacino et al., 2018; Surges et al., 2024).

A calibration system should therefore avoid one symptom-to-valence shortcut. A pain score is not a valence score. Respiratory

distress is not automatically total burden. Agitation is not always suffering, and stillness is not always relief. Each symptom requires its own observation bridge and its own relation to the target construct.

Symptoms also interact. Dyspnea can increase fear, pain can increase fatigue, fatigue can suppress report, delirium can alter expression, and medications can change all of them. A model that treats dependent indicators as independent can misstate uncertainty and overstate the amount of independent evidence.

Clinical calibration should use symptom-specific annotations, medication timing, care procedures, report when possible, clinician context, and physiological channels. The goal is not to replace experience with clinical labels. The goal is to prevent symptom confounding from being mistaken for Law-specific dynamics.

A high-burden symptom state may still support useful research. Within-person response to routine care, natural symptom fluctuation, and ethically available anchors can calibrate direction. What the chapter forbids is treating clinical severity as direct evidence for or against terminal valence closure without the bridge.

The humane consequence is immediate. When symptoms make measurement uncertain, care does not wait for measurement. Comfort-first remains the clinical rule; calibration governs scientific interpretation, not treatment priority.

10.5.2 — Sedation and Analgesia

Sedation and analgesia change experience, expression, physiology, report, and the possibility of report. They can relieve suffering, reduce visible distress, alter autonomic channels, impair communication, and change memory. Any calibration that treats reduced signal as reduced burden without modeling treatment has failed both science and care (World Health Organization, 2020; World Medical Association, 2024).

Clinical interventions can affect the target and the channels differently. Analgesia may reduce pain while preserving access; sedation may alter awareness, expression, or recall; anxiolysis may reduce fear without changing nociception. Protocols should therefore model treatment-specific pathways rather than interpreting every quiet signal as comfort or every absent report as absence of experience.

Medication timing is part of the measurement record. Dose, route, onset, expected peak effect, accumulation, tolerance, renal or hepatic impairment, and co-medications can affect channels. If treatment is not recorded, the model cannot distinguish relief from signal suppression. Missing treatment data should widen uncertainty or stop the claim.

Sedation changes consent, reporting capacity, and the available observation channels. The analysis records these transitions and evaluates auxiliary channels within the relevant state.

The Law's terminal studies will be especially vulnerable to this confusion. A terminal pattern that looks like compression may reflect good palliative care, sedation, reduced movement, device

gain, or observation attenuation. These are not annoyances after the fact. They are rival explanations that calibration must anticipate.

Treatment effects can illuminate care, experienced state, and the observation process together. When treatment changes the measurement bridge, the analysis identifies that change and states which comparisons remain meaningful.

10.5.3 — Communication-Limited States

Communication loss removes or degrades a channel; it does not establish the absence of experience. Aphasia, motor impairment, fluctuating attention, intubation, or impaired command following may prevent speech, writing, gesture, or device use. Evidence from alternative behavioral and neurophysiological assessments can inform the state, but the correct conclusion may remain uncertain (Giacino et al., 2018; World Health Organization, 2020; World Medical Association, 2024).

The calibration plan should distinguish inability, refusal, fatigue, sleep, delirium, sedation, language barrier, device inaccessibility, and care interruption. Each has a different meaning. Lumping them into missing report hides precisely the information needed to interpret the measured cumulative estimate.

Alternative communication can help: eye gaze, yes-no systems, assistive devices, simplified prompts, caregiver context, clinician observation, or physiological indicators. But each alternative has a context of use. A caregiver can provide context, not direct access. A clinician can report observed signs, not the full stream.

A physiological channel can suggest state, not testify as the person.

Silence should trigger calibration humility. It may require wider identified sets, state-specific models, or abstention. It may also require ethical modification of the protocol if measurement burden contributes to silence. A person should not be pressed into response so that a ledger can become smoother.

Communication limits are not rare edge cases. They occur in fatigue, pain, disability, delirium, severe illness, terminal weakness, language mismatch, childhood, and cognitive impairment. A scale that cannot handle them should not claim broad scientific authority.

Interpret silence through the available context: grief, exhaustion, comfort, sedation, confusion, refusal, communication difficulty, or peace. Preserve the uncertainty when the observations support several interpretations.

10.5.4 — Terminal Physiology

Terminal physiology can compress signals for ordinary reasons unrelated to PTV. Reduced movement, altered respiration and circulation, palliative sedation, metabolic disturbance, changing communication access, and sensor degradation may create apparent convergence or silence. The observation model must separate those mechanisms from any Law-facing interpretation before visual resemblance is allowed to count (Giacino et al., 2018; Surges et al., 2024; Shiffman et al., 2008).

The endpoint chapters will handle death-of-mind adjudication. This chapter owns the calibration question: does the measurement

relation still mean what it meant earlier? Near death, the answer may be no. Channels can decouple from experience, become dominated by physiology, lose sign, or become unavailable. That is a measurement result, not a reason to force the bridge.

Terminal calibration should separate physiological decline from valence inference. A falling variance in a channel may reflect reduced movement, sedation, low sensor gain, reduced perfusion, or observation loss. It may also be compatible with a Law-specific prediction in some designs. The distinction requires independent reserve measures, treatment records, negative controls, and rival models.

Common-scale origin becomes especially fragile near terminal states. If the only available data are late-window increments, the whole-life ledger remains unidentified without assumptions about the pre-enrollment ledger. If terminal physiology changes the scale, even late-window level may be uncertain. Calibration must carry those limits into the verdict.

The risk is subtle: a dying person can become a symbolic endpoint for other people's theories. This chapter refuses that conversion. Terminal data are evidence only under humane protocols, state-specific calibration, and observation bridges that permit abstention when the person becomes less observable.

Terminal calibration can reveal which channels are useful, which procedures are too burdensome, which rivals explain the data, and which states need different instruments. Those findings guide the next design.

10.5.5 — Sleep, Anesthesia, and Covert Activity

Sleep and anesthesia show why visible report cannot define experience. Dreams, partial awareness, covert responsiveness, memory failure, and altered unity can all complicate calibration. The absence of waking report is not a stable zero. It is a state-specific observation condition (Siclari et al., 2017; Sanders et al., 2012).

Sleep calibration must distinguish wake, non-rapid-eye-movement sleep, rapid-eye-movement sleep, awakenings, dream reports, nightmares, and next-day residue. A channel that tracks waking distress may not track dream valence. Dream reports are filtered by memory and awakening conditions. The measurement relation changes with state.

Anesthesia and disorders of consciousness impose still higher burdens. Behavioral unresponsiveness may coexist with residual processing or rare awareness, while physiological channels can be dominated by drugs, surgery, pain, temperature, ventilation, and clinical intervention. Calibration in these states must be treated as a distinct edge-state problem with its own reference conditions, error asymmetry, and abstention rule, not as an ordinary estimator operating under unusual lighting.

Covert activity makes error asymmetry explicit. A false negative may erase experience from the record; a false positive may convert noise into an unwarranted claim. Edge-state calibration therefore requires separate false-negative and false-positive analyses, not one aggregate accuracy score (Giacino et al., 2018).

These states belong partly to later consciousness and endpoint chapters, but calibration must prepare the ground. The question here is not whether a stream exists. It is whether the instrument's relation to the target remains valid under the state. If not, the later chapter receives uncertainty rather than a cleaned score.

10.5.6 — Clinical Context of Use

Context of use bounds an instrument's clinical authority. Calibration in ambulatory adults cannot be assumed to survive acute pain, medication change, intensive care, delirium, sedation, terminal physiology, sleep, anesthesia, or communication loss. Each setting changes target expression and observation and therefore requires setting-specific evidence (U.S. Food and Drug Administration, 2025b; International Council for Harmonisation, 2026).

Clinical qualification should follow the setting's actual failure routes. The record must separate treatment effect from measurement suppression, symptom-specific signals from total burden, comfort from reduced observability, and deterioration from a Law-specific trajectory. State, medication, device, care event, and missingness histories belong to the bridge.

A care-aware context file names the setting, population, state range, cadence, devices, anchors, communication routes, burden ceiling, stop rules, estimand, prohibited uses, and No adequate estimate path. It also excludes autonomous triage and comfort-denial uses.

A terminal example shows the risk. Physiological variance may narrow after sedation or low perfusion while self-report and

device coverage decline. Relief, observation shutdown, treatment, disease progression, or several processes may explain the pattern; terminal-valence language remains unavailable until the measured-to-latent, endpoint, and rival bridges survive (Surges et al., 2024).

The same discipline governs sleep, anesthesia, delirium, and covert activity. Unresponsiveness does not identify absence of experience, and a channel validated in waking report-rich states may fail when memory, communication, or motor output changes. Edge-state results must remain labeled by state and observation regime (Giacino et al., 2018).

Clinical calibration also protects caregivers and families. Prompts, devices, annotations, and challenge procedures must not displace care, create unpaid workflow, or turn relatives into continuous witnesses. Burden endpoints and automatic stopping rules remain operative even when the data are valuable.

Available outputs include symptom-specific direction, state-specific calibration, treatment-labeled sensitivity analysis, uncertainty-expanded identified sets, and No adequate estimate. The protocol specifies the appropriate output for each evidence state (World Medical Association, 2024).

10.6 — Identified Sets and Uncertainty

When origin, sign, unit, linking, invariance, or context of use remains only partly identified, the output should be the set of target values or conclusions compatible with the evidence and declared assumptions. That identified set is distinct from a confidence set, which expresses sampling uncertainty under a chosen inferential procedure. A complete report may need both: first identify the admissible target region, then quantify sampling uncertainty without pretending the first problem has disappeared (Manski, 2003; Imbens & Manski, 2004).

Uncertainty becomes scientifically useful when it is decomposed. Bounds can reveal whether origin, sign, linking, missingness, channel noise, model choice, or sampling variation drives the result; they can also show when between-person associations reverse within persons. The decomposition should point to the evidence that could actually narrow each component rather than using one general caution label for every uncertainty.

$$C(D) = \{h(\theta): \theta \in \Theta(D), \theta \text{ satisfies the calibration gates}\}$$

$$Var(Q|D) = E[Var(Q|D, M)|D] + Var(E[Q|D, M]|D)$$

One object reports the compatible set of conclusions; another separates uncertainty within a model from uncertainty across models and representations. Both belong in the public claim. A narrow interval conditional on one disputed calibration is not stronger than a wider set that honestly carries the calibration alternatives.

An uncertainty example can be more revealing than a point estimate. Suppose a late-window study estimates endpoint

proximity under three plausible calibration bridges. One bridge gives near-neutrality, another gives mild residual burden, and the third is inconclusive because sign weakens under sedation. A single averaged estimate would hide the fact that the conclusion depends on the bridge.

An identified-set report keeps that dependence visible. It says which conclusions survive all admissible calibrations, which survive only some, and which cannot be stated. Such a report may disappoint readers seeking a simple verdict, but it gives researchers something stronger: a map of what additional evidence would shrink the set.

The same logic applies to uncertainty decomposition. If the channel noise is small but linking error is large, gathering more signal from the same channel will not solve the problem. If model uncertainty dominates, a larger sample under the same model may sharpen the wrong answer. If state labels are uncertain, clinical annotation may matter more than sensor precision.

This is where calibration becomes strategic. It tells the program where to improve next. Sometimes the next study should not be bigger; it should be better linked, better anchored, better translated, or better state-labeled.

The public sentence follows the uncertainty map. It identifies the quantity estimated precisely, the bridge assumptions used, and the layers that call for a wider uncertainty set or additional measurement.

This turns uncertainty from a defensive paragraph into a research agenda. Uncertainty should remain visible and scientifically productive.

Public verdicts are fair only when uncertainty survives translation. People should not be asked to live under claims whose dependence on anchors, links, states, or models was known in analysis but removed from the sentence they receive.

10.6.1 — Partial Identification

Apply the partial-identification framework from §8.4 to calibration by carrying the admissible origins, links, transformations, measurement models, and invariance structures into the identified set (Manski, 2003; Imbens & Manski, 2004).

Partial identification may be the correct result whenever scalar valence, temporal additivity, common origin, or cross-person comparability remains uncertain. A late-window study may bound an observed increment, a cross-cultural study may bound linked levels, and a terminal study may bound endpoint estimates across admissible calibration bridges.

A point estimate can be misleading even when it is computed correctly. If the point depends on one arbitrary anchor, one chosen prior, or one unverified link, the precision is conditional on a fragile bridge. An identified set makes that dependence visible. It says: here is the family of conclusions the data have not ruled out.

The admissible model and transformation class should be fixed before public interpretation. The analysis should specify origins, links, invariance classes, bridge models, anchor assumptions, and sensitivity thresholds, then construct the identified set under those

rules. Widening the class only after an unfavorable result is rescue; narrowing it only after a favorable result is overclaim. Prospective specification gives both favorable and adverse conclusions the same geometry.

Partial identification can support strong conclusions when all admissible calibrations agree. If every admissible bridge rejects common neutrality, the result is a robust defeat for that claim. If every admissible bridge supports a within-person drift pattern, the result may support a narrower dynamical claim. If admissible bridges disagree, the result is representation-sensitive.

This approach is deeply fair to the reader. It refuses to hide the burden of uncertainty in a single number. It also refuses to pretend that incomplete identification means no knowledge. The world often gives ranges before it gives points.

10.6.2 — Measurement-Error Decomposition

Measurement error is often discussed as if it were a single band around an estimate. Calibration requires a sharper decomposition. Channel noise, item unreliability, sampling error, calibration error, model uncertainty, linking error, state-label uncertainty, and transport error are distinct. Some are aleatory under a model; others arise because the model, coordinate, or bridge is not identified. Each source enters differently and should remain separate whenever it can change the claim (Tsiatis, 2006; Little & Rubin, 2019; Vogelsmeier et al., 2024).

Channel noise concerns the observed signal: sensor artifacts, item unreliability, environmental disturbance, or short-term fluctuation. Calibration error concerns the relationship between

signal and target. Model uncertainty concerns which statistical structure is appropriate. Linking error concerns transformations across instruments, populations, languages, or versions. Transport error concerns whether the bridge travels to the new context.

Integrating posterior means can provide a point estimate when the required integrability conditions hold. Its uncertainty must still be computed from the joint path model, including temporal covariance, calibration, missingness, and linking uncertainty; attaching isolated pointwise error bars does not provide uncertainty for the integral. The law of total variance separates uncertainty within a model from uncertainty across the declared model family.

A simple error budget shows why calibration deserves separate attention. For equal-exposure increments on a common signed unit, suppose $Y_k = X_k + b + e_k$, with a shared zero-mean random offset b of variance σ_b^2 and independent zero-mean errors e_k of variance σ_e^2 . Assume the offset and error sequence are independent of one another and of the latent increments. If $A_n = \sum_{k=1}^n X_k$ and $\hat{A}_n = \sum_{k=1}^n Y_k$, then

$$\text{Var}(\hat{A}_n - A_n) = n^2 \sigma_b^2 + n \sigma_e^2.$$

A fixed offset instead produces bias nb ; a bound $|b| \leq \delta$ allows cumulative error $n\delta$. For unequal weights, the shared-offset variance is $\sigma_b^2 (\sum_k w_k)^2$ and the independent-error variance is $\sigma_e^2 \sum_k w_k^2$. Serial errors require the full weighted covariance matrix. Denser sampling therefore cannot, by itself, remove shared origin error.

Qualified replicate channels provide a complementary diagnostic. If $Y_k^{(r)} = X_k + e_k^{(r)}$ for $r = 1, 2$, both complete error paths have zero conditional means given the latent path and zero conditional cross-covariances, and all quantities have finite second moments, then

$$\text{Cov}(\sum_k Y_k^{(1)}, \sum_k Y_k^{(2)}) = \text{Var}(\sum_k X_k).$$

This identifies cumulative latent variance under the stated observation model. Shared bias, unequal loadings, or different measured quantities invalidate that interpretation; physiology and self-report require qualification before being treated as replicate channels. The covariance identity does not identify the neutral origin.

A practical reporting template can separate four layers: observed channel uncertainty, latent-state uncertainty, calibration-bridge uncertainty, and public-claim uncertainty. The final layer is often widest because it includes the assumptions required to translate a technical estimate into a verdict.

Error decomposition prevents false precision. A device may be highly repeatable while the construct bridge is weak. A questionnaire may have high internal consistency while translation, temporal structure, or within-person reliability fails. A model may fit well while sign remains unidentified. Reliability is level-specific, validity is claim-specific, and neither guarantees transport (Vogelsmeier et al., 2024; Castro-Alvarez et al., 2026).

The practical question is who bears the cost when distinct uncertainties are collapsed into one reassuring interval. Usually it

is the person whose result is treated as clearer than the evidence allows. Decomposition keeps uncertainty attached to its source so that correction can repair the right layer of the bridge.

10.6.3 — Within–Between Sign Reversal

Within-between reversal occurs when a relationship observed across people differs from the relationship operating within one person over time. A channel can be higher among people with greater average burden yet fall during an individual acute episode because medication, fatigue, withdrawal, or care changes the signal. Group-level direction therefore cannot be used as a trajectory bridge without a within-person model (Molenaar, 2004; Hamaker, 2012).

This problem is not exotic. It is a structural risk in longitudinal measurement. Between-person variation includes stable traits, diagnoses, environments, devices, medications, culture, disability, and care access. Within-person variation includes momentary state, adaptation, symptom fluctuation, and response timing. A single coefficient can mix them.

The measured cumulative estimate is primarily a path object. Applying a between-person calibration to within-person change without testing the relation can reverse sign and misread a terminal trajectory. Group association may inform a candidate bridge, but it cannot substitute for a within-stream model.

The analysis should therefore decompose within and between effects. Multilevel models, person-mean centering, dynamic structural models, and time-forward validation can help, but the

claim must state which level is being inferred. A between-person association is not a within-stream law.

A worked example is simple. People with chronic severe illness may have lower heart-rate variability on average than healthier people, but within one person, a further drop may indicate sedation rather than worsening experience. If the model treats the group association as a within-person sign rule, it may call sedation relief or burden incorrectly.

The public sentence should remain level-specific. Say that a channel predicts between-person differences when that is all it does. Say that it tracks within-person change only when the within-person test has passed. Never let a group relation borrow authority for a life trajectory.

10.6.4 — Sensitivity to Anchors and Priors

Anchors and priors contribute information and assumptions to difficult measurement; their roles and influence should be explicit. Calibration should report how conclusions change when plausible anchors, bridge samples, priors, transformation families, and state labels are varied within declared ranges (Bollen, 1989; Borsboom, 2005).

Anchor sensitivity asks whether the result depends on a particular reference event or item. If one relief anchor produces terminal proximity and another does not, the claim is anchor-sensitive. If a language bridge depends on one set of common items, the result should say so. If a terminal valence closure result appears only after a convenient anchor, the claim should narrow or withdraw.

Prior sensitivity matters in hierarchical and Bayesian calibration. Priors may stabilize estimates in sparse terminal data, rare states, small language groups, or edge conditions. That can be valuable, but the posterior should not be described as data-driven certainty when prior structure carries the conclusion.

Sensitivity analysis should include direction, level, and verdict. It is not enough to show that a parameter changes slightly. The analysis should ask whether public claim status changes: support, component support, narrowing, abstention, rival dominance, or defeat. Calibration sensitivity matters most when it changes the sentence.

The study should also record why anchors and priors were chosen. Scientific reasons, clinical reasons, accessibility reasons, and historical reasons differ from outcome-favoring reasons. The reader should be able to tell which kind of reason was used.

Dependence on assumptions does not disqualify a result; hidden dependence does. An anchor-sensitive estimate can be useful when the anchor family, sensitivity range, and conclusions that change are reported with it. The public statement should be no stronger than the most fragile assumption that it needs.

10.6.5 — Common-Scale Abstention

Common-scale abstention is a valid scientific result: the evidence does not support the proposed comparison at the required level. It may follow unidentified origin, unstable sign, weak unit meaning, failed linking, inadequate construct coverage, scalar noninvariance, dominant response shift, or an identified set that spans incompatible verdicts. The output names the exact

comparison that failed, the lower-tier relations that survive, and the evidence needed to reopen the bridge instead of filling the gap with a convenient score (Manski, 2003; Imbens & Manski, 2004).

Abstention is not the same as nonsignificance. A nonsignificant estimate may reflect limited information about a well-defined target; common-scale abstention means that the coordinate relation required to define or compare that target has not been earned. More observations cannot repair a missing origin, sign, unit, or transport bridge by themselves.

Abstention is also distinct from defeat. If a prerequisite bridge fails before the Law-specific proposition is reached, the study yields unusable or narrower evidence rather than evidence against PTVC. If the bridge survives and the protocol-fixed target is contradicted, the result is adverse to that target. The location of failure must remain visible.

The abstention rule should be fixed in the protocol in operational terms. Calibration uncertainty exceeding the equivalence margin, failed scalar invariance for essential indicators, unsupported sign orientation, insufficient anchor overlap, or model dependence across credible missingness assumptions can each trigger a no-common-scale verdict. Prospective rules prevent disappointment from becoming rhetorical rescue.

Abstention can preserve lower-tier results. The same data may support within-person direction, state-specific calibration, subgroup models, origin-free relations, identified sets, or future bridge development. Public reporting should name the surviving

object, the failed comparison, and the evidence needed to reopen it.

10.6.6 — Uncertainty in Public Language

Public reports should present the finding in clear language, with the material population, context, measurement, and uncertainty information stated once in the accompanying methods note or caption. Later discussion can refer to that description and repeat a qualification only when the comparison or conclusion changes (Manski, 2003).

An uncertainty report should map sources to consequences rather than append one interval at the end. Channel noise affects local estimates; missingness affects who and when was observed; linking uncertainty affects version continuity; origin uncertainty affects zero language; invariance uncertainty affects comparability; and context uncertainty affects transport.

Consider three prospectively specified plausible neutral anchors. If the valid terminal-window uncertainty sets under the three anchors fall, respectively, entirely inside the equivalence band, entirely above it, and entirely below it, the proper result is that common-zero terminal equivalence is not identified across those anchors. Averaging the anchors would hide the dependency, although some origin-free ordering or shape features may remain available (Manski, 2003; Imbens & Manski, 2004).

The same logic applies to cross-language and within-between relations. A bridge may support rank without common origin, or a channel may predict differences across people while failing to track change within a person. Public summaries should state the

level and relation actually supported rather than converting the output to a common score with false precision.

Typed uncertainty strengthens negative as well as favorable results. Failure under every admissible calibration is more discriminating than failure under one arbitrary scale, while a favorable pattern that survives only one anchor is weaker than it appears. Uncertainty is therefore part of falsification, not an apology after the result.

The ambiguity belongs to the instrument, not the person. High calibration uncertainty never makes dignity, care, rights, or credibility uncertain, and it does not authorize more intrusive measurement merely to force a decisive number.

The operational rule is exact: report bounds when assumptions leave a range, identified sets when several values remain compatible, and abstention when the target cannot be identified or validly bounded. A measured cumulative estimate is valuable because its uncertainty is typed, propagated, contestable, and open to reduction.

10.7 — Calibration Audit and Correction

Calibration is maintained rather than completed once. Instruments drift, populations and clinical routines change, languages evolve, devices update, and models age. Audit schedules, version tags, bridge samples, requalification triggers, and correction routes therefore belong to the measurement object itself, while measurement-property and reporting standards make the maintenance evidence inspectable (Mokkink et al., 2024; Gagnier et al., 2025; Nosek et al., 2018).

Calibration governance asks how anchors, samples, thresholds, software, challenges, reanalyses, and retirement decisions are recorded and acted upon. Its purpose is to keep each active claim aligned with the evidence for the bridge on which it depends.

A calibration program that can correct itself is more credible than one that presents permanence. For PTVC to become answerable, the instruments that test it must also remain answerable.

Table 10.3. Calibration audit triggers, actions, and correction records.

Audit trigger	Immediate action	Claim-status consequence	Record to preserve
Anchor instability	Pause affected comparison	Widen, split, or withdraw	Anchor version and context
DIF or channel functioning	Review affected indicators	Separate models or noncomparability	Group and item diagnostics
Device or code update	Dual scoring or bridge study	Version-specific claims	Hardware, code, and transform

Audit trigger	Immediate action	Claim-status consequence	Record to preserve
Participant challenge	Context review	Correction, explanation, or no change	Challenge and adjudication path
Cross-site failure	Restrict context of use	No transport without new evidence	Site, population, and protocol differences

An audit example closes the chapter. A scale qualified for within-person ambulatory tracking is used for two years. During that time, the device firmware changes, a translated version is introduced, a new medication becomes common in the study population, and a clinician notices that the score behaves oddly during delirium. Without audit, the same label covers several instruments.

A useful audit can begin with a concrete failure chain: a firmware update changes contact quality, medication alters autonomic responsiveness, a translation shifts an item's threshold, and delirium pushes observations outside the qualified state range. The audit asks which outputs are affected, whether a bridge can be recovered, which claims must be relabeled, and where use must stop. Its purpose is correction, not defense of the previous scale.

Correction may change old claims. Some estimates may be reanalyzed, some public summaries narrowed, some figures relabeled, and some contexts retired. A project afraid of correction will hide these changes. A serious project will make them part of the scientific record.

Participant and clinician challenge are crucial in this example because they see contexts the model may miss. A patient may know that a prompt is misunderstood. A clinician may know that a procedure altered signal. Neither should automatically override the model, but both should have a formal path into review.

Retirement is the most honest ending when the scale no longer supports its use. The instrument may still be historically important, developmentally useful, or valid in a narrower context. It should not remain active for a claim it cannot carry.

The final discipline is institutional as well as statistical: a tool must be able to step back before a person is made to carry its overreach. That requires named human responsibility, a correction channel, a withdrawal mechanism, and records sufficient to find every dependent output.

A retired instrument can still be honored as a stage of learning. Its failure can show what later instruments must measure, which populations were missed, which states were misread, and which public sentences were too large.

Retirement also prevents obsolete authority from surviving by inertia. Responsible science updates or withdraws an instrument when its bridge fails, while preserving the history needed to understand what changed.

The final calibration promise is modest and demanding: no scale may speak beyond the bridge that carries it, and every bridge must be inspectable when it starts to fail.

10.7.1 — Prospectively Specified Calibration Plan

Apply the prospective-specification terminology in §6.7. The calibration plan names the construct, measurement model, context of use, measure and channel selection, scoring and modifications, comparison tier, origin and anchors, bridge samples, invariance tests, state labels, model family, missingness assumptions, sensitivity analyses, failure thresholds, version rules, and permitted public language (American Educational Research Association et al., 2014; Nosek et al., 2018; Flake & Fried, 2020; Gagnier et al., 2025).

The plan should separate development from confirmation. Development may explore items, channels, links, and anchors. Confirmation freezes the bridge long enough to let the world answer. If the bridge changes during confirmation, the claim version changes. The result may still be useful, but it is no longer the same test.

Failure thresholds should be concrete. Scalar invariance failure may stop level comparison. Sign failure may stop signed interpretation. Link uncertainty exceeding the equivalence margin may trigger abstention. Drift beyond a declared threshold may split the trajectory. These rules should be visible before the result.

The plan should also include burden thresholds. Calibration procedures can impose prompts, devices, interviews, or clinical workflow demands. If participant or staff burden alters response, missingness, or care, the instrument has changed the data-

generating process. A measurement plan that ignores burden is incomplete.

A prospectively specified plan does not make the instrument true. It makes the test answerable. A mistaken plan can fail cleanly, be corrected, and produce better science. An unfrozen plan can preserve itself indefinitely by adapting to every result.

10.7.2 — External and Cross-Site Audit

External audit asks whether the calibration survives outside the development team. Cross-site audit asks whether it survives different devices, care routines, languages, populations, staff practices, and environmental conditions. Both are essential before claims travel beyond the site that built the instrument (Munafò et al., 2017; Nosek et al., 2018).

Cross-site audit should reproduce the deployment problem rather than reshuffle the development data. Site, device, language, and time holdouts test different transport claims, and each should be tied to a prospectively specified failure rule. A model that succeeds only after local refitting has demonstrated adaptability, not transport of one frozen bridge.

External reviewers should examine construct coverage, invariance tests, missingness, drift, version provenance, anchor selection, burden, adverse calibration decisions, and public language. A model can fit well while making a public claim that the calibration does not support. Audit must include interpretation, not only metrics.

Cross-site failure should be informative. It may reveal a language issue, a device issue, a clinical routine, a population difference, or

a hidden confound. The response should be narrowing, model revision, new bridge samples, or retirement for that context. It should not be public confidence with a footnote.

An audit trail should preserve disagreements. If clinicians or participants challenge a calibration interpretation, the challenge should be recorded, categorized, and reviewed. It may be mistaken, but it may also reveal context the model missed. Challenge data are part of calibration learning.

10.7.3 — Drift and Version Alerts

Drift alerts indicate that the observation-to-target relation may have changed; version alerts indicate that the instrument, preprocessing, or model has changed. Both require prospectively specified thresholds, bridge samples, and requalification decisions so that slow degradation, abrupt breaks, and comparison across incompatible versions become visible (American Educational Research Association et al., 2014; Wilkinson et al., 2016; Nosek et al., 2018).

Drift can arise from population shifts, new treatment practices, device replacement, firmware updates, new prompts, translation revisions, staff training, changed care workflow, or environmental conditions. Each can alter origin, sign, unit, invariance, or missingness. A drift alert should ask which coordinate is threatened.

Versioning should be granular. Hardware version, sensor placement, preprocessing, item wording, language adaptation, weighting, model code, calibration sample, and public claim

template should all have identifiers. A result without version identifiers cannot be fully interpreted later.

Drift monitoring should combine statistical and practical triggers. Residual change, anchor instability, differential item functioning, missingness shifts, device diagnostics, participant challenge, clinician concern, and changed treatment or workflow can each reveal a threatened coordinate. Statistical alerts without contextual review can miss clinically obvious failure; contextual concern without defined evidence can become untraceable discretion.

When an alert fires, the response is versioned triage rather than automatic defense or deletion. The team may continue under monitoring, pause a class of claims, split the version, reestimate through a bridge sample, widen uncertainty, requalify the context, or retire the use. The trigger, evidence, decision, and affected outputs must be recorded.

10.7.4 — Participant and Clinician Challenge

Participant and clinician challenge gives contextual evidence a route into calibration review without making anecdote sovereign over data. People and clinicians may detect failures the model cannot see, including distress caused by a sensor, a misunderstood translation, edema that disrupts a device, or an output that contradicts a documented clinical state. The challenge, evidence reviewed, disposition, and appeal route should be recorded (American Educational Research Association et al., 2014; Council for International Organizations of Medical Sciences, 2016; World Medical Association, 2024).

A challenge system should be accessible. Participants should be able to contest an interpretation, request explanation, report burden, correct context, stop future optional research collection without penalty, and learn what the score may not mean. Clinicians should be able to flag treatment changes, workflow artifacts, symptom confounds, or state changes that threaten calibration.

The challenge should trigger review, not automatic rescoring. The review asks whether the challenge identifies a data error, context error, model limitation, device issue, missing state label, unmodeled medication effect, translation problem, or public-language problem. Different causes require different corrections.

Challenge evidence should be protected from coercion. A participant should not have to justify their inner life to defeat a score. The instrument carries the burden of proof. The person carries no burden to perform legibility for the model.

Clinician challenge also has limits. Clinical impressions can be biased by culture, disability, communication style, workload, and expectations. The correct balance is neither model supremacy nor anecdotal veto. It is a review route where both model and context can be wrong.

This is one of the chapter's most important public-risk controls. A measurement system without contestability can become authority infrastructure. A bounded research instrument with challenge routes remains a scientific tool.

10.7.5 — Correction and Reanalysis

When calibration changes, affected estimates and claims must be corrected. The correction should identify the old bridge, new bridge, reason for change, affected population, affected dates, affected instruments, uncertainty change, and public claim consequences. A correction that changes the science but leaves public language untouched is incomplete (Gagnier et al., 2025).

Reanalysis should preserve provenance. Old estimates should not disappear as if they were never used. They should be marked as superseded, linked to the old version, and compared with the corrected estimates where appropriate. Historical transparency is part of trust.

Correction may narrow, widen, reverse, or abstain. A new bridge may show that a previous common-scale claim was unsupported. It may widen equivalence intervals beyond the decision margin. It may preserve within-person direction while removing cross-person level comparison. It may reveal that an apparent terminal pattern was calibration artifact.

Each instrument version should have reproducible code, synthetic fixtures, expected outputs, and migration tests. When recalibration changes a result, the program must identify which historical records remain recoverable, which require reanalysis, and which cannot be translated. Reproducibility is the mechanism that lets correction propagate rather than remain an announcement (Wilkinson et al., 2016; Center for Open Science, 2025; Nosek et al., 2018).

Public corrections should be calm and precise. The project should not treat correction as dishonor or suggest that measurement error alone decides the Law. It should identify the changed bridge, affected outputs, and surviving claims. This preserves claim continuity without hiding the reason for revision.

10.7.6 — Retirement of Nontransportable Scales

Retirement is appropriate when an instrument cannot support its claim; drift or invariance failure cannot be repaired; sign or origin is unidentified; provenance unrecoverable; participant burden or disclosure risk excessive; or foreseeable misuse uncontrolled. Retirement is versioned and scoped: an estimator may remain useful for ordinary within-person change while losing terminal, cross-language, cross-site, or cross-person authority.

Retirement ends an instrument's authority within a context of use. Care, listening, participant reports, and research continue: clinicians can comfort and treat while researchers develop a better bridge. A retired context should remain visible in instrument documentation so later users do not mistake continued use elsewhere for renewed qualification there.

The audit trail records development and freeze dates, qualified settings, anchors, versions, exclusions, drift alerts, challenges, failed invariance tests, corrections, and withdrawn claims. Reviewers use this history to reproduce where the scale gained or lost authority (Nosek et al., 2018; Mokkink et al., 2024). The history should preserve superseded calibrations rather than overwrite them, so later reanalysis can reconstruct which scale governed each published result.

An estimator valid in ambulatory adults may fail in palliative care as medication, low perfusion, care events, and observation loss alter its channels. Retire terminal use, requalify ordinary use, rerun affected analyses, and describe the surviving scope accurately. A split qualification can retain ordinary-use evidence while explicitly severing terminal claims, avoiding the false choice between total approval and total retirement.

Remove retired scales from public artifacts and operational systems. Correct, withdraw, delete, or restrict figures, summaries, websites, donor materials, model cards, and datasets as recorded. Keep unsafe outputs out of ranking, triage, employment, insurance, civic or spiritual status, and surveillance (National Institute of Standards and Technology, 2020; U.S. Food and Drug Administration, 2025b). Retirement should include machine-readable status where feasible so automated systems do not keep serving an output that human documentation has already withdrawn.

Part IV — Consciousness, Stream Routing, and Endpoints

A science of fairness cannot study a complete life until it specifies what carries the experience being accumulated. Bodies persist through many states, biographies can outlive report, legal persons are institutional objects, and records are traces. None is automatically identical to the separately routed maximal qualifying stream that bears the formal phenomenal measure. Part IV begins where those familiar identifiers cease to answer the scientific question on their own (Bayne, 2010).

Part IV therefore takes on a narrower, testable task. For a declared research purpose, it decides which experienced intervals may be joined, which remain separate, which gaps preserve several live routing models, and when the evidence licenses only an unresolved result. Each decision changes the domain of the later terminal test, so bearer definition and routing uncertainty must be fixed before endpoint evidence can carry weight.

The distinction matters because the formal ledger depends on declared intervals assigned to a qualifying stream under explicit unity and routing rules. If the gate is drawn too generously, the measured path may include intervals that were not part of the stream under study. If the gate is drawn too harshly, the program may erase experience because it was quiet, unreported, inaccessible, or inconvenient to the model. Either error can make the evidence cleaner while making the science less true.

The costs of error become concrete in a neurocritical-care room. A patient may show no reliable movement while task-sensitive neural activity remains detectable; clinicians may have to act before research converges; and families may hear different classifications from different teams. A well-governed protocol

preserves that conflict as an auditable record of channels, timing, and uncertainty instead of converting silence into absence (Bodien et al., 2024; Giacino et al., 2018).

This Part builds one dependency chain. Chapter 11 specifies provisional bearer ownership and routing. Chapter 12 asks how competing theories and boundary states alter the marker families used in that routing. Chapter 13 then constructs truth-level and protocol endpoints from independently governed evidence. The sequence matters because an endpoint estimate is interpretable only after the study has stated whose stream, which intervals, and which uncertainty class the ending belongs to.

Good bearer science must be exact enough to guide analysis and modest enough to preserve live alternatives. Biography can preserve social continuity where direct access is absent, while a classifier can create false discontinuity when a channel fails. The disciplined middle course records competing stream models, the evidence supporting each, the consequences of error, and the point at which classification authority ends.

Unknown is a typed result in this Part. Its causes include insufficient access, conflicting marker families, unsupported transport, unresolved routing, endpoint nonidentification, and observation shutdown. Naming the cause preserves the next scientific step and prevents uncertainty from becoming a convenient zero, a false absence, or an administrative judgment.

The hard cases in this Part are chosen because each breaks a different shortcut. Sleep separates experience from immediate access; anesthesia separates experience from later memory and

movement; disorders of consciousness separate organized cognition from overt response; artificial systems separate linguistic performance from warranted phenomenality; and terminal care separates observation from the truth-level end. Each case therefore tests a distinct link in the bearer-to-endpoint chain (Siclari et al., 2017; Giacino et al., 2018; Butlin et al., 2026).

This architecture makes negative results interpretable. A terminal study can fail because the bearer rule was wrong, the endpoint was chosen by convenience, or a low-signal interval was erased by an unexamined gate. By keeping those layers separate, the study can locate the failure instead of turning every adverse result into a mystery.

A persistent name, family memory, legal file, or public profile can secure obligations and social continuity without identifying the relation among experienced intervals. Those records matter, but they answer different questions. Part IV keeps administrative persistence available for care, accountability, and provenance while preventing it from becoming an unexamined proxy for phenomenal continuity.

Falsifiability improves when more than one stream model is specified in advance. A one-body-one-stream rule, a memory-gap boundary, or a low-signal exclusion may look economical, yet each can hard-code the result. Explicit alternatives reveal where evidence favors continuity, partition, rebinding, or abstention and where the later ledger remains conditional on unresolved bearer assumptions.

Endpoint discipline begins before any terminal curve is drawn. The truth-level end must be distinguished from somatic events, legal declarations, last observations, data outages, and analyst-selected windows. It must also be insulated from the ledger it is meant to test. What later becomes a stopping-time and adjudication problem begins here as a commitment to preserve cases in which no observed clock identifies the endpoint.

For a reader outside consciousness science, the edge cases provide a practical lesson: ordinary words such as awake, absent, returned, split, and ended compress several separable claims. The Part opens those words into access, report, memory, integration, causal continuity, routing, and endpoint evidence. That decomposition is what makes disagreement reviewable rather than merely philosophical (Siclari et al., 2017; Bodien et al., 2024; Andrews et al., 2024).

The dependency chain is noncompensatory. A persuasive terminal pattern cannot rescue an invalid bearer rule; an independently constructed endpoint cannot rescue a mis-zeroed measure; and a large sample cannot identify an undefined target. Stream confidence, routing alternatives, endpoint construction, observation coverage, and error consequences therefore remain separately auditable. This separation lets one failed layer stop only the inferences that depend on it, preserving valid observations without allowing them to bypass the failed gate.

The practical task is to keep that dependency chain visible. A bearer decision fixes ownership; ownership determines which observations may be combined; continuity distinguishes a pause from a boundary; and the endpoint rule fixes the domain of the

terminal claim. An explicit chain localizes a negative result. A hidden chain lets every failure retreat into an undefined bearer, interval, or ending. The chain also identifies which new evidence would reopen a blocked inference, making uncertainty actionable rather than merely descriptive.

The dossier architecture can travel across sleep, anesthesia, disorders of consciousness, development, comparative cases, artificial candidates, sudden death, and diffuse decline. What travels is the governance of evidence. Every marker retains its population, task, timing, theory dependence, qualification domain, and failure modes (Giacino et al., 2018; Butlin et al., 2026). A shared dossier schema permits comparison across states without pretending that the same markers carry identical meaning in every state.

Chapter 11 — Conscious Unity, Stream Identity, and Routing

A person may be visible and still unreachable. A body may breathe, sleep, heal, decline, or return while the scientific question of unified experience remains unresolved. A biography may continue through family memory, legal records, medical charts, and public accounts, while the research question asks something smaller and more difficult: what evidence permits us to say that a stream of experience is continuous through time (Bayne, 2010; Giacino et al., 2018)?

Chapter 11 defines the research bearer for this science: a candidate separately routed maximal qualifying stream to which felt experience is provisionally assigned for analysis. That object is narrower than legal personhood, spiritual identity, civic standing, family meaning, or the worth of a life, all of which remain governed by their own authorities.

A research bearer is a versioned evidential object, not a discovery of the person's ultimate nature. It records which intervals a study may provisionally analyze together, which alternatives remain live, and which uses are prohibited. The record may guide a sensitivity analysis or endpoint audit; it does not become the person, the soul, the public identity, the legal status, or an archive that claims to contain inner life.

The scientific problem begins with markers. Access, integration, reportability, command following, memory, learning, causal recurrence, affective carryover, physiology, and neural dynamics all provide evidence. None is sovereign. Report can fail when movement fails. Memory can fail while experience continues. A neural index can be informative without being identity. A family

story can preserve meaning without proving continuity. A public record can remain after experience has ended.

Because the unity gate determines which intervals enter the phenomenal ledger, it is part of the model rather than a clerical filter. A hard threshold can erase low-signal experience, while a threshold tuned after outcome inspection can manufacture apparent closure. The gate therefore carries sensitivity analysis, provenance, and an explicit relation to the tested endpoint.

Threshold families, soft gates, and confidence classes make this uncertainty analyzable. Their purpose is not permanent indecision, but proportional classification with enough version history to revise the record when evidence improves. Unknown remains an adequate result when no available rule can separate the live models without overreach.

Hard cases reveal which variable a continuity rule is actually tracking. Sleep can preserve vivid experience while external access falls; anesthesia can permit return without autobiographical recall; cognitive motor dissociation can preserve command-following without reliable movement; and split-access tasks can reveal restricted information flow without proving multiple subjects. Each case therefore tests a different component of continuity rather than supplying one dramatic verdict (Bodien et al., 2024; Gazzaniga, 2000).

These cases occur in operating rooms, rehabilitation units, homes, laboratories, and family decisions, not only in philosophical examples. Every classification is therefore treated as a limited research act with a context of use, a revision date, and a

prohibited-use field. That design lets the science become more exact without allowing provisional labels to migrate into treatment denial, eligibility, publicity, or moral rank.

By the end, the reader should be able to define a stream precisely enough to analyze its intervals, endpoints, and ledger, and to show how the classification can change with new evidence. Clear purpose, revisable rules, and participant protections make that work practical.

The vocabulary stays typed throughout. Stream names the proposed bearer; unity names a relation among experiences; confidence names support for an inference; partition and fusion name competing routing structures; and No adequate estimate names a limit of adjudication. None of those terms is a category of human worth.

Responsible inference proceeds from substitutes to evidence, from evidence to gates, and from gates to routing. The chapter first separates body, biography, law, memory, and record from the phenomenal target. It then assembles continuity markers, tests threshold families, examines pauses and returns, and finally confronts partition and fusion. Error costs and abstention close the sequence because every routing decision must declare what happens when the evidence is wrong.

Each bearer packet identifies candidate models, evidence channels, calibration population, confidence range, excluded alternatives, permitted analyses, and revision triggers. The packet narrows only scientific claims. When evidence cannot distinguish

continuity from interruption or partition, it returns a bounded model set or No adequate estimate.

Consider a person admitted unresponsive after injury. Motor output is unreliable, repeated examinations disagree, task-based neuroimaging later reveals organized command following, and recovery changes what can be said about the earlier interval. A versioned routing record preserves each evidence state and judgment instead of rewriting the gap as obvious in hindsight (Bodien et al., 2024; Giacino et al., 2018).

Uncertainty is treated here as structured information rather than a residual category. A confidence class records what was observed, which channels failed, which thresholds were used, which rival classifications remain live, and which downstream uses are barred. That record makes uncertainty corrigible without turning it into stigma or allowing a single score to hide the evidence chain.

The metaphysical literature remains useful because it reveals where intuition breaks. Memory can continue without unity, unity can falter without loss of dignity, and branching can make ordinary survival language unstable. The scientific task here is narrower: construct an operational bearer whose assumptions, alternatives, and limits can be inspected.

The recurring question is operational: what analysis is licensed by the evidence available at that time? A continuity marker may support inclusion in a sensitivity analysis without licensing a confirmatory ledger. A partition hypothesis may remain live without supporting public claims about multiple minds. Later

evidence may improve the record while the earlier uncertainty remains visible.

Permanent refusal to classify would also abandon decisions that evidence can sometimes support. Terminal studies, boundary-state research, and measurement models need disciplined outputs when their gates are met. Proportionate science treats yes, no, maybe, not yet, and No adequate estimate as serious results, then states what each result permits and what remains outside its authority.

11.1 — Bearer Is Not Body or Biography

The first boundary is not technical decoration; it is the condition of a responsible science. Body, memory, law, and record may each be necessary in ordinary cases, yet none is sufficient in hard cases. The stream concept is introduced not to deny those realities, but to stop them from doing work they cannot do alone.

Contemporary consciousness science increasingly separates the biological carrier, the psychological narrative, and the target of a specific measurement. Split-brain findings, memory-system dissociations, and disorders of consciousness all show why body, biography, legal person, and candidate stream cannot be collapsed into one evidential object (Bayne, 2010; Gazzaniga, 2000; Giacino et al., 2018).

The chapter uses body as support, biography as context, law as jurisdiction, record as trace, and stream as research bearer. This vocabulary gives the later terminal chapters a consistent way to connect evidence with its intended target.

The first mistake is to point at the body and call the problem solved. The organism is indispensable evidence. It carries the nervous system, the injury, the physiology, the medication exposure, the sleep state, and the clinical history. Yet the organism is not identical to the research bearer because the Law's formal object concerns unified conscious experience, not biological continuity alone.

A second mistake is to point at the biography. A life story can preserve meaning, responsibility, love, habit, memory, intention, and public recognition. But narrative continuity is too broad and

too narrow at once. It is too broad because stories can continue after conscious experience ends. It is too narrow because experience can continue when memory, report, or autobiography is impaired.

A third mistake is to point at legal personhood or public record. Law and record systems protect people, organize obligations, and preserve accountability. They must not be imported into the scientific bearer definition. A legal person can be unconscious. A public record can remain after death. An archive can contain traces of a life without becoming that life.

11.1.1 — Organism and Stream

A robust study file should keep organism, session, candidate stream, unity-gate version, routing model, and reviewer decision in separate fields. The separation permits the same body to contribute observations under more than one live routing model without duplicating any phenomenal event. It also prevents a hospital identifier or session row from silently becoming the stream because the database happened to place them together (Bayne, 2010; Bayne & Chalmers, 2003).

A useful way to hold the distinction is to treat the organism as the support condition and the stream as the target condition. Support conditions can be necessary without being identical to what they support. A lung is necessary for breathing in the ordinary human case, but breathing is not the lung; a nervous system may be necessary for conscious life in the ordinary human case, but the stream is not simply a body part named by anatomy.

This distinction also prepares later endpoint work. Somatic death, circulatory collapse, respiratory failure, brain injury, and device cessation are biological or observational events. They may be powerful evidence about the stream, but they must pass through declared endpoint and unity criteria. The science becomes fragile if it lets biology alone settle an object whose formal definition is conscious trajectory.

This distinction protects the Law from biological reduction. A pulse, an EEG pattern, a metabolic trace, a reflex, or a motor response can contribute to evidence, but each still asks what it bears on. Some markers speak to arousal. Some speak to access. Some speak to integration. Some speak to motor output. None alone says, with unrestricted authority, that one stream has continued.

The distinction also protects against the opposite error: treating bodily impairment as absence of experience. Motor paralysis, language loss, medication, fatigue, pain, sensory impairment, and injury can narrow expression without ending consciousness. A science that equates visible responsiveness with stream presence would exclude precisely the cases where caution matters most.

The organism table and the bearer table should therefore communicate through declared joins rather than collapse into one file. Age, injury, diagnosis, medication, physiology, sensory access, and motor capacity constrain interpretation. Access, recurrence, learning, integration, command following, and transition evidence bear on stream models. A join records how support evidence updates the bearer; it does not make body and stream identical.

Organism-level evidence is indispensable but typed. Anatomy, physiology, and causal continuity can support a one-stream model, while split access or independent control may keep partition alternatives alive. The result should state the model, confidence, and unresolved alternatives; insufficient evidence yields unresolved, not absent, and never changes the protection owed to the organism or person.

11.1.2 — Biography and Memory

Family memory, clinical records, and public biography preserve obligations, relationships, preferences, prior function, and grief even when scientific access is weak. The research program should honor those continuities without using love, narrative coherence, or archival persistence as a consciousness detector. They provide context and recognition while remaining indirect evidence about present phenomenal unity (Tulving, 1985; Squire, 2004).

Memory also has directionality. A later remembered episode can support the claim that something was experienced earlier, but failure of later recall is not symmetric evidence of absence. Amnesia, aphasia, sedation, trauma, sleep, delirium, and developmental limits break the symmetry. The classifier must therefore record memory as one channel with known failure modes, not as the court of last appeal.

Narrative fluency creates a systematic selection risk. Adults who can recount episodes, understand tasks, and describe a stable self are easier to classify than infants, people with amnesia or aphasia, heavily sedated patients, and others whose experience may be less narratable. The bearer model must therefore treat language and

autobiographical memory as channels with access requirements, not as admission tickets to the phenomenal domain.

Memory and biography contribute only through a declared evidential role. Consistent, causally plausible retention can strengthen continuity, while rehearsal, suggestion, record exposure, reconstruction, and amnesia remain live rivals. The absence of autobiographical recall cannot by itself close a gap, and the presence of a narrative cannot by itself prove phenomenal continuity (Nadel & Moscovitch, 1997; Squire, 2004).

11.1.3 — Legal Person and Research Bearer

Legal person and research bearer should occupy separate columns because they carry different powers. Legal status organizes rights, duties, consent authority, and institutional action. Bearer status restricts what one analysis may infer about phenomenal continuity. A change in scientific confidence must not alter legal protection, and a legal declaration must not be imported as evidence that a stream began, continued, or ended.

The distinction is especially important because legal categories are designed for public administration and protection, not for detecting conscious unity. They answer questions such as who may consent, who may inherit, who may be represented, and what duties institutions owe. The research bearer answers a different question: what candidate stream, if any, is the object of a scientific claim about felt trajectory.

Confusing legal and scientific categories weakens both. Law may be tempted to borrow neuroscientific language as if it settled rights or institutional status, while science may borrow the finality

of a legal declaration as if it settled phenomenal continuity. Legal status is therefore treated as protected context and authority, not as a measurement channel or an output of the bearer classifier.

Confusing the two would make the science dangerous. A low-confidence unity classification could be misread as reduced personhood. A no-estimate state could be misused as permission to reduce care. A partition hypothesis could be sensationalized as a legal division of identity. None of those uses follows from this chapter, and each is explicitly barred.

This separation also protects science. Legal categories are sometimes coarse relative to experience. A legal person can undergo sleep, anesthesia, coma, dissociation, or dementia while retaining status. That continuity of status is ethically necessary, but it does not solve the scientific problem of which experiential intervals are open, closed, uncertain, or partitioned.

Bearer classifications belong in restricted scientific records rather than administrative eligibility systems. Access is role-limited, labels expire or undergo review, and public summaries omit confidence classes that could become stigma, triage, insurance logic, employment inference, or rank.

11.1.4 — Public Identity and Record

Public identity is especially prone to uncontrolled reuse. A name, image, biography, diagnosis, or famous case can attract attention far beyond the original protocol and make later reviewers less independent. The safer record links public identity to the research dataset only through restricted provenance, while analytic files

retain the minimum variables needed to test routing and endpoint claims.

Medical records, social-media accounts, letters, video, voice notes, photographs, wearable traces, and model-generated summaries preserve different aspects of a person's public history. Routing analysis records what each archive contains and the continuity relation it can inform.

This matters for public artifacts as much as for research. A diagram that shows a line continuing through an archive, a caption that speaks of a person living in data, or a public page that treats model output as continuing witness would violate the chapter's boundary. Records can help interpret the past. They do not become the stream.

Public records are also selective. They preserve what was documented, not what was felt. They privilege visible actions, language, official encounters, social participation, and institutional access. A person's hidden burden can be absent from records precisely because it was hidden. Treating the record as the stream would repeat the injustice the Law's lens was built to expose.

The record has legitimate scientific uses. It can establish timing, medication, clinical events, injury history, sleep schedules, public behavior, consent records, and version history. It can show what evidence was available to a reviewer at a given time. It can preserve uncertainty instead of overwriting it. Its role is evidential and protective.

11.1.5 — One Body, Possible Multiple Streams

One organism usually supports the initial one-stream model because it is parsimonious and consistent with ordinary integration. Parsimony is a starting rule, not a metaphysical axiom. Evidence of sustained access barriers, partly independent control, conflicting report channels, or causal separation may require partition alternatives, while ordinary shifts in mood, role, or attention do not.

The key distinction is between complexity within one stream and evidence for more than one stream. Multiple goals, voices, perspectives, or behavioral modes can coexist in an integrated system. A partition hypothesis becomes scientifically relevant only when the evidence concerns restricted coaccess, independent control, causal insulation, or incompatible ownership of phenomenal events.

A partition hypothesis enters only when it explains access, memory, agency, or integration patterns better than a one-stream alternative under the same evidence budget. It is not added for novelty and not suppressed for tidiness. Whatever the scientific result, public and moral status remain unchanged.

Split-brain phenomena, severe dissociation, focal injury, seizure states, developmental anomalies, and possible artificial or hybrid cases all pressure-test the one-body-one-stream assumption. Their value lies in forcing explicit unity, ownership, routing, maximality, and domain rules, not in dramatizing multiplicity.

A research model should therefore allow a state space with options: one continuous stream, uncertain continuity, interrupted

stream, partitioned streams, remerged stream, or no-estimate. The existence of options does not mean the options are common. It means the program does not force the world into a shape convenient for the ledger.

The two error directions require different repairs. Collapsing a genuine partition can assign distinct event sets to one ledger; over-partitioning ordinary complexity can duplicate events, inflate apparent model flexibility, and create harmful public narratives. The protocol should therefore compare routing models under a nonduplication constraint and report the analyses that change when partition remains unresolved.

11.1.6 — Dignity Does Not Depend on Classification

Dignity is not an empirical confidence level. Under support, narrowing, nonmeasurement, or defeat, uncertainty about consciousness cannot reduce care, privacy, communication, legal protection, or ordinary human regard (Giacino et al., 2018; World Medical Association, 2024).

The protocol therefore separates scientific and care consequences. A classification may determine primary, sensitivity, or excluded analysis, but never comfort, analgesia, visitation, rehabilitation, communication support, or clinical seriousness. This separation also prevents classification-driven care changes from contaminating observation.

A no-estimate bearer state means evidence is inadequate for the declared inference, not that the person is absent from medicine, family, law, or moral consideration. Continuity may remain possible without being sufficient for a confirmatory ledger.

Bearer uncertainty remains visible downstream through parallel routing analyses, model families, identified sets, or No adequate estimate. Statistical precision cannot erase identity uncertainty, and a clean terminal result cannot repair unresolved ownership.

Transport must be shown for the marker-to-target relation. A classifier calibrated in communicative adults may change meaning in infancy, aphasia, motor impairment, sedation, brain injury, nonhuman species, or artificial architectures. New domains require documented prerequisites, calibration, thresholds, and failure modes; otherwise evidence remains restricted or unavailable (Giacino et al., 2018; Andrews et al., 2024). Transport evidence should include error asymmetry, because a marker that fails mainly through false exclusion has different scientific consequences from one that fails through false inclusion.

Review should be protected from biography and publicity. Blinding fame, legal controversy, commercial value, political meaning, or emotional vividness cannot remove every bias, but it reveals when public identity is doing work the markers cannot support. Review materials should therefore foreground marker evidence and uncertainty before identifying narrative context that could anchor interpretation.

The bearer object is a versioned decision packet recording admissible stream models, evidence date, uncertainty, excluded alternatives, permitted analyses, prohibited uses, and revision triggers. It can travel into later chapters without becoming a portable identity score. Separating bearer evidence from public

identity also makes later corrections safer, because a revised stream model need not rewrite a biography or legal record.

Even when one stream cannot be identified, the research can show which assumptions failed, which ownership models remain live, which analyses are prohibited, and which protections remain fixed. Uncertainty becomes a structured result rather than a gap hidden beneath the ledger. A structured uncertainty set can still support conservative ownership bounds when all live models agree that certain events cannot belong to the same stream.

11.2 — Continuity Evidence and Confidence

Continuity evidence is deliberately plural because no single aperture reveals consciousness. A person can be accessible yet unable to report, recurrent yet unable to remember, physiologically organized yet behaviorally silent, or behaviorally active without enough evidence of the unity under study. A plural framework reduces both premature exclusion and premature inflation.

No single continuity marker is sufficient across healthy, clinical, developmental, and nonhuman cases. Access, integration, memory, causal recurrence, command following, and perturbational complexity each carry different sensitivities and failure modes, so confidence must be assembled from converging families rather than one privileged signal (Casali et al., 2013; Dehaene et al., 2017; Bodien et al., 2024).

Confidence classes state exactly what the study can carry forward: continuity within a window, unresolved status across a gap, possible partition under a task, or No adequate estimate when the required evidence is unavailable. Each class connects a result with its next permitted analysis.

Continuity confidence is assembled from channels that answer different questions. Access asks what information becomes usable; memory asks what persists; recurrence asks what causal organization continues; command following asks whether instructions can guide activity; physiology and neural measures ask about state and capacity. The dossier records which

component each marker updates, how the marker can fail, and what routing claims remain licensed.

A useful continuity model should preserve three distinctions. Access is not memory. Reportability is not experience. Physiological organization is not stream identity. Markers can support a classification only when their scope is named and their alternatives are kept alive.

The output is therefore a confidence class, not a final identity proclamation. A stream may be classified as probable continuity, uncertain continuity, probable interruption, candidate partition, candidate rebinding, or no-estimate. Each label remains purpose-limited, versioned, and open to revision.

Table 11.1. Continuity marker families, limits, and confounds.

Marker family	Primary evidence	Cannot establish by itself	Main rival or confound
Access and integration	Coordinated availability of information across channels	Numerical identity or moral status	Motor bottleneck, reflex coordination, theory-specific overread
Memory and learning	Retention, updating, affective carryover, procedural change	Presence or absence of experience in every interval	Reconstruction, priming, suggestion, nonconscious learning

Marker family	Primary evidence	Cannot establish by itself	Main rival or confound
Report and command following	First-person statement or intentional task response	Absence of experience when missing	Language, motor, arousal, fatigue, pain, task burden
Physiology and neural dynamics	System-level state markers and response patterns	Conscious stream identity by metric alone	Arousal, medication, artifact, nonconscious processing
Causal recurrence	State dependence and continuity of trajectory	Full unity across gaps	Homeostatic persistence, public record, organism continuity

11.2.1 — Access and Integration

Integration should not be confused with agreement among channels. Fear and resolve, pain and relief, or conflicting action tendencies can coexist within one stream, while identical behavioral outputs can be generated by very different internal organizations. A continuity model should therefore ask whether channels participate in a common causal organization, not whether every measurement produces the same sign or story (Dehaene et al., 2017; Tononi et al., 2016).

Access evidence is strongest when it is specific about routing. Does visual information reach action selection? Does auditory command content alter neural or behavioral state? Does painful stimulation enter affective regulation or only spinal reflex? Does

interoceptive disturbance alter report, autonomic pattern, or avoidance? These questions prevent access from becoming a vague compliment attached to any complex system.

Integration also has a burden side. A person in pain may appear disorganized not because experience is absent, but because burden is overwhelming the systems by which experience becomes orderly report. The classifier should not demand the calm integration of a healthy person from someone whose condition makes calm integration impossible.

Access and integration concern whether information is available in coordinated form within a system. If sensory, affective, cognitive, and control processes can influence one another in organized ways, the evidence may support a unified state. If access is fragmented, delayed, or separated, the evidence may support uncertainty, interruption, or partition.

The observation channels can include behavior, task performance, communication, neural connectivity, autonomic coordination, response to stimuli, and state-transition patterns. Each channel has its own temporal resolution. A second-by-second neural pattern may reveal integration that a bedside exam misses; a long behavioral record may reveal continuity that a brief scan cannot.

Integration evidence is theory-dependent. Global-availability accounts, recurrent-processing accounts, integrated-information accounts, predictive-processing accounts, and higher-order accounts do not weight the same markers equally. Chapter 12 will compare those theories. Here the rule is to record which

theoretical bridge is being used and what a rival theory would say about the same evidence.

Access evidence can also mislead. A motor bottleneck can make integration invisible. Sedation can reduce output while leaving some internal coordination. Reflexive coordination can appear without conscious unity. A strong marker under one condition can be weak under another.

Access should not be operationalized as performance alone. Paralysis, fatigue, pain, aphasia, sensory barriers, task misunderstanding, and low arousal can all reduce visible response while leaving the relevant experiential question open. Confidence in continuity should therefore depend on the accessibility of the channel and the alternatives that could suppress it, not on how elegantly a person can demonstrate access.

Access and integration markers should be reported by channel, task, state, and theory. Convergent evidence can raise continuity confidence; disagreement can reveal motor, sensory, arousal, or model failure. The marker family supports a bounded classification only when its rivals and transport limits are visible.

11.2.2 — Memory and Learning

A learning marker is most useful when it includes a counterfactual: what would the system have done if the prior interval had not occurred? Without that contrast, learning can be confused with drift, medication effect, fatigue, or changing environment. Continuity evidence becomes stronger when the alteration is specific to prior exposure rather than general change (Nadel & Moscovitch, 1997; Squire, 2004).

The most useful memory evidence is often not a dramatic autobiographical report. It may be a changed startle pattern, a learned preference, a persistent aversion, a familiar voice effect, or a procedural adjustment. These small traces can matter because they show that the system was not merely passing through unrelated states. They still require careful rivals, but they keep the evidence field from being restricted to speech.

Memory-based continuity rules systematically disadvantage people whose encoding, retrieval, language, or autobiographical organization is impaired. Dementia, delirium, trauma, developmental difference, anesthesia, and focal amnesia can weaken later narrative without establishing absence of earlier experience. The dossier should therefore let memory strengthen continuity when its prerequisites are met, but never let failed recall close the bearer question by itself.

Episodic memory supports one kind of continuity. Procedural learning supports another. Emotional conditioning, habituation, priming, and preference shifts support still others. A person may lack a reportable memory while the system has learned. A later state may be shaped by an earlier one without narrating it.

Learning evidence also has rival explanations. Repetition can train a reflex. Environmental cues can guide behavior without conscious recall. Family or clinician prompting can supply story. A model must ask whether the learned content is causally linked to the candidate stream or explainable through nonconscious mechanisms, external reconstruction, or ordinary conditioning.

The Law's ledger problem adds a particular constraint. Memory after the fact does not decide whether an interval was open when it occurred. The unity gate concerns the interval itself, not only later report. Learning can strengthen the case that something continued, but it cannot rewrite the original uncertainty into certainty.

Memory and learning must remain separate evidence families because explicit recall, procedural retention, conditioning, and affective carryover have different mechanisms and lags. A retained trace may support causal continuity without establishing conscious presence throughout the interval; a missing trace may reflect encoding or retrieval failure. The classification should preserve that asymmetry.

11.2.3 — Recurrence and Causal Continuity

Recurrence matters here as evidence about carried causal organization, not as a vote for one grand theory of consciousness. The question is whether a later candidate state depends on an earlier organized process in a way that distinguishes continuation from restart, coincidence, or reconstruction. Recurrent processing and higher-order accounts offer different marker families, so the protocol must state which continuity claim each marker is meant to bear (Lamme, 2006; Brown et al., 2019).

A continuity model must name what persists, how it is carried, the time scale on which it operates, the observations that can reveal it, and the rival that would explain the same data without continuation. Candidate carriers may include network organization, synaptic state, bodily regulation, learned

association, affective tone, attentional set, or action policy. The model must also say what follows when the proposed carrier is blocked, destroyed, disconnected, or pharmacologically suppressed; a theory that explains persistence but cannot describe loss has not earned the word continuity.

Evidence may come from state-transition patterns, restored context, physiological rhythms, recurrent neural dynamics, behavioral coherence, affective carryover, learning transfer, and recovery of task sets. Hidden-state or hidden semi-Markov models can represent continuous, interrupted, partitioned, rebound, merged, and no-estimate states while allowing their dwell times to differ. Those states are analytic hypotheses, not ontological declarations, and their value depends on whether they improve held-out prediction or discrimination against simpler restart and access-failure rivals.

The dossier must separate continuity of substrate, continuity of causal organization, continuity of accessible content, and continuity of a candidate phenomenal field. Local recurrent loops may survive while global coordination fails; arousal may persist while content-specific access disappears; public records may persist while the relevant experiential organization is unknown. Evidence for a weaker layer cannot silently stand in for a stronger one.

Intervention can strengthen the claim when it is ethically and scientifically appropriate. Clinically indicated treatment changes, natural transitions, noninvasive perturbations, and already occurring disconnections can test whether later organization depends on the earlier state as the routing model predicts. The

purpose is never to disrupt a vulnerable person for theory; it is to distinguish a causal continuation edge from a descriptive correlation using admissible evidence (Pearl, 2009; Peters et al., 2017).

Counterfactual continuity should be written as explicit questions. Would the later pattern persist if one access channel were blocked? Would learned information transfer if the proposed bridge were removed? Would recoordination recur after the same perturbation under another protocol-fixed gate? A protocol that cannot name an observation that would count against its continuation edge has drawn a narrative arrow rather than a scientific route.

Persistence is easy to overread. A machine can preserve a record, a body can maintain homeostasis, a reflex loop can continue, and a public account can remain active without establishing a continuing unified field of experience. The relevant inference is therefore not that something endured, but that the declared evidence favors one routed continuity model over equal-information alternatives.

The proper output is a versioned graph of admissible continuation, interruption, partition, and unresolved edges, together with the evidence and uncertainty attached to each. When two routing graphs remain observationally equivalent, the result is an equivalence class and a statement of what additional observation could separate it. This preserves what has been learned without converting underidentification into a confident identity claim.

11.2.4 — Report and Command Following

Where report is available, respect for report includes respect for refusal. A participant who can communicate may decline tasks, correct language, or withdraw from parts of the protocol. Command following should not become command extraction. The ability to answer is not a license for investigators to demand more and more proof of inner life (Claassen et al., 2019; Bodien et al., 2024).

Section 12.3.3 develops covert command following in boundary states; here it enters only as one source of continuity evidence when overt behavior is unavailable.

Task-based neural responses are evaluated through replication, controls, sensory access, arousal, artifact review, and chance performance. A reproducible command-specific response adds evidence of retained cognitive capacity under the tested conditions.

Report is valuable because it gives experience a direct first-person bridge when conditions allow. A person can say what was present, absent, remembered, confusing, painful, dreamlike, or continuous. Command following is valuable for showing intentional responsiveness even when spontaneous behavior is limited.

Yet report and command following are constrained by access, language, motor capacity, arousal, attention, culture, pain, fear, fatigue, medication, and task design. A failed report can mean absence of experience, but it can also mean inability to express,

inability to understand, inability to move, inability to sustain attention, or inability to map the task onto a response.

The same discipline applies in ordinary and psychiatric cases. Dissociation, trauma, language limits, neurodivergence, and clinical stress can alter reporting. A person may report discontinuity because memory is inaccessible, not because experience ended. Another may report continuity because the narrative self repairs gaps after the fact.

A research protocol should therefore classify report and command following by context. What was the command? What sensory channel carried it? What motor or neural response was permitted? What burden did the task impose? Was the person fatigued, sedated, afraid, or in pain? What alternatives explain silence or success?

Valid report and command following provide strong positive evidence because they demonstrate organized access under a defined task. Their absence is much weaker when language, sensory input, motor output, arousal, pain, or fatigue can fail. The confidence system should therefore treat positive and negative observations asymmetrically rather than making silence decisive (Giacino et al., 2018; Bodien et al., 2024).

11.2.5 — Physiological and Neural Evidence

Marker reports need verbs that preserve their evidential role. A neural or physiological result may support, constrain, challenge, or leave open a continuity model. It does not certify consciousness, reveal personhood, or rank a bearer. The verb attached to a result should match the qualification domain and

uncertainty of the marker, especially when the sentence may circulate outside the technical context (Casali et al., 2013; Jang et al., 2024).

Every physiological or neural marker should travel with provenance. The record should name the acquisition system, preprocessing version, artifact policy, development population, task, medication and state context, calibration target, and transport limits. Without that packet, a locally useful marker can become a universal-looking number whose failures are concentrated in the populations least able to contest it.

Neural and physiological markers can also conflict with each other. A person may show low behavioral responsiveness but preserved task activation, preserved arousal but poor integration, or strong autonomic response but uncertain subjective experience. The chapter treats such conflict as information rather than noise because discordance often reveals where the model is underdeveloped.

Physiological and neural evidence can reveal organization that behavior misses. Sleep architecture, evoked responses, autonomic coordination, functional connectivity, perturbational complexity, task-based activity, and recovery patterns can all bear on access and unity. They are indispensable in cases where report is absent or unreliable.

The strongest use is triangulation. If neural evidence, physiological organization, command-following tasks, learning traces, and later recovery converge, confidence rises. If they diverge, the divergence is information. It may show motor

bottleneck, sedation, measurement artifact, partition, state fluctuation, or inadequate theory.

Biomarker sovereignty begins when a useful index is treated as self-interpreting. Complexity, connectivity, command following, autonomic response, or behavioral performance each depends on a target, task, population, preprocessing chain, and rival explanation. The bearer dossier should therefore preserve those dependencies and prohibit any single metric from becoming a portable oracle.

11.2.6 — Confidence Classes

A confidence class should read as a bounded scientific proposition, not a badge. A statement such as qualified continuity across a specified recovery window under routing model M, with marker families A and B available and command following unavailable, is less convenient than one word but identifies the target, interval, evidence, and limitation that give the classification meaning (Green & Swets, 1966; Berger, 1985).

The record should include version, date, target event, reference class, available and missing channels, threshold family, uncertainty, unresolved rivals, reviewers, permitted analyses, prohibited uses, and expiration conditions. Behavioral recovery, covert command following, continuity across an interval, and admissibility for ledger analysis are distinct events; a model trained for one cannot be renamed as another because inputs overlap.

Numerical confidence requires held-out evaluation under a frozen outcome, horizon, score, and reference class. Reliability curves

and proper scoring rules can test calibration, but selective verification from recovery, repeated assessment, survival, site resources, and family advocacy must also be modeled. Predictive calibration alone does not validate the bearer construct (Gneiting & Raftery, 2007; Bodien et al., 2024; Little & Rubin, 2019).

Decision thresholds remain separate from evidence and should be tested as a family. One threshold may justify additional noninvasive assessment and another entry into a primary analysis; the loss function belongs to that decision. Transport across sites, languages, injuries, ages, species, or devices likewise requires evidence rather than a portable universal score (Manski, 2003).

Public reports state the supported relation, interval, model, uncertainty, and permitted use. They do not convert a confidence class into conscious, unconscious, same person, different person, or another claim beyond scope, and they provide challenge, review, and revocation routes without risking care or participation (Tabassi, 2023).

The final system reports admissible stream models, unavailable evidence, instability across approved analyses, and triggers for renewal, narrowing, retirement, or No adequate estimate. Confidence constrains what may be claimed; it never grades the worth, rights, or standing of the being described.

11.3 — Soft Unity Gates and Threshold Families

A declared unity gate makes its role in the mathematics inspectable. Testing it across a prospectively specified threshold family reveals how membership uncertainty affects the result. The gate must remain independent of the terminal outcome so the study tests its chosen bearer instead of selecting the bearer that produces the preferred pattern.

A threshold is a decision rule layered onto evidence, not a discovered line in nature. Signal-detection and Bayesian decision theory make the costs of false inclusion and false exclusion explicit, while threshold-family analysis reveals whether a routing conclusion depends on one convenient cut point (Green & Swets, 1966; Berger, 1985).

Low-signal intervals must remain humanly visible. A low weight in a model is not a lower person. A zero in an inclusion rule is not a moral zero. A threshold boundary is a claim about evidence under a model, and every public sentence must keep that limited status alive.

A unity gate decides which intervals are eligible to enter a stream-bound ledger. Under the stream-routing rules in Section 5.1, the gate is necessary because the Law concerns separately routed qualifying streams, not every biological event in an organism. In empirical work, however, the gate is never a pure metaphysical switch. It is estimated through uncertain evidence.

The hard gate is useful as a protocol-fixed baseline because it makes inclusion decisions reproducible. It is not final authority. A threshold chosen because it produces a cleaner ledger, fewer

unresolved intervals, or a more attractive terminal curve has converted a sensitivity parameter into an outcome-selection device. The study should freeze the baseline and publish the result across approved threshold families.

Soft gates and threshold families preserve the structure of the formal idea while acknowledging that the evidence may be graded. They ask how conclusions change when plausible unity rules vary. If a result survives only one cutoff, it is threshold-sensitive and requires independent justification of that cutoff before it can support the broader claim.

False inclusion and false exclusion are symmetric sources of model error, but their consequences are not identical. False inclusion can contaminate ownership and terminal estimates. False exclusion can erase possible experience and hide the missingness that produced a clean sample. The audit therefore reports both rates, their downstream effects, and the protections that remain fixed regardless of classification.

Table 11.2. Soft unity gates, failure modes, and controls.

Gate type	Scientific use	Failure mode	Required control
Hard gate	Primary protocol-fixed inclusion rule	False precision near threshold	Threshold-family sensitivity
Soft gate	Represents graded or uncertain inclusion	Opaque model confidence	Calibration, priors, theory labels

Gate type	Scientific use	Failure mode	Required control
Conservative gate	Avoids false inclusion	False exclusion of low-signal experience	Protective no-estimate and sensitivity
Permissive gate	Avoids erasing possible experience	False inclusion or ledger inflation	Independent motivation and public labels
Outcome-tuned gate	None in confirmatory use	Circular closure or rescue	Disallow confirmatory claim

11.3.1 — Hard-Gate Baseline

A hard gate can still be useful in preregistration because it makes failure possible. If the gate is declared and the study fails under it, the result cannot be escaped by calling the cutoff merely illustrative. The project may later test a changed gate, but that becomes a new version of the claim, not a reinterpretation of the same result (Green & Swets, 1966; Berger, 1985).

The hard gate should be viewed like a ruler with a visible edge. It is useful because the edge is explicit; it is dangerous because reality near the edge does not become sharp simply because the ruler is. A serious chapter lets readers see the edge and then asks how much of the conclusion depends on it.

A hard gate can be appropriate for an engineering check, a simulation baseline, or a conservative sensitivity condition. It becomes unsafe when it is written as if nature itself has agreed to the cutoff. The chapter's language should therefore say 'under this gate' rather than 'the stream is absent' whenever the evidence rests on threshold convention.

The hard-gate baseline says that an interval either enters the stream analysis or it does not. In notation, the formal gate can be represented as open when the unity proxy exceeds a prospectively specified threshold and closed when it does not. This is clean enough for a first model and dangerous enough to require immediate limits.

The advantage is auditability. A hard gate can be fixed in the protocol, replicated, challenged, and tested against alternatives. It prevents analysts from silently changing inclusion after seeing the ledger. It gives the study a rule before emotion, hope, or theory preference can move the line.

The disadvantage is false precision. A person near a threshold may be classified differently because of noise, medication, sleep stage, artifact, task burden, device version, or sampling time. A continuous biological and experiential reality can be forced into a binary file. The line can create certainty the evidence does not deserve.

Hard gates are most vulnerable in low-signal and edge states. A person may have weak reportability, partial access, impaired motor output, or fluctuating arousal. A rigid threshold can exclude precisely those intervals where caution and care should be highest.

For the Law's empirical program, the hard-gate baseline is never enough by itself. It can be the primary protocol-fixed rule only when paired with sensitivity across threshold families, missingness analysis, and explicit reporting of intervals near the boundary.

11.3.2 — Soft Gate $g_0(t)$

Soft gates also need calibration. A model can produce smooth probabilities that look elegant but are badly calibrated. If intervals assigned 0.8 confidence behave like 0.4 confidence under later review, the gate is overconfident. Calibration error should propagate into the ledger and verdict rather than being hidden in the consciousness layer (Casali et al., 2013; Dehaene et al., 2017).

The soft gate has one valid function: propagate stream-membership uncertainty through a declared research calculation. Its parameters, calibration, and sensitivity are available for critique, while its output remains barred from person-scoring, consciousness grading, eligibility, or spiritual interpretation.

In the probabilistic implementation described here, the soft gate represents uncertainty about whether an interval belongs to the declared stream. An inclusion probability is not a claim that the experience itself is fractionally present. A genuinely graded unity representation is a different modeling choice and requires its own interpretation and bridge to the formal target.

This approach is especially useful when markers are partial. Report may be absent, physiology organized, neural evidence ambiguous, and later recovery informative but not decisive. A soft gate can express the fact that the interval contributes to a range of possible ledgers rather than one asserted path.

Soft gates also make uncertainty visible. If an interval has high probability of unity under one theory and lower probability under another, the result can be shown as a family of trajectories. This

prevents the public graph from hiding the unresolved evidence behind one smooth line.

The risk is that soft gates can look more sophisticated than they are. A probability is only as good as the model, training data, priors, calibration, and context of use behind it. A poorly justified soft gate is not safer than a hard threshold. It is merely harder to question.

A soft gate is a model, not a moral compromise. Its evidence sources, calibration domain, theory dependence, time resolution, uncertainty, and failure conditions should be declared before outcome analysis. Competing gate families should receive the same information and scoring opportunities so that the terminal conclusion cannot depend on an unreported preference for one smooth classifier.

11.3.3 — Threshold Families

A threshold family is a prospectively specified set of plausible unity rules, not a collection assembled after the terminal result is visible. It may vary cutoffs, marker combinations, smoothing windows, filtering rules, artifact exclusions, and theory-weighted evidence, but every variant must have an independent scientific rationale. The family should also include a burden check because the most data-hungry gate may be clinically or ethically unacceptable (Berger, 1985; Manski, 2003).

Rule variants matter as much as numeric cutoffs. A conclusion may survive several thresholds while depending entirely on one preprocessing choice, one marker family, or retrospective smoothing. The approved family should therefore expose the

major ways classification can change without changing the underlying observations.

Selection rules must be frozen before outcome inspection. The protocol should state how near-boundary intervals, missing channels, discordant markers, and low-quality observations are represented. If the family changes after the ledger is known, it becomes an endpoint-rescue device rather than a robustness analysis.

Robustness should be matched to the claim. A stable access bottleneck may survive a wider family than exact cumulative contribution, and a routing conclusion may remain unresolved even when a behavioral distinction is robust. The verdict should inherit the stability of the specific proposition tested, not the ambition of the surrounding theory.

Threshold families require calibration as well as discrimination. A rule may separate groups while assigning poorly calibrated probabilities to individual cases. Held-out reliability, proper scoring, sensitivity, specificity, and decision-curve consequences should therefore be reported together when the gate influences confidence classes or routing (Gneiting & Raftery, 2007).

Different uses may justify different loss functions. A discovery study may accept more false inclusions to avoid overlooking candidate experience, while a primary terminal analysis may require stronger evidential support before assigning a specific route. Publishing both choices makes the ethical and inferential tradeoff visible and prevents one cutoff from being marketed as a universal boundary.

Public presentation should preserve the family rather than collapse it into one dramatic curve. Ranges, shaded trajectories, status tables, and explicit threshold-sensitive conclusions usually communicate the result more honestly than a single line. A finding that appears under only one convenient rule must remain gate-specific.

Transport must be tested separately. A threshold learned in healthy adults may fail under anesthesia, infancy, severe injury, nonhuman neuroanatomy, organoids, or artificial architecture because both the marker distribution and the observation process change. A nontransportable cutoff receives a reference-class limit; additional decimal places do not make it universal.

11.3.4 — False Inclusion Costs

False inclusion can also occur through compassion. Researchers may want to honor a difficult case by recognizing experience, but compassion cannot replace evidence. The fairer act may be to protect the person fully while narrowing the scientific claim. Care can be generous even when classification is restrained (Giacino et al., 2018; Bodien et al., 2024).

False inclusion also matters for artificial or archival systems. A system that produces fluent language, coherent behavior, or an imitation of a person may invite attribution. This chapter does not decide artificial consciousness, but it installs the caution that a trace or output must not be promoted to bearer status without a declared theory and evidence path. The next chapter carries the broader boundary-state comparison.

The scientific repair for false inclusion is usually not ridicule. It is narrower status language. A channel may be called context, behavioral output, auxiliary evidence, or simulation trace rather than stream evidence. Naming the lesser status preserves useful information without granting it the wrong authority.

Unsupported inclusion occurs when an interval is assigned to a candidate stream without sufficient evidence under the declared unity and routing rules. False inclusion occurs when the interval does not in fact belong to that stream. Either problem can compromise inference; actual false inclusion can add non-bearer time to a ledger, blur partition, or misclassify interruption as continuity.

The cost is not merely numerical. False inclusion can make a trajectory look smoother, more complete, or more closed than it is. It can also conceal a real discontinuity or partition, producing a single cumulative story where the evidence warrants several alternatives.

False inclusion has ethical costs as well. It can lead researchers to describe a person's interior life with more certainty than evidence permits. It can burden families with claims about hidden experience that are not justified. It can make public artifacts feel more intimate or authoritative than they are.

The scientific protection is conservative labeling. Intervals with weak evidence should be marked uncertain, low signal, no estimate, or sensitivity-only rather than silently included. If they are included under a permissive gate, the analysis should say so and show how the result changes when they are excluded.

False inclusion is especially dangerous when it helps the Law. If including uncertain intervals improves apparent closure, the result must be treated as threshold-sensitive unless the inclusion rule was independent, prospectively specified, and robust under rivals.

11.3.5 — False Exclusion Costs

False exclusion should be tracked as a live rival in every low-signal context. The analysis should ask not only whether the signal is below threshold, but whether the threshold is blind to the very forms of consciousness most likely in that state. A detector that works only for healthy expressive adults is not a universal unity gate (World Medical Association, 2024; Andrews et al., 2024).

The false-exclusion problem also has a data-design form. If a study collects evidence only when a participant is easy to measure, the excluded intervals may be precisely those with higher burden. Device intolerance, fatigue, delirium, pain, communication difficulty, and clinical instability can all create missingness that mimics absence. Exclusion can become a hidden selection effect.

A low-confidence interval should enter the data model with a reason code and an uncertainty state, not as zero exposure or absence. Downstream analyses can then carry it through sensitivity sets, alternative routing models, or no-estimate rules. This preserves the distinction between an interval that contributes neutral value and an interval the study cannot responsibly classify.

False exclusion occurs when a conscious interval is omitted because the available markers are weak, missing, delayed,

behaviorally silent, or misread. Scientifically, this can erase parts of the path. Ethically, it can deny evidence of experience where care and humility should remain active.

False exclusion is particularly serious in disorders of consciousness, locked-in or motor-limited states, deep fatigue, sedation, sleep, delirium, dissociation, and severe disability. Behavioral silence may reflect motor output failure, language barrier, task design, arousal fluctuation, or measurement limits rather than absence of experience.

The cost to the Law is direct. A ledger built from visible intervals only may become a ledger of access, not experience. If the program excludes the hardest intervals because they are inconvenient, it may test a cleaned version of the hypothesis rather than the hypothesis itself.

The protection is precaution with status discipline. Precaution does not mean declaring consciousness present. It means preserving uncertain intervals, seeking additional evidence where ethically possible, using soft or sensitivity analyses, and refusing public language that equates silence with absence.

False exclusion is also a public-risk problem. If a confidence class becomes visible outside the study, low-signal persons may be treated as less present, less protected, or less socially meaningful. The chapter prohibits that leakage.

False exclusion has a different consequence: it can erase possible experience and bias the ledger toward easily observed states. Where exclusion would affect care or conceal plausible burden, the response is protective uncertainty and a no-estimate route, not

automatic inclusion in the formal object. Ethical protection can be broader than scientific classification.

11.3.6 — No Threshold Chosen for Closure

No unity threshold may be chosen because it makes the terminal result look favorable. Features, priors, thresholds, exception rules, and the approved threshold family must be fixed before the ledger or endpoint outcome is examined. Otherwise the bearer is defined by the closure pattern the study later presents as evidence, creating a direct form of outcome-dependent selection (Hernán & Robins, 2020).

The protocol-fixed primary gate should be accompanied by a limited family of scientifically motivated alternatives. The alternatives are not an invitation to search for the best-looking result. They are a sensitivity design that shows whether the conclusion survives plausible uncertainty about unity and continuity.

False inclusion and false exclusion must remain separate error classes. A permissive threshold may join intervals that do not belong to one routed stream; a restrictive threshold may erase quiet, inaccessible, or weakly measured experience. The ethical response to those errors is protection, but the scientific response is to estimate their different consequences rather than hide them inside one accuracy number.

Soft gates can preserve uncertainty when the evidence does not support a hard boundary. Their weights must still have a declared interpretation, calibration domain, and downstream rule. A smooth curve is not automatically more truthful than a threshold,

and a weight chosen after ledger inspection is no less circular than a post hoc binary gate. Weight uncertainty should propagate into downstream ledger or endpoint conclusions rather than vanish when the soft gate is summarized by one expected value.

Any post-registration change begins a new model version. The original analysis remains visible, the reason for change is recorded, and the revised gate is evaluated on new or properly held-out data. An unfavorable primary result cannot be rescued by silently moving the threshold. A revised gate should also be tested against cases that motivated the change, but only in a separate validation role so they do not serve simultaneously as tuning and confirmation data.

Sensitivity should include threshold perturbation, leave-one-channel-out analyses, alternative missingness assumptions, and, where justified, model averaging over the prospectively specified family. Proper scoring may compare predictive calibration across gates, but it does not determine which gate identifies phenomenal unity (Gneiting & Raftery, 2007). Sensitivity should also report threshold regions over which the substantive verdict is unchanged, distinguishing robust conclusions from decisions balanced on a narrow cutpoint.

A gate may legitimately make the study unusable. If every plausible threshold produces unstable ownership, excessive double counting, or loss of essential intervals, the affected evidence is Unusable when a required ownership or measurement gate fails. If the required gates pass but the target still cannot be identified or validly bounded, the result is No adequate estimate. That outcome protects the universal claim from a manufactured

test and identifies the exact layer that needs better evidence. The failed layer should be named explicitly so later work knows whether better markers, routing evidence, or a different estimand could restore adjudicability.

Threshold discipline therefore makes failure informative. The study can report which marker families control eligibility, how sensitive the ledger is to the unity rule, and which conclusions survive. It cannot choose the bearer that closes. This converts threshold choice from a hidden tuning parameter into an observable source of verdict sensitivity.

11.4 — Pause, Interruption, and Rebinding

The gap cases are where ordinary intuition often breaks down. A person may return with no memory, with partial memory, with a changed sense of time, with a restored communication channel, or with evidence that later clarifies the interval. The analysis preserves the difference between what happened and what could be detected at the time.

Sleep and anesthesia demonstrate that responsiveness, report, memory, and experience can dissociate. Dreaming during low behavioral access and connected consciousness during anesthesia make pause and rebinding empirical questions rather than intuitions about what an unresponsive body must contain (Siclari et al., 2017; Sanders et al., 2012; Linassi et al., 2018).

A gap is recorded as an evidence object rather than a blank interval waiting for a preferred story. Its state, observation process, missingness, burden, medication, review, and revision history tell later analyses which continuity claims remain licensed.

Scientific routing distinguishes reversible loss of access, temporary interruption, suspension, restart, branching, and rebinding. Comparing these models lets pause, memory gaps, and return contribute to an explicit account of continuity.

Pause and return cases require a versioned sequence rather than one retrospective label. The record should identify the last well-supported pre-gap state, evidence available during the gap, return evidence, and the date on which continuity confidence changed. Sleep, anesthesia, temporary disconnection, and recovery then

become comparable transition structures without being forced into one ontology.

Later recovery can sharpen retrospective classification without converting uncertainty into a fact that was available earlier. The primary prospective record should retain its original confidence class; a secondary smoothed record may incorporate return, report, and learning evidence; and the difference between the two should remain visible. That separation prevents hindsight from entering a supposed pre-gap decision rule.

The output is a pause-return timeline: pre-gap state, entry event, evidence during gap, exit event, post-gap evidence, continuity rivals, confidence class, and revision rule. The timeline belongs to research. It does not decide care or dignity.

Table 11.3. Pause-return timeline fields and inferential purpose.

Timeline field	What must be recorded	Why it matters
Pre-gap state	Access, report, physiology, clinical context, confidence class	Establishes the last known status without assuming continuity
Entry event	Sleep onset, induction, injury, seizure, disconnection, or unknown transition	Prevents a visible event from becoming a false boundary
Gap evidence	Signals, missingness, artifacts, care events, possible reports	Keeps low signal distinct from absence

Timeline field	What must be recorded	Why it matters
Exit event	Awakening, emergence, recovery, communication return, or observation change	Prevents return from retroactively settling the gap
Post-gap evidence	Memory, learning, affective carryover, command following, neural organization	Supports or weakens rebinding without erasing uncertainty
Revision status	Current class, previous class, reviewer, reason for change	Preserves scientific memory and family burden

11.4.1 — Sleep and Reversible Loss of Access

Sleep also protects the chapter from a common rhetorical shortcut: treating wakefulness as the template for consciousness. Wakefulness is one access regime, not the essence of the stream. A fair bearer model asks what forms of experience and unity may occur outside the waking report style that research convenience prefers (Siclari et al., 2017; Cataldi et al., 2024).

Sleep also reveals how time scale affects identity. Over seconds, integration may fragment; over hours, the organism cycles; over mornings, the person returns to ordinary orientation. A chapter that asks only one time-scale question will misclassify the phenomenon. The stream model must say whether it is classifying momentary inclusion, overnight continuity, or longer narrative persistence.

The familiarity of sleep provides an accessible starting point for precise research. A useful study specifies the sleep state, evidence

channels, report filter, unity gate, memory bias, and intended inference. Those choices let an ordinary experience become an informative test of the bearer model.

Sleep is the ordinary teacher of this chapter. It reduces access, reportability, environmental responsiveness, and voluntary control, yet it does not simply remove experience. Dreams, partial awareness, memory gaps, and sleep-stage transitions show that the relation between behavior and experience is not binary.

For the Law's formal structure, sleep raises the unity-gate question. Some intervals may involve unified experience. Some may involve low or no reportable experience. Some may involve state-dependent forms of affective processing. A chapter on sleep later in the book will examine those signatures; here the issue is stream identity across reduced access.

The continuity evidence after sleep includes ordinary waking orientation, memory fragments, physiological state transitions, recurrence of goals, and preservation of person-specific patterns. Those markers usually support continuity, but they do not license a simple rule that every sleep interval is open or closed.

A research file separates sleep onset, sleep stage, dream report, physiological markers, awakening, and later recall. Recording the timing and availability of each channel helps distinguish the experience sampled from the portions later remembered.

Sleep contains large domains of experience whose accessibility varies with stage, awakening, recall, distress, and physiology. Restricting the bearer to ordinary waking report would erase potentially experienced intervals; admitting every organized sleep

pattern would count physiology without adequate evidence. The scientific response is a family of protocol-fixed gates and visible sensitivity analyses, not a universal sleep switch.

Sleep commonly supports organism-level continuity, while interval-level stream inclusion depends on state and evidence. Alternative unity gates can be compared using stage labels, dream reports, neural markers, and awakening procedures (Siclari et al., 2017).

11.4.2 — Anesthesia and Return

Anesthesia cases should record the difference between clinical purpose and research interpretation. The drug is given for care, comfort, surgery, or procedure, not to test the Law. Research may learn from clinically indicated care under an appropriate protocol, while care decisions remain independent of the theory (Sanders et al., 2012; Linassi et al., 2018).

Clinical anesthesia monitoring serves patient safety, dosing, analgesia, and recovery. Those signals can inform a research state model only under a separate protocol that does not alter care or imply that a depth index identifies the phenomenal bearer. The scientific use must remain subordinate to clinical purpose, especially when movement, memory, and report are pharmacologically unavailable (Sanders et al., 2012; Jang et al., 2024).

Emergence is especially instructive because return is not a single instant. A patient may regain eye opening, then command following, then orientation, then memory formation, then executive control, with variation across drugs and persons. A

stream-identity model that forces one return time should report how much uncertainty it has discarded.

Anesthesia offers a clinical setting for studying profound unresponsiveness, altered neural dynamics, amnesia, and later return. The observation model distinguishes awareness, implicit processing, state transitions, and subsequent recall.

The scientific record should separate induction, maintenance, surgical stimulation, medication, physiological monitoring, neural markers where available, emergence, post-anesthesia report, and later follow-up. Each stage bears on a different claim. The entry into anesthesia is not the same as truth-level endpoint, and return does not automatically classify every intervening moment.

Anesthesia also exposes the danger of single-threshold unity. If the threshold is too strict, it may erase low-level or intermittent experience. If too permissive, it may include intervals of purely physiological response. Both errors matter, and both should be reported through sensitivity rather than hidden inside one verdict.

A return case should preserve versioned uncertainty. At time of emergence, a reviewer may classify the gap as probable interruption with possible unreported experience. Later evidence may revise that classification. The revision should append to the record, not overwrite the earlier state as if certainty was always present.

Anesthesia also shows how research can misallocate uncertainty. Calling an unresponsive interval empty can erase inaccessible experience; describing every possibility as hidden awareness can

impose fear on patients and families. Drug-specific evidence, state-specific markers, prospective consent, and clinical independence provide a narrower route between those errors.

Anesthetic interruption should be classified by agent, dose, task conditions, physiological state, memory effects, emergence pattern, and available neural evidence. Return supports continued organismal and often personal continuity, but it does not retroactively establish conscious presence through every unobserved interval. Gap status remains model-relative until the evidence can discriminate it.

11.4.3 — Temporary Disconnection

The protocol should also test whether study procedures degrade the observation channels. A burdensome device, confusing task, repeated awakening, or anxiety-producing protocol should be logged as a possible source of reduced responsiveness, unreliable reporting, or missing data. The classification record should distinguish these observation failures from disease-related disconnection and from interruption of the stream itself.

Disconnection can be environmental or communicative as well as neural. Language mismatch, sensory loss, fear, restraint, institutional neglect, and inaccessible interfaces can make a present person appear unreachable. Continuity analysis should therefore model the relation among organism, environment, observer, and channel before interpreting failed communication as interruption of the stream.

This matters for fairness because some people are repeatedly misclassified by systems built around the communication style of

others. Disability, trauma, unfamiliar language, poverty, race, age, and clinical context can all alter the chance that a stream becomes visible to researchers. A disconnection model that ignores those conditions imports social bias into consciousness science.

Temporary disconnection covers cases where ordinary coordination among access, report, memory, motor output, or neural integration is disrupted without immediate evidence that the stream has ended. It includes neurological injury, seizure-related interruption, communication loss, medication effects, severe fatigue, dissociation, and technology-mediated future cases.

The key question is whether the disconnection is an access problem, an integration problem, a report problem, a control problem, or a stream-continuity problem. Those are different. A locked-in patient may retain experience with impaired output. A dissociative state may alter access to memory or self-organization. A seizure may disrupt control while leaving later continuity complex.

A temporary-disconnection record should document onset, observed channels, unavailable channels, likely confounds, duration, recovery markers, and competing models. It should also include a no-estimate option when evidence cannot distinguish access disruption from interruption or partition.

Temporary disconnection is a place where public language must be especially careful. Saying the person was gone can overstate absence. Saying the person was fully present can overstate

evidence. Saying the stream is unresolved may be the only honest research phrase.

Visible coherence is not a prerequisite for possible experience. A person whose access is disrupted may be unable to demonstrate continuity through report, movement, or narrative even when other evidence remains. The routing model should therefore separate failure to perform continuity from evidence of discontinuity and preserve a no-estimate state when those explanations cannot be distinguished.

Temporary disconnection should be decomposed into the functions that failed: external access, internal integration, motor output, communication, memory, or cross-module coordination. Different failures support different continuity models. The classification concerns the disrupted relation, not a diminished person.

11.4.4 — Rebinding After Recovery

Rebinding evidence should be strongest when it is convergent across time rather than dramatic at one moment. A single striking statement after recovery may matter, but stable orientation, affective continuity, learning, and functional reintegration across repeated observations usually carry more scientific weight. The model should privilege patterned evidence over the most moving anecdote (Jang et al., 2024; Nadel & Moscovitch, 1997).

Rebinding should be evaluated with humility toward the person's own later testimony where communication is possible. A participant's report cannot settle every interval, but it can correct misunderstanding, identify hidden awareness, explain missing

behavior, or challenge the model's assumptions. The challenge route belongs inside the science rather than outside it.

The same recovery can support different claims at different levels. It may support legal continuity, ordinary social continuity, clinical recovery, and research continuity in different ways. This chapter owns only the research level. It should not borrow the warmth of social return to overstate stream evidence, and it should not borrow scientific uncertainty to chill social welcome.

Rebinding asks whether later evidence supports connecting a post-gap state to a pre-gap stream. It is not the same as waking up, speaking again, or recovering behavior. Those events are evidence, but the scientific question is whether the same unified trajectory should include intervals before and after the gap, and with what confidence.

Evidence for rebinding can include restored context, recognition, learning continuity, affective carryover, recurrent goals, neural-state recovery, physiological rhythms, and coherent response to earlier material. The evidence is stronger when it cannot be explained by external prompting, record exposure, ordinary reconstruction, or generic recovery.

Rebinding also has limits. A person may regain function while remaining uncertain about the gap. A later story may be coherent because humans are narrative repairers. A neural return may show system recovery without resolving whether the intervening interval was continuous, interrupted, or absent.

The versioned record should therefore distinguish confirmed post-gap function from gap classification. The person has

returned to accessible interaction. The gap remains classified according to its evidence. Those two sentences can coexist without contradiction.

This distinction protects families from false comfort and false fear. It also protects science from post hoc smoothing. A good ending does not retroactively clean the evidence. A difficult ending does not retroactively erase possible continuity.

Rebinding requires evidence, evaluated under a declared information set, that the later state is causally and structurally connected to the earlier candidate stream. Recovery, memory, recurrent dynamics, and affective carryover can update confidence, but none by itself converts an unknown gap into known continuity. The original uncertainty remains in the version history.

11.4.5 — Competing Continuity Models

The model family also keeps the book from turning continuity into consolation. Persistence may be emotionally comforting in some cases and frightening in others. Restart may be comforting in some interpretations and disturbing in others. The science should not choose the model whose emotional tone is easiest; it should choose the model best supported by evidence and safety (Cogitate Consortium et al., 2025; Bayne, 2010).

The model family should be presented before case interpretation. If the available options are defined only after a puzzling case appears, the program will invent categories to fit anecdotes. By naming persistence, suspension, restart, and branching in

advance, the chapter gives later protocols a disciplined menu of hypotheses.

Model choice should also affect public language. A persistence model can support continuity language; a suspension model supports return language; a restart model supports new-stream language only within research; a branching model supports unresolved inheritance language. None supports casual statements about worth, identity value, or spiritual completion.

The same pause-return evidence can support several models. Persistence says the stream continued through the gap. Suspension says the stream paused and resumed. Restart says a new stream began after the gap. Branching says more than one trajectory may have emerged. Partition says coordination changed without a simple single-stream story.

These model labels do not by themselves entail distinct observable predictions. A declared operational version may predict differences in affective carryover, learning traces, state-dependent markers, or access, memory, and control; those contrasts must be specified before selection and justified by the version's mechanism and observation model. When versions yield the same observable law, the result remains an observationally equivalent model set.

A model comparison should be modest. The evidence may not distinguish persistence from suspension, especially when the interval is low signal. It may distinguish both from a crude death-of-mind claim. The verdict can be narrowed without being final.

The program should also consider theory dependence. Some consciousness theories will favor access continuity. Others will emphasize phenomenal unity, recurrent processing, integration, or higher-order availability. The chapter does not settle theory; it records how the classification depends on theory family.

Competing continuity models should not be chosen for narrative appeal. Persistence can feel comforting, restart can feel decisive, suspension can simplify the ledger, and branching can make the theory seem profound. None of those aesthetic advantages is evidence. Model comparison should instead use frozen predictions, state-transition data, transport checks, and explicit consequences for downstream ownership.

11.4.6 — Uncertainty Across the Gap

A gap does not interpret itself. Persistence with reduced access, suspension, restart, rebinding, and unresolved routing can fit the same interval while joining later evidence to the ledger differently. Sedation, sensor loss, motor or language failure, fatigue, transfer, and selective awakening remain inside the observation model rather than becoming evidence of absent experience.

Prospective filtering and retrospective smoothing stay separate. Later recovery or improved data may revise a secondary reconstruction, but cannot enter the primary model as if available at the time. Missingness may also be informative because clinical instability, death, withdrawal, burden, or technical failure often removes the hardest intervals (Särkkä, 2013; Little & Rubin, 2019). A primary filtered analysis can remain valid even when a

later smoothed reconstruction becomes more accurate, because the two answer different information-time questions.

Competing gap models face common predictions about return, recurrence, learning, cross-gap transfer, and later verification. The protocol ranks gaps by inferential role, since a short endpoint-adjacent interval may control the verdict while a longer earlier gap adds little uncertainty. Prioritizing gaps by inferential leverage can reduce participant burden by avoiding intensive recovery work on intervals that cannot materially change the verdict.

When evidence cannot separate the admissible models, results remain conditional or are withheld. No adequate estimate is preferable to an invented continuation, and the preserved set prepares partition and fusion analysis without assuming that every return restores one stream or every silence ends one (Giacino et al., 2018). Conditional reporting should identify which continuity models support each conclusion, allowing later evidence to update the model set without rewriting the observed record.

11.5 — Partition, Fusion, and Multiplicity

Partition and fusion affect which experiences enter each ledger. The analysis must distinguish evidence of divided access from evidence of separate streams, and keep unresolved ownership visible without turning a research classification into a public identity.

Partition research cautions against two opposite simplifications: assuming one organism always carries exactly one stream, and treating every functional division as a separate consciousness. The strongest recent analyses of split brains support graded and task-dependent interpretations, which is precisely why routing models must expose their criteria and uncertainty (Pinto et al., 2017; Schechter, 2018).

The ledger consequences are why this material belongs in the science volume. If the bearer is one stream, a path can be integrated one way. If the bearer is partitioned, allocation and ownership become open problems. If the bearer fuses, inheritance becomes open. These are not side stories; they are mathematical and ethical constraints on later inference.

Partition cases test whether the model can tolerate complexity without turning people into spectacle. One apparent bearer may show partial access separation, altered self-organization, or conflicting streams of control. The question is not whether the case is interesting. The question is what evidence supports one stream, more than one stream, intermittent partition, or unresolved access disruption.

Partition is a model class, not a dramatic conclusion. Split access, dissociation, and hemispheric asymmetry may support restricted information flow or partly independent control without establishing multiple consciousnesses. Conversely, declaring one stream by definition would prevent the science from learning when ordinary unity assumptions fail. The dossier should keep the smallest set of routing models compatible with the evidence.

The section therefore treats partition, fusion, and multiplicity as hypotheses with evidence requirements. Each requires marker families, rival models, and protective governance. No classification may become public drama, moral rank, legal division, or clinical verdict.

Partition and integration raise a specific question of ledger ownership: how should intervals be assigned, bounded, or left unresolved? This chapter states the competing assignments and the evidence needed to distinguish them, preparing the formal routing analysis developed later.

11.5.1 — Split Access and Hemispheric Partition

A split-access discussion should avoid both denial and mythology. Denial pretends the experiments teach nothing because daily life continues. Mythology pretends the experiments prove two fully independent lives. The chapter's scientific path lies between them: identify the level of access under strain and state how far that strain travels (Gazzaniga, 2000; Pinto et al., 2017).

Split-brain cases also teach that evidence can be layered. One layer may show separated access under laboratory tasks. Another

layer may show unified behavior in ordinary life. Another may involve subjective report that does not match the experimental dissociation. A serious account should let layers disagree without forcing a cartoon conclusion.

The chapter therefore compares unity and partition models under a common evidential standard. A split-access finding should trigger questions about what kind of unity is under pressure and what kind remains intact. That is exactly the kind of distinction the Law needs before it assigns ledger continuity.

Split access refers to partial separation of information, control, or report across systems that normally coordinate. Split-brain research is the familiar example, but the scientific lesson is broader: access can be divided without the ontology being settled. The evidence may support one stream with divided access, two partially independent access systems, or unresolved structure.

Task evidence cuts both ways. If one hand responds to information unavailable to speech, the result supports access separation under those conditions. It neither establishes two complete conscious streams nor secures one undivided stream. The observation creates a routing-model comparison that must be resolved, bounded, or carried forward as uncertainty.

The relevant markers include cross-cue transfer, conflict resolution, coordinated affective response, learning across channels, bodily control, report asymmetry, neural connectivity, and temporal stability of the dissociation. A single demonstration can be fascinating and still insufficient for bearer classification.

Laboratory tasks can magnify asymmetry because they are built to isolate information channels. A striking dissociation under controlled instruction may coexist with substantial coordination in ordinary activity. The routing analysis should therefore compare task-specific separation, spontaneous behavior, cross-cue transfer, longitudinal stability, and causal evidence before promoting a laboratory effect into a persistent partition model.

Split-access findings demand interpretation without spectacle. The scientific record may examine restricted coaccess, lateralized control, transfer failures, and task dependence. Public description should avoid turning a person into a metaphysical exhibit or using a laboratory dissociation to question legal standing, dignity, or care.

Split access supports partition only when intervention, information flow, control, and report patterns are better explained by more than one stream than by divided access within one stream. The analysis should compare those models directly and preserve uncertainty about event ownership. Split-brain evidence is a test case, not a template for every dissociation (Gazzaniga, 2000; Pinto et al., 2017).

11.5.2 — Dissociation and Altered Self-Organization

Research on dissociation can illuminate altered self-organization while remaining attentive to the burdens people may experience. Clinical collaboration and respectful communication help researchers understand those experiences in context (Bayne, 2010; Schechter, 2018).

Dissociation enters first as a lived and clinical phenomenon. Trauma, stress, memory disruption, altered agency, and changing self-organization can shape both experience and report. Participants are never required to resolve the metaphysics of their own state, and public description must not turn coping or distress into spectacle.

A respectful evidence model can still be rigorous. It can ask about amnesia boundaries, state-dependent access, executive control, physiological shifts, affective continuity, and therapy-related integration. What it cannot do is convert diagnosis into ledger allocation without a formal and clinical bridge.

Dissociation presents another challenge because it can alter memory, self-relation, agency, emotional access, and narrative continuity. Some presentations include distinct self-states or access patterns. The scientific question is not whether those experiences are real or worthy of care. They are. The question is what kind of stream classification the evidence supports.

Clinical diagnosis cannot be translated directly into stream multiplicity. Diagnosis serves treatment, safety, and understanding. Research bearer classification asks a different and narrower question about unified experience across intervals. The two domains should collaborate without collapsing into one another.

Evidence should include within-person history, state transitions, amnesia patterns, co-consciousness, physiological changes, trauma context, report conditions, clinician assessment, longitudinal stability, and participant interpretation. It should also

include rival explanations such as access barriers, memory compartmentalization, state-dependent recall, role enactment, suggestion, medication, or stress response where relevant.

Research language must be trauma-sensitive. The person should not be asked to perform identity complexity for scientific curiosity. Interview burden, public exposure, destabilization, and clinical disruption can alter the very access patterns being studied. Safety is part of validity.

Dissociation is especially vulnerable to public spectacle. A striking narrative can be memorable while remaining diagnostically incomplete, and publicity can make the participant carry risks that the audience never sees. Research use therefore requires clinical context, privacy controls, and a question narrow enough that the classification need not become a public identity.

Dissociative symptoms do not map one-to-one onto literal stream division. Clinical context, state fluctuation, memory, control, trauma, suggestion, and treatment effects can support several models. Research use therefore requires collaboration with clinicians, privacy protection, and an explicit refusal to turn diagnosis into metaphysical proof.

11.5.3 — Parallel or Overlapping Streams

Parallel or overlapping streams are hypotheses about more than one candidate experiential organization within one apparent support system. The possibility belongs in the technical analysis because some clinical, theoretical, artificial, or hybrid cases may resist both simple unity and clean partition. It should remain rare

in public summaries and should never be presented as common, settled, or personally diagnostic (Bayne, 2010; Schechter, 2018).

The evidence burden is much higher than simultaneous processing, ambivalence, divided attention, changing roles, dissociative symptoms, or competing motivations. A multiplicity model requires patterned limits on joint availability, partially independent learning or control, and evidence that the separation is stable enough to distinguish it from ordinary segregation within one stream.

Overlapping models require event-token ownership rules. The model must say which events are exclusive, shared, unresolved, or conditionally assigned, and it must prove that no contribution is counted twice. When shared ownership cannot be identified, an uncertain or set-valued ledger is more honest than a clean division invented for convenience.

The alternatives are best represented as competing routing graphs. One graph may describe one stream with segregated access, another two streams sharing resources, and another alternation across time. They should be fitted and scored with the same observations, comparable complexity penalties, and the same opportunity to explain missingness so that a richer ontology does not win by construction.

Identifiability may fail even when every observed task is measured precisely. Distinct routing graphs can generate the same reports, choices, and neural summaries while differing only in unobserved phenomenal ownership. The correct output is then an

equivalence class of routes and a statement of what intervention or observation could distinguish them, not a forced partition.

Ordinary psychological conflict should not be reclassified as stream multiplicity. The one-stream and unresolved models remain preferable until evidence about causal insulation, ownership, nonduplication, and cross-context persistence defeats them. This asymmetry protects both scientific parsimony and people who could otherwise be sensationalized by a narrow research hypothesis.

A multiplicity analysis belongs in a purpose-limited research dossier, not a public identity file. The record may preserve the model, tasks, uncertainties, and prohibited uses while withholding a simplified label that could be misunderstood socially, legally, or spiritually. Privacy and dignity are part of the evidential design because publicity can change the cost of error.

When current theory cannot distinguish unity, overlap, alternation, and partition, abstention is the scientific result. The program should retain the competing graphs, identify the missing discriminator, and continue care and ordinary rights without waiting for an ontology to become available.

11.5.4 — Fusion and Recoordination

A later return of integrated access may support a rebinding model, clarify earlier uncertainty, or show that a task-specific partition was transient. These observations help reconstruct the trajectory of access and coordination (Pinto et al., 2017; Tononi et al., 2016).

Fusion creates an unresolved ownership question rather than an intuitive inheritance rule. If previously separated candidate paths

later re-coordinate, the model must state whether earlier events belong to one ancestor, several descendants, a jointly owned domain, or an identified set of possibilities. Until a formal bridge is justified, ledger inheritance under fusion remains conditional and should be reported as such.

Clinically, recoordination may be meaningful long before it is formally resolved. A person's recovery of communication, agency, or coherence can guide care without resolving stream metaphysics. The chapter keeps that distinction so the science does not make clinical hope wait for a theorem.

Fusion and recoordination ask whether previously separated, partially separated, or independently modeled processes can form or resume a coordinated candidate stream. The issue arises after recovery, treatment, neurological change, task-context change, or future systems in which coordination can be altered.

Fusion should not be assumed because behavior becomes smoother. Coordination can improve at the level of motor control, report, clinical function, or public narrative without proving full experiential unity. Conversely, a person may experience increased internal communication or integration before external behavior makes that visible.

Evidence for fusion includes improved cross-access, shared memory, coordinated affective response, unified report, stable control, reduced internal barriers, and longitudinal consistency across contexts. The evidence should be gathered without forcing a person into a public story of becoming whole.

A recoordination model may be more accurate than fusion. Recoordination says separated channels or states are communicating better, not that a metaphysical merger has occurred. This distinction matters because the research may be about access and control rather than stream identity itself.

The record should keep pre-fusion, transition, and post-fusion evidence distinct. If earlier partition was uncertain, later integration does not prove that earlier multiplicity existed. If earlier partition was well-supported, later coordination does not erase the old classification; it revises the trajectory.

Fusion or recoordination describes a change in present organization; it does not retroactively settle the identity of earlier states. The protocol should test whether previously independent channels now share access, control, memory, and causal dependence, while preserving the pre-fusion routing record. Recovery is not permission to rewrite uncertainty as unity.

11.5.5 — Ledger Ownership Under Partition

The open problem remains visible throughout the book. A protocol that excludes partition cases names the exclusion; one that includes them specifies an allocation rule or returns identified-set results. Silence is not a neutral choice because it hides the assumption that determines event ownership (Bayne & Chalmers, 2003).

One safe production practice is to treat partitioned ledgers as scenario-specific. A study can report what follows under the one-stream assumption, what follows under a partition assumption, and what remains unidentified. That is more honest than hiding

the assumption in one number and more useful than refusing to analyze the case at all.

The open problem also has measurement consequences. Candidate momentary-valence and interval-contribution estimators are built for a candidate stream under conditions. If streams partition, channel-to-stream assignment becomes uncertain. Physiological signals may be shared, reports may be channel-limited, and context may affect multiple candidates. Measurement cannot be cleaner than bearer classification.

Ledger ownership is the formal problem created by partition. If one apparent organism supports more than one candidate stream, which intervals belong to which stream-bound ledger? If streams overlap, can an interval be shared? If a partition later recoordinates, does the ledger combine, continue separately, or remain unresolved? This chapter does not pretend those questions are solved.

The safest first answer is status labeling. A ledger analysis should say one-stream model, partition model, overlapping-stream model, merged-stream model, or no-estimate. It should not silently integrate all intervals into one path merely because that is easier to graph.

Under a partition hypothesis, each candidate stream would require its own evidence basis, unity gate, temporal window, and uncertainty. If the evidence cannot assign an interval responsibly, the interval should be marked unresolved rather than forced into the favored ledger.

The problem becomes more serious near endpoint research. If partition, fusion, or rebinding occurs near truth-level endpoint, endpoint classification and ledger interpretation become linked. The endpoint chapter will handle final adjudication; this chapter prepares the ownership discipline so endpoint science cannot inherit a hidden simplification.

A single cumulative line can conceal uncertainty about its bearer. Visual simplicity is therefore not a reason to collapse competing routing models or erase unclassified intervals. A visibly branched or partially identified record is preferable when that is what the evidence supports, because an honest complex graphic is more informative than a precise line attached to the wrong stream.

When partition is plausible and ownership is unresolved, the correct object may be set-valued or model-indexed rather than a single ledger. Analyses should report the range across admissible routings and stop if conclusions depend on arbitrary allocation. Administrative convenience is never an ownership principle.

11.5.6 — No Personhood or Moral Rank Inference

Partition, fusion, overlap, and unresolved multiplicity are research models of organization. They are not findings about personhood, authenticity, moral rank, legal identity, spiritual status, or the value of a life. That boundary must remain explicit even when the evidence for one routing model becomes strong (World Medical Association, 2024; Parfit, 1984).

The legal and moral person may continue to receive one coherent set of rights and protections while the scientific analysis compares several candidate ownership structures. Conversely, one routed

research stream does not exhaust the person's social, legal, relational, or narrative identity. The objects interact through consent and care, but neither replaces the other.

Reports and graphics require an anti-ordinal design. One-stream, partitioned, fused, overlapping, and unresolved models must not be arranged on a ladder that resembles health, worth, authenticity, or sophistication. Legends should name candidate routing structures, evidence strength, and uncertainty rather than higher and lower kinds of being. Ordering the models by confidence rather than by structure can help preserve evidence strength without implying that one routing form is intrinsically superior.

Privacy risk increases when unusual cases are described in detail. Rare trajectories, split-access patterns, family histories, timestamps, and clinical images can reidentify people even after names are removed. Purpose-limited records, consented communication, narrative restraint, and hostile-crop review are therefore part of scientific validity as well as dignity. Aggregation thresholds should be set before publication review so privacy protection does not depend on how compelling a particular case appears.

Case selection should resist novelty bias. Dramatic partition or dissociation cases may reveal that a simple one-stream rule fails, but ordinary null and ambiguous cases are needed to estimate when a more complex routing model is actually warranted. A literature of striking exceptions can exaggerate both prevalence and confidence. Prevalence estimation should therefore draw from prospectively defined sampling frames rather than

collections assembled because the cases were theoretically dramatic.

The scientific output is a constrained set of routing models, the evidence that distinguishes them, and a record of what remains unallocated. That structure prevents unresolved events from being pooled merely because a single total is easier to compute, and it prevents one event from being counted in more than one stream. Set-valued routing can still support exclusion claims when every admissible model agrees that a particular event is not jointly owned.

A routing verdict therefore narrows a scientific model and nothing more. The more consequential the public interpretation, the narrower the permitted language must become. The public report should describe uncertainty in the routing model rather than translating multiplicity into a claim about personal identity or worth.

11.6 — Error Costs, Abstention, and Dignity

Abstention is a positive scientific act when it identifies the failed gate. A no-estimate result can reveal inadequate channels, unresolved routing, poor transport, excessive burden, or model inadequacy and can direct the next protocol toward the actual bottleneck. Treating abstention as honorable reduces pressure to manufacture a definitive bearer solely to keep the study moving.

The closing section distinguishes scientific loss from ethical loss. A false bearer classification can corrupt a ledger, endpoint, or route verdict; its ethical consequences arise only if the label is allowed to influence care, publicity, access, or standing. The protocol should reduce both forms of error while never treating improved scientific accuracy as permission to weaken the ethical floor.

Error matrices should therefore include more than sensitivity and specificity. They should identify who bears the consequence, which downstream objects change, whether a claim can be corrected, whether data can be withdrawn, and which protections remain invariant. This turns error analysis from an abstract table into a map of scientific and human consequences.

Every classification system has error costs. In this chapter, the costs are not only statistical. A false stream label can distort a ledger, but it can also alter care conversations, family understanding, public identity, or the perceived presence of a vulnerable person. The science must distinguish model error from ethical harm without pretending they are unrelated.

The four central scientific errors are false continuity, false discontinuity, false partition, and false rebinding. They do not fail in the same way. False continuity can join intervals wrongly. False discontinuity can erase continuation. False partition can multiply streams beyond the evidence. False rebinding can connect what remains unresolved. Each requires a different correction route.

The safest system is not one that never classifies. The safest system is one that classifies only within scope, preserves abstention, invites multidisciplinary review, supports appeal, records revision, and blocks administrative leakage. That is the difference between scientific classification and institutional ranking.

Asymmetric protection means that uncertainty can narrow the study before it narrows care. When evidence is weak, the analysis may exclude a confirmatory claim, preserve multiple routing models, or return no estimate. The person still receives communication attempts, comfort, privacy, and ordinary protection because those duties do not depend on successful stream classification.

Table 11.4. Routing error classes, ethical risks, and preferred responses.

Error class	Scientific consequence	Ethical risk	Preferred response
False continuity	Wrongly joins intervals or streams	Misleads families or public meaning	Model comparison and revised confidence

Error class	Scientific consequence	Ethical risk	Preferred response
False discontinuity	Wrongly breaks a stream	Erases possible experience or care salience	Protective uncertainty and further evidence
False partition	Wrongly multiplies streams	Stigma, spectacle, identity confusion	Higher evidence burden and review
False rebinding	Wrongly reconnects unresolved states	False reassurance or retrospective certainty	Versioned uncertainty and appeal
Administrative leakage	Label travels beyond research	Eligibility, treatment, rank, or status harm	Access restriction and prohibition

11.6.1 — Scientific Error Versus Ethical Error

The no-estimate class should be structured enough to teach. It should record whether failure arose from unavailable channels, incompatible markers, unvalidated transport, unresolved partition, observation shutdown, excessive burden, or model inadequacy. Those reasons guide redesign and prevent an inconclusive case from being silently recoded as absence or neutrality.

Scientific error concerns the model's relation to the evidence. A continuity classifier may join intervals that should be separate. A partition model may overfit task asymmetry. A confidence class may be too strong for the marker set. These errors can be studied, corrected, and reported.

Ethical error concerns the person's exposure to harm. A model label may burden a family, stigmatize a participant, influence care, invite public spectacle, or diminish perceived dignity. Ethical error can occur even when a scientific model is carefully hedged, if the label travels to the wrong context.

The two error types interact. If classification changes behavior toward the person, the data-generating process changes. Staff attention, family anxiety, participant stress, consent pressure, and clinical workflow can all alter evidence. That means ethical leakage can become scientific contamination.

A good protocol writes both error types into the design through model diagnostics, adversarial review, label access, communication limits, incident reporting, correction routes, and stop rules. Ethical analysis is part of the inferential architecture because misuse can change both human welfare and the data-generating process; it is not a preface to the statistical work (Emanuel et al., 2000; World Medical Association, 2024).

Every classification decision carries two loss functions. One concerns inferential error in routing, ownership, or endpoint analysis; the other concerns the human consequences of stigma, reduced care, false reassurance, or public exposure. The review record should report both because a scientifically convenient label can still be an ethically disastrous one.

11.6.2 — Asymmetric Protection

Asymmetric protection is prospectively specified before cases appear. Possible false exclusion triggers protective caution, while possible false inclusion narrows the claim and restricts public use.

The two responses address different harms and can operate together without turning caution into a bearer verdict.

The scientific error rates for false inclusion and false exclusion are reported in §11.3. The ethical asymmetry is separate: false exclusion can also reduce precaution and erase possible experience from the record, so uncertainty should bias the system toward protected abstention rather than confident absence.

Asymmetric protection means that, where evidence is weak and false exclusion could reduce care or erase possible experience, the protocol should preserve uncertainty rather than declare absence. This does not mean declaring consciousness present. It means keeping the person protected while the research claim narrows.

Asymmetric protection also affects data interpretation. A low signal may be labeled low signal rather than closed. Estimated absence may be kept separate from confirmed absence. Unknown may remain unknown. These distinctions prevent false clarity from becoming policy or public meaning.

The rule is especially important in disorders of consciousness and communication-limited states. Behavioral unresponsiveness cannot be a safe exclusion rule when neural command-following evidence may reveal cognitive-motor dissociation in some patients. The correct response is not to overclaim presence, but to treat absence claims as fragile.

Asymmetric protection must still be bounded. It cannot become a license to infer rich experience from every faint signal. It should trigger additional review, conservative public language, care-first defaults, and sensitivity analysis, not dramatic assertions.

11.6.3 — Abstention as Valid Output

Abstention is a protocol-fixed scientific output. It means that the available evidence does not justify classifying continuity, interruption, partition, rebinding, or absence at the level required for the intended claim. It is not silence, indecision, or a failure to finish; it is a positive verdict about the limits of the evidence.

The reason for abstention must be typed. Marker conflict, insufficient temporal resolution, missing report, confounded physiology, theory disagreement, threshold instability, unresolved routing, clinical burden, and lack of independent review are different failures and lead to different next steps. A specific no-estimate state teaches more than a generic inconclusive label.

Triggers should be prospective. The protocol must state which combinations of low signal, missing access, threshold sensitivity, model equivalence, or routing nonidentification produce No adequate estimate and which produce Model-ambiguous. A refusal issued only after an inconvenient result is selective reporting rather than disciplined abstention.

Abstention belongs in evidence accumulation. Repeated no-estimate results caused by one device expose an instrument problem; concentration in one population exposes a reference-class or access problem; concentration in a high-burden setting may show that the study should not be run there. The rate and causes of abstention are therefore scientific outcomes, not missing rows.

A classification may return to review after recovery, improved calibration, additional evidence, or external audit. The earlier

abstention should remain in the version history, followed by the new evidence and decision, rather than being overwritten. Revision is more credible when the path of uncertainty remains visible.

Multidisciplinary disagreement should remain auditable. Neurology, anesthesia, sleep science, psychiatry, psychology, philosophy, statistics, ethics, and lived-experience expertise may weight the same record differently. Votes or confidence ranges, reasons for dissent, conflicts of interest, and the rule used to construct the admissible model set should be preserved.

Public language should be calm and bounded: this study cannot responsibly classify the stream for this purpose. The sentence concerns the research claim, not the person, and it cannot lower care, dignity, rights, or participation. Calm precision prevents uncertainty from being mistaken for concealment or failure.

A useful abstention policy also reveals exclusion. Reports should show which groups were disproportionately unclassifiable and what evidence would reduce that uncertainty. This makes visible whether an evidential system systematically leaves infants, disabled people, nonverbal patients, nonhuman animals, or unfamiliar architectures outside the record, and it allows redesign without forcing labels.

11.6.4 — Blinded and Multidisciplinary Review

Review quality should itself be auditable. The record should state reviewer roles, independence, conflicts, evidence access, blinding limits, dissent, and revision triggers. Without that audit, multidisciplinary review can become a prestige shield rather than

a real protection against theory-driven classification (Yakhkind et al., 2024; Giacino et al., 2018).

The review process should also have an adverse-outcome route. If a reviewer discovers that classification burden is affecting care, family communication, participant distress, or staff workflow, the protocol should be able to pause. The purpose of review is not only better labels; it is better distribution of burden.

A multidisciplinary record distinguishes consensus from agreement by exhaustion. Material dissent is preserved with its evidentiary basis, even when a bounded conclusion remains justified. Visible disagreement creates a review path; hidden disagreement creates a future credibility failure.

Bearer adjudication is vulnerable to theory desire. Researchers may want continuity because it preserves a ledger, partition because it is novel, absence because it simplifies a protocol, or rebinding because it completes a story. Blinded and multidisciplinary review reduces that pressure.

Blinding should separate, where possible, the continuity classification from ledger outcomes, terminal-neutrality expectations, public narratives, and investigator hopes. A reviewer should not know that a particular classification makes a later result look favorable. Otherwise the gate can become an outcome-selection device.

Multidisciplinary review should include consciousness science, neurology, psychiatry or psychology where relevant, palliative or clinical expertise, statistics, ethics, and lived-experience

consultation where appropriate and safe. No single discipline owns unity. Each can see a different failure mode.

The review file should record disagreement. A neurologist may see marker weakness, a clinician may see risk, a philosopher may see identity ambiguity, a statistician may see nonidentifiability, and a participant advocate may see burden. A mature classification does not hide such disagreement; it routes it into confidence or abstention.

Review should also be proportional. Ordinary clear cases do not need the same process as disorders of consciousness, dissociation, or endpoint-adjacent uncertainty. The burden of review should be scaled to risk, ambiguity, and claim consequence.

High-consequence classifications require outcome-blind, multidisciplinary review. Reviewers should see the marker evidence and rival models without seeing whether a particular class improves terminal neutrality, and disagreements should be preserved as confidence or abstention. Exploratory classifications remain clearly labeled and cannot silently enter confirmatory work.

11.6.5 — Appeal and Revision

Appeal and revision also make the framework durable as consciousness science changes. New evidence may strengthen, narrow, or overturn a classification, example, or procedure. A visible change history makes correction an expected scientific duty rather than a reputational crisis (World Medical Association, 2024; Center for Open Science, 2025).

Appeal should be designed for accessibility. A challenge route that requires technical language, legal sophistication, or institutional confidence will not serve the people most likely to need it. Plain-language challenge forms, clinician-supported routes, family-support routes where appropriate, and independent ombuds review can make revision more than a theoretical right.

Revision should also propagate. If a bearer classification changes, related ledger estimates, endpoint interpretations, figures, summaries, and public claims may need update. The change is not local if downstream claims relied on the old label. Correction must follow dependency, not convenience.

A classification system must be contestable. Participants, authorized surrogates, clinicians, reviewers, or later investigators may have evidence that the original classification missed. Appeal does not mean every objection overrides the model. It means the model remains answerable.

Revision is equally important. New evidence may show that a gap was more likely interruption, that a presumed interruption was likely continuity, that a partition hypothesis was overfit, or that rebinding was unsupported. The classification should change when the evidence changes.

The version history should preserve all major states: initial class, evidence basis, reviewer identity, permitted use, challenge, new evidence, revised class, and affected claims. This prevents a later clean record from hiding the uncertainty people lived through or the scientific path that produced the conclusion.

Appeal remains private enough to be usable. Families and participants can challenge a classification without exposing intimate details in public, making care contingent on winning, or entering adversarial theater. The record preserves the grounds, response, and correction while minimizing collateral disclosure.

An appeal initiates a formal reanalysis rather than an informal exception. Participants, authorized surrogates, clinicians, and independent reviewers can challenge the evidence, threshold, permitted use, or retention period without risking care or participation. Any accepted revision propagates to every downstream model, figure, summary, and public artifact that depended on the earlier state.

11.6.6 — No Administrative Use

Bearer classifications are purpose-limited research objects. They may qualify the scientific claim that created them, but they may not determine triage, insurance, employment, education, legal status, public rank, spiritual standing, or resources. The institution carries the uncertainty (Tabassi, 2023; World Medical Association, 2024).

Architecture enforces that boundary. Research classifications, clinical records, identity, contact information, and public outputs occupy separate access domains and retention schedules. Administrative systems never receive a portable bearer score.

Each label has a declared lifecycle for access, retention, revision, expiration, and deletion. It narrows or disappears when context ends, calibration fails, admissible models change, or privacy risk exceeds scientific value.

Automation may assist documentation and audit, but bearer labels may not train systems for triage, surveillance, eligibility, or ranking. A new use requires fresh justification, independent review, and accountable human authority.

The audit trail records who accessed a classification, for what authorized purpose, and whether export or model-training use occurred. Unusual access or attempted linkage triggers review and suspension authority.

Challenge must be usable without technical expertise. The project explains evidence, uncertainty, and permitted uses plainly, accepts contrary information, and supplies correction. Explanation and revision remain the project's burden.

Public reporting defaults to cohort-level methods and uncertainty. An indispensable case still requires consent, de-identification, narrative restraint, and hostile-crop review; reproducibility does not require indefinite exposure of rare trajectories.

Revisions remain traceable and propagate to affected estimates, models, figures, summaries, and public statements without preserving a permanent public identity (Center for Open Science, 2025).

Chapter 12 — Consciousness Theories and Boundary States

Consciousness is a prerequisite layer for terminal science. The research program needs to know where experience may occur, how access can fail, how continuity can be obscured, and which signals remain informative when report is unavailable. Chapter 12 uses consciousness theories as generators of testable marker families and predictable errors.

The previous chapter built the research bearer as a provisional classification rather than an ontology. That work now meets the state of consciousness science itself. A stream may be awake, asleep, sedated, injured, fragmented, developing, nonhuman, synthetic, or silent under conditions that make ordinary report unavailable. If the book let one favored theory decide every boundary, the endpoint architecture would inherit that theory's blind spots and call them discipline.

The chapter compares global availability, integrated and causal, recurrent, higher-order, predictive, active-inference, enactive, and embodied families by the evidence each makes salient. For each family, it asks which marker is predicted, which state and scale it addresses, which rival can mimic it, where it is qualified, and which cases expose its blind spots.

That pluralism increases testability. A marker can fail because movement is unavailable, language is absent, memory was never formed, sedation altered report, a species expresses pain differently, or a machine learned the language of experience. Each failure becomes a discriminating question rather than a shortcut to certainty.

Boundary-state error is typed. Motor dependence can erase covertly responsive patients; adult-human tasks can fail in infants or animals; fluent language can inflate confidence in artificial systems; and a complexity index can change with drug, injury, scale, or artifact. Every marker therefore carries its target, prerequisites, qualification domain, error direction, and abstention condition.

Dream reports provide evidence filtered by awakening, memory, language, salience, and sampling. Sleep therefore offers an everyday setting for studying how experience, access, report, and recall relate to one another.

Anesthesia sharpens the problem further. A motionless patient may be insentient, conscious without response, responsive without later memory, dreaming, fragmented, or passing through states that change with drug class, dose, physiology, and time. The scientific task is to build graded state evidence without letting the Law influence care. Anesthesia monitoring belongs to clinical safety before it belongs to any research program.

Disorders of consciousness give this work immediate clinical relevance. Covert command following can reveal retained capacities in behaviorally unresponsive patients. Cognitive motor dissociation and related findings help improve assessment and identify additional communication possibilities.

Developmental and nonhuman research broadens the range of evidence the science can use. Infants, children, and unfamiliar species call for age-appropriate and species-appropriate markers, welfare protections, and methods that reflect their capacities and

environments. Naturalistic observation and independently justified care provide valuable starting points.

Artificial and synthetic candidates create a different temptation. Fluent language, emotional mimicry, self-descriptions, and simulated pain labels can be persuasive because they resemble the social forms through which humans recognize one another. Yet performance is not experience. At the same time, convenience cannot permanently exclude future systems from examination if their architecture, causal organization, embodiment, memory, self-modeling, and adaptive integration make the question scientifically serious.

The chapter's practical result is a versioned boundary-state dossier. It records observed markers, theory mappings, confounds, plausible false positives and negatives, transport limits, active classification, review needs, permitted analyses, and prohibited public uses. The dossier advances routing and endpoint analysis without becoming a universal consciousness score. A dossier can also preserve temporal changes in marker reliability, preventing a classification earned in one state from being carried unchanged into another.

The chapter moves from theory families to states that break ordinary inference. Sleep tests experience without stable external access; anesthesia tests return without reliable memory or movement; disorders of consciousness test covert cognition; dementia and delirium test fluctuating access and narrative loss; development and comparative cases test transport; artificial systems test the difference between functional resemblance and warranted phenomenality. These states therefore function as

stress tests for different assumptions, revealing whether access, memory, behavior, or continuity is responsible when a marker fails.

The output is a set of constrained updates. A marker may raise or lower confidence in one component, expose a failed channel, or force a no-estimate state. Progress is measured by which uncertainty became smaller, which rival gained ground, and which claim remains unavailable. The same accounting keeps progress visible even when no single theory or marker family wins the entire comparison.

12.1 — Theory Pluralism and Marker Families

A scientific program that depends on consciousness has to decide how to treat disagreement among consciousness theories. It cannot wait for a final theory before doing any work, because measurement, endpoint adjudication, and human-subject safeguards must already operate under uncertainty. It also cannot choose the theory that best fits its preferred endpoint architecture. That would turn science into instrument selection after the verdict.

Theories of consciousness are most useful here when they generate marker families and risky predictions. Section 12.1.6 develops adversarial comparison as a concrete implementation of that principle.

Theory pluralism becomes operational through a matrix with rows for theory families and columns for marker target, state, temporal scale, task dependence, transport domain, false-positive routes, false-negative routes, and abstention conditions. The matrix is not a vote. It reveals when apparently convergent markers share the same hidden dependency and when genuinely independent channels support a stronger update.

Theory pluralism matters because every theory makes some cases easy to see and others easy to miss. Report-heavy accounts may exclude people without motor or language access; complexity-heavy accounts may mistake measurement failure for absence; performance-heavy approaches may overread artificial fluency. Comparing these blind spots is therefore part of classification, not an optional philosophical preface.

Table 12.1. Theory-to-marker matrix for boundary-state use.

Theory family	Primary marker family	Known hazard
Global availability	Broadcast, flexible access, task use, report-independent response	Motor or language failure can hide access; fluent output can imitate access.
Integrated and causal	Effective connectivity, perturbational complexity, differentiated causal response	Complexity can be artifact; low response can reflect measurement failure.
Recurrent and higher-order	Feedback loops, metacognition, confidence, self-monitoring	Recurrence can be unconscious; metacognition can fail while experience remains.
Predictive and active-inference	Interoception, generative control, embodied regulation	Viability and control can exist without felt experience.
Enactive and embodied	Organism-environment coupling, situated agency, sensorimotor world-involvement	Embodiment can be overextended, simulated, or too tied to human forms.

12.1.1 — Global Availability Accounts

Global availability accounts begin with a practical observation: some information becomes conscious when it is made broadly available for reasoning, report, memory, action, and flexible control. In that family, consciousness is not merely local processing. It is a change in functional reach. A stimulus or state

matters because it can become available to systems that use it across tasks and times (Dehaene et al., 2017; Mashour et al., 2020).

The observable implications are access markers: delayed, widespread, or task-relevant activation; flexible use in report or decision; candidate signatures of broadcasting; and contrasts between subliminal processing and contents that enter control. Their value lies in functional reach, while their principal risk is confusing availability with speech or motor output.

Boundary states reveal the limits of global-availability accounts. Motor disconnection can block report while experience remains possible; dreams can contain vivid experience without ordinary external access; children and nonhuman animals can use information flexibly without adult language; and synthetic systems can broadcast text without a validated phenomenal bridge. Global availability supplies important evidence, but its evidential role remains theory- and context-specific.

For PTVC, global availability matters because report cannot define the unity gate. Excluding every low-access interval would preferentially remove sleep, sedation, severe injury, infancy, and other states in which experience may be difficult to express. Including every system that flexibly broadcasts symbols would create the opposite error. Availability therefore updates access, while the bearer decision remains conditional on additional marker families.

The scientific contribution of global-availability accounts is strongest when they separate access from experience. Report-

independent tasks, alternative response channels, and timing controls can reveal flexible use without demanding speech. Negative evidence remains weak when sensory input, comprehension, attention, memory, fatigue, or motor output is compromised; positive evidence supports organized access without mapping every untested interval.

12.1.2 — Integrated and Causal Accounts

Integrated and causal accounts begin from a different intuition. Consciousness seems to require a system whose parts are not merely coactive but causally integrated in a way that produces a unified field. These theories make differentiation and integration central. A conscious state is not a loose list of contents; it is structured, unified, and causally organized (Tononi et al., 2016; Albantakis et al., 2023).

Candidate markers include effective connectivity, perturbational response, complexity, differentiation, and causal interaction. The strongest versions ask whether perturbing one part of the system produces a richly structured response that is neither local reflex nor global silence, making the approach especially relevant to anesthesia, sleep, and severe brain injury.

The principal failure mode is index sovereignty. Perturbational complexity or effective-connectivity measures can fall because experience is absent, because drugs or injury alter propagation, because the perturbation misses the relevant scale, or because data quality is poor. High values can also arise from rich dynamics that do not establish the kind of unity the theory intends. No scalar therefore becomes a context-free unity meter.

Integration evidence should change scientific confidence, not human status. Presence under qualified conditions may support a candidate-stream model; absence may indicate low integration, theory mismatch, impaired propagation, or measurement failure. The report should state which inference is licensed and leave care, personhood, and legal protection outside the index.

The adjudication rule is to pair integration markers with context. Drug state, arousal, injury pattern, sensory access, motor access, sleep stage, and data quality must travel with the marker. A perturbational result without context is like a ledger estimate without origin: it may be mathematically clean and scientifically incomplete.

Integrated and causal accounts contribute a demanding question: does the system respond as a differentiated causal whole rather than as isolated modules or undirected noise? That question can be compared with access, recurrence, report-free tasks, anatomy, and state history. Its value lies in risky predictions and cross-theory disagreement, not in supplying final authority over who or what is conscious.

Progress is already measurable. Casarotto and colleagues (2016) tested a perturbational-complexity threshold in 81 patients after establishing it in a 150-person benchmark. It detected 36 of 38 minimally conscious patients, while 9 of 43 behaviorally unresponsive patients had complexity values overlapping the conscious benchmark. This provides a practical route toward identifying capacities that behavior alone can miss.

12.1.3 — Recurrent and Higher-Order Accounts

Recurrent processing accounts emphasize feedback loops rather than one-way feedforward registration. A stimulus may be processed deeply enough to guide behavior without becoming conscious unless recurrent interactions stabilize or amplify it. Higher-order accounts add a different condition: a state becomes conscious when the system represents, monitors, or is in some way aware of its own state (Lamme, 2006; Brown et al., 2019).

These accounts produce markers that are especially useful in borderline cases. Recurrent processing directs attention to sustained or feedback-mediated activity within sensory and association networks. Higher-order approaches ask whether metacognitive access, confidence, self-monitoring, or error awareness is present. Both families help explain why content, access, and self-evaluation can dissociate.

Their limits are immediate. Infants, animals, patients with language impairment, and people in altered states may lack adult forms of metacognitive report while still having experience. A higher-order criterion that is too demanding can make consciousness disappear wherever explicit self-report is weak. A recurrence criterion that is too permissive can include processing loops that never become felt.

A responsible boundary protocol therefore asks what kind of recurrence is observed, whether it is content-specific, whether it persists across tasks, whether it is paired with integration or access, and whether it survives artifact controls. It asks what kind

of higher-order capacity is being tested and whether the case could have experience without that capacity.

Boundary states make the distinction concrete. Dreaming may contain recurrent sensory organization with weak metacognitive access; severe injury may preserve local recurrence while disrupting global use; dementia or delirium may impair monitoring and report while affective experience continues. The dossier should therefore specify which relation each marker targets and which alternative explanation remains live.

Recurrence and higher-order markers should be decomposed by level: local feedback, long-range recurrence, metacognitive monitoring, confidence, and error awareness are not interchangeable. Their absence may reflect task or report limits, while their presence may show processing rather than experience. They strengthen a bearer classification only when the protocol names the process measured and the rival it excludes (Lamme, 2006; Brown et al., 2019).

12.1.4 — Predictive and Active-Inference Accounts

Predictive and active-inference accounts treat conscious systems as organisms or agents that model the world, the body, and the consequences of action. Their emphasis falls on generative models, prediction error, interoception, action, control, and the active maintenance of viable states. Consciousness is not simply a broadcast or a complexity score. It is tied to situated regulation (Friston, 2010; Seth & Friston, 2016).

Candidate markers are dynamic: prediction-error updating, uncertainty or precision weighting, interoceptive coupling,

perception-action coordination, attention, and state regulation. In human cases they can illuminate pain, dyspnea, nausea, anxiety, delirium, and terminal physiology because experience is often entangled with bodily prediction.

The danger is viability inflation. A system can regulate itself without feeling. A thermostat has control loops. A cell has homeostatic organization. A hospital monitor tracks physiology. None of those examples alone establishes a conscious stream. Active inference becomes relevant to consciousness only when the control architecture is rich enough, integrated enough, and situated enough to bear on felt perspective.

These models can explain why access, salience, and felt state change across sleep, anesthesia, illness, and stress. Their flexibility also creates a recovery problem: a model that can reinterpret every trajectory after the fact offers little discrimination unless its state variables and predictions are frozen in advance (Friston, 2010; Seth & Friston, 2016).

A boundary-state protocol tests whether predictive and active-inference markers are specific to conscious modeling or reflect generic regulation. It examines their relation to reportable experience, covert command following, perturbational evidence, and clinical context, while stating whether each marker targets level, content, valence, or only background capacity.

12.1.5 — No Theory as Endpoint Oracle

Enactive and embodied approaches remind the program that consciousness is sustained through an organism's active relation with its environment. Posture, movement, breathing, sensory

sampling, autonomic regulation, pain, medication, and social interaction can change both experience and the channels used to infer it. Boundary-state analysis should therefore record the coupling conditions rather than treat the brain trace as an isolated verdict.

No theory is comprehensive enough to serve as an oracle across all states. Global availability can miss covert consciousness. Integration metrics can be theory-laden and artifact-sensitive. Recurrence can be present without conscious report or absent from measured channels. Higher-order criteria can exclude infants and impaired persons too readily. Predictive accounts can overinclude homeostatic systems.

Cross-theory robustness strengthens classification when independently imperfect theories converge under declared evidence. Classification narrows when theories diverge in ledger-relevant ways and abstains when theory dependence prevents supported inclusion or exclusion.

When theory dependence dominates, abstention preserves evidence. The dossier records disagreement, identifies discriminating observations, and restricts downstream use until they exist. Averaging incompatible theories into one score would erase the uncertainty the review should expose.

A later endpoint study should therefore record which theory families were used, which markers each supported, where they disagreed, and what that disagreement permits. A favorable terminal pattern cannot repair a failed consciousness gate. The

dependence is noncompensatory: endpoint evidence is interpretable only after the bearer and state gates have survived.

Embodied evidence is especially important when conventional report is unavailable. Changes in orienting, autonomic response, sensorimotor contingency, pain behavior, and environmental engagement can constrain candidate models. Each channel remains fallible: reflexes can occur without the target experience, motor impairment can suppress meaningful response, and clinical intervention can alter the very dynamics being observed.

Endpoint use requires cross-theory stress. One theory may license a local-state marker but cannot decide a stream's endpoint when rivals predict different inclusions, exclusions, or uncertainty zones. Material divergence requires a theory-version label on the public scientific claim or abstention from endpoint interpretation.

Every theory family faces a characteristic failure zone. Access accounts confront report-independent cases; integration accounts confront scale and artifact sensitivity; higher-order accounts confront experience without testable metacognition; predictive accounts confront flexibility and recovery; and embodied accounts must distinguish meaningful coupling from reflex. The comparison becomes most informative where each theory's preferred marker is least secure.

12.1.6 — Theory-to-Marker Matrix

A theory-to-marker matrix exposes disagreement. Each row identifies the theory version, typed target, contrast, time scale, observation, confounds, and conditions under which either result is interpretable.

Targets are fixed before scoring. State presence, content, access, integration, metacognition, continuity, report capacity, and action control are different objects; evidence cannot migrate among them by resemblance.

Predictions remain tied to the theory version that generated the test. Later revision belongs in a secondary update with a visible change log, preventing rescue after the data.

Rows record population, task, preprocessing, scale, prerequisites, missingness, direction, uncertainty, detection opportunity, and failure modes. A prospectively specified conflict rule preserves disagreement instead of averaging it.

Adversarial collaboration is stronger than isolated illustration. The 2025 comparison of global neuronal workspace and integrated information theories constrained both sides before theory-neutral testing, showing how rival comparison can narrow consciousness claims without becoming PTVC evidence (Cogitate Consortium et al., 2025).

Open multisite fMRI data from 118 participants and MEG-EEG data from 100 preserve common events, quality reports, metadata, and code across cohorts and modalities. Openness does not settle consciousness, but it makes preprocessing, rival testing, and transport inspectable (Khalaf et al., 2026; Liu et al., 2026). Shared acquisition protocols also allow site and modality effects to be estimated rather than conflated with theory performance.

Held-out calibration, proper scoring, and recovery test declared predictions; transport tests their performance in new settings (Gneiting & Raftery, 2007). Interpretation also uses the construct

definition and checks on delivery, task access, signal quality, and the intended contrast. A model that scores well only after task-specific preprocessing changes should be distinguished from one whose predictions survive a frozen cross-site pipeline.

The matrix is a versioned comparison tool, not an endpoint oracle. It records support, challenge, conflict, and permitted classifications without granting any theory authority over care, personhood, routing, or the terminal hypothesis (Seth & Friston, 2016; Cogitate Consortium et al., 2025). The matrix should preserve unresolved disagreements rather than collapse them into a consensus score that hides which evidence each theory explains.

12.2 — Sleep, Dreams, and Reversible Low Access

Sleep is a useful first boundary state because it is ordinary, reversible, and rich in evidence about the relationship between experience and access. Conscious experience can occur while ordinary responsiveness is reduced and later recall is incomplete. Studying those differences helps the book develop state-sensitive measures that extend beyond waking report.

Sleep research shows that report absence, recall failure, and experiential absence are separable. High-density recordings link dream reports to local and distributed changes that vary across REM, non-REM, and parasomnia states, making within-state sampling and awakening design central to any continuity inference (Siclari et al., 2017; Cataldi et al., 2024).

Dreaming also tempts overinterpretation. A dream may contain fear, desire, pain, grief, relief, absurdity, memory, or meaning, but it is not an unfiltered sample of the latent ledger. It is recalled after awakening, narrated through memory, and shaped by the questions asked. Sleep gives the research program evidence about access and unity, not a shortcut around measurement.

Sleep offers a controlled way to study experience when ordinary access, report, and memory separate. The scientific question is how reversible low-access states should be included, excluded, or labeled when unity gates and measured ledgers encounter weak or delayed signals. Dream content remains auxiliary evidence rather than a privileged message about lifetime closure.

12.2.1 — Sleep Stage and Access

Sleep stages differ in arousal threshold, physiology, neural dynamics, and report probability. Rapid eye movement sleep, non-rapid eye movement sleep, slow-wave sleep, light sleep, microarousals, and transitional states should not be collapsed into one category called unconscious. A state label is only the beginning of inference (Siclari et al., 2017; Nir & Tononi, 2010).

Access matters because a person may have experience without immediate report, and may report after awakening an experience that was already filtered by stage, timing, and memory. A sleep-stage model therefore needs arousal markers, electroencephalographic features, autonomic context, awakening protocol, and report procedure. The marker family determines what counts as evidence.

Theories disagree about sleep. Some emphasize reduced global access; some emphasize local posterior content networks; some emphasize altered integration; some emphasize predictive disconnection from the external world. The disagreement is useful because it forces the chapter to distinguish conscious content, environmental access, metacognitive control, and stream continuity.

Sleep-stage labels affect eligibility because they alter the prior probability of access, dreaming, memory, and external responsiveness. A stage label should therefore enter the unity model as contextual evidence, not as a direct consciousness switch. Threshold-family analyses should show how stage, report,

physiology, and marker confidence jointly change the included phenomenal domain.

A sleep state can support several verdicts: included conscious interval, probable low-access experience, no-estimate interval, or excluded nonconscious interval under declared assumptions. Those labels must be versioned because later research may revise how sleep stages map to experience.

Sleep stage is therefore not a minor preprocessing detail. It is the first demonstration that a life ledger, if it is ever measured, must be built from state-specific evidence rather than from the public convenience of waking reports.

Sleep staging organizes sampling once the target is specified. Electroencephalographic stage, arousal threshold, autonomic state, eye movement, motor inhibition, recall probability, and reported experience enter the analysis as distinct variables whose relationships can be tested.

12.2.2 — Dreaming and Non-Dreaming Reports

Dream reports are reports after a transition. They do not arrive from inside the dream untouched. Awakening changes attention, memory, language, and motivation, and the absence of a report may reflect nonexperience, failed recall, weak encoding, question wording, or the timing of awakening (Siclari et al., 2017; Tempesta et al., 2018).

A serious protocol therefore separates dream experience, report of experience, report with recall, report without recall, and nonreport. Those categories are often compressed in ordinary

speech, but they have different implications for the unity gate. A person who cannot retrieve content may still have had experience.

Evidence from sleep research suggests that reports of dreaming can occur in both rapid eye movement and non-rapid eye movement sleep, and that posterior cortical activity has been associated with dream reports. The point for this chapter is not to make a posterior region sovereign. It is to show why stage labels and report labels are not enough.

Dream reports constrain boundary-state models through a documented observation chain. They can test how low-access experience is later reported, how recall filters sampled content, and how continuity is reconstructed after awakening.

The failure conditions are clear. If dream reports depend strongly on awakening method, subject training, salience, or retrospective reconstruction, then dream evidence must be labeled report-filtered. If no report is obtained, the correct inference may be absence, nonidentification, or insufficient access, depending on the full marker family.

Sleep evidence enters the routing analysis through awakening design, memory, confidence, stage, and marker context. Recording that chain makes each update to the candidate stream inspectable.

A report of no dream can arise from no experience, failed encoding, failed retrieval, delayed questioning, low salience, language limits, or burden-related nonresponse. A strong protocol varies awakening timing, records confidence, distinguishes immediate from delayed report, and models those alternatives

rather than treating one word after waking as an exhaustive classification.

12.2.3 — Lucid and Fragmented States

Lucid dreaming and fragmented sleep states show that consciousness is not a single knob. A dreamer may have vivid content, partial metacognition, weak voluntary control, altered time, unstable selfhood, and little external access. That mixture is scientifically useful because it separates dimensions that ordinary waking life often bundles together (Cataldi et al., 2024; Nir & Tononi, 2010).

The marker families diverge. A higher-order account may treat lucidity as a special increase in metacognitive awareness. A global-access account may ask whether information becomes available for control within the dream world. A predictive account may ask how internal generative models dominate external input. An integration account may ask whether the state remains unified enough to count as one stream interval.

Sleep is a family of changing states rather than one block of reduced access. Brief awakenings, nonrapid-eye-movement imagery, rapid-eye-movement dreams, sleep paralysis, nightmares, hypnagogic and hypnopompic states, and fragmented arousal can differ in content, agency, memory, physiology, and external responsiveness. The dossier should preserve those distinctions before testing a unity gate.

Lucid and fragmented states show why unity gates need dimensions rather than a single dial. Access, metacognition, agency, self-location, memory, bodily control, and narrative

coherence can separate within one episode. The analysis should report which dimensions support inclusion and how ledger conclusions change when the gate treats them differently.

A fair classification records the nature of fragmentation rather than smoothing it away. Was the fragmentation about content, agency, memory, self-location, bodily control, emotional tone, or temporal continuity? Each kind of fragmentation creates a different risk for ledger allocation.

The scientific task is not to multiply streams whenever organization becomes unusual. It is to test whether the fragmentation concerns content, access, agency, memory, self-model, or causal ownership and whether those changes require a different routing model. Partial disruption can remain within one candidate stream when the evidence does not establish independent ownership.

Lucid dreams are valuable because they partially dissociate metacognition from ordinary waking control. Fragmented states are valuable because they show that contents may appear without stable narrative integration. Together they test whether the unity gate is all-or-nothing, graded, or state-family dependent, while keeping dream content outside any claim of direct ledger access.

12.2.4 — Awakening and Sampling Bias

Awakening is an intervention. The moment of waking, the question asked, the delay before response, the subject's expectation, and the emotional intensity of the experience all affect what becomes reportable. A dream study that ignores

sampling bias may measure reportability more than experience (Siclari et al., 2017; Cataldi et al., 2024).

Sampling bias appears in several places. People may remember vivid or late dreams more than quiet states. They may be trained to report more. They may confabulate when pressured. They may forget dreams that occurred earlier in the night. They may translate nonverbal or affective experiences into a story because the protocol asks for one.

Theories of consciousness do not remove this bias. A report-friendly theory may mistake retrieval for presence. A report-free marker may avoid report bias but introduce sensor and model bias. The fair approach is to report the whole sampling chain: sleep stage, awakening schedule, question form, time to report, confidence, and nonresponse interpretation.

A report-derived ledger would preferentially sample experiences that survive awakening, language, salience, and willingness to disclose. Quiet, bodily, confusing, shame-laden, or rapidly forgotten affect would be underrepresented. Sleep research therefore teaches the measurement program to model the report-selection process before interpreting the content that passed through it.

The correction is not to discard dream reports. It is to classify them properly. A dream report is a post-awakening artifact with evidential value under a known sampling design. It can support boundary-state modeling, but it cannot be treated as an unbiased draw from the latent stream.

The same architecture later governs terminal observation. Near an endpoint, arousal, memory, language, sampling frequency, caregiver availability, and sensor quality may change together. Sleep provides a safer domain in which to learn how observation windows select what becomes visible without pretending that the visible record exhausts experience.

Awakening protocols create their own data-generating process. The alarm, stage-selection rule, delay to interview, interviewer wording, fatigue, and selective exclusion of difficult awakenings can all shape what is remembered and reported. A sleep inference is credible only when those design choices are prospectively specified and their missingness is visible (Cataldi et al., 2024; Little & Rubin, 2019).

12.2.5 — Unity-Gate Sensitivity

The unity gate decides whether an interval is open to ledger contribution. In sleep, that gate is especially difficult because low access is common, continuity is altered, and later report is incomplete. A hard threshold would simplify analysis by hiding the hardest cases (Casali et al., 2013; Jang et al., 2024).

Sensitivity analysis is therefore mandatory. The protocol should test how conclusions change under a strict waking-access gate, a broader experience-likelihood gate, a theory-plural soft gate, and a no-estimate category for ambiguous intervals. If the measured result depends on one convenient sleep gate, the result is not robust.

Different theories support different gate shapes. A global-access account may narrow the gate during deep sleep. An integration

account may allow some low-access states if perturbational or connectivity markers remain rich. A dream-content account may include intervals around later reports. A predictive account may emphasize internal generative modeling even when external access is reduced.

A unity gate is an eligibility rule for one analysis, not a hierarchy of lives or states. Excluding a sleep interval because the marker dossier is insufficient says only that the study cannot use that interval for the declared computation. The record should preserve the uncertainty and prohibit any translation into worth, personhood, or care priority.

The failure condition is post hoc threshold selection. If a unity gate is chosen after seeing whether a ledger estimate moves toward neutrality, the study has contaminated its endpoint. The gate must be declared before the relevant outcome is analyzed, and alternative gates must be reported.

Sleep makes the exclusion rule testable. An interval may leave the confirmatory computation only when the gate, reason code, and sensitivity treatment were declared in advance. The exclusion remains visible in the denominator and cannot be converted into evidence that the interval was phenomenally empty.

Threshold-family analysis is the scientific heart of this subsection. A high threshold may exclude low-access conscious intervals; a low threshold may include organized unconscious activity. The section therefore requires reports across multiple threshold families and asks whether any claimed signature survives strict, moderate, and protective unity gates.

In dream research, selective inclusion is the danger. A stringent gate can discard poorly recalled but genuine experience, while a permissive gate can admit reconstructed reports or organized physiology that does not establish experience. The analysis should report how sleep stage, awakening, recall, and unity thresholds alter the included domain instead of letting one threshold silently determine the ledger.

12.2.6 — No Dream Privilege

Dream experience, dream report, and later recall are different objects. A person may experience without retaining a report, report fragments altered by awakening, or construct a coherent narrative from sparse memory. The study must preserve these distinctions rather than treat remembered dream content as a direct transcript of the sleeping stream (Nir & Tononi, 2010).

Sampling is selective. Awakenings are more likely in some stages, after some physiological changes, and when participants can respond. Reportable or vivid dreams therefore receive disproportionate representation, while silent intervals remain difficult to interpret. A dream dataset is a record of both sleep experience and the procedure used to interrupt and sample it.

Dream evidence is useful for testing state-dependent report, affective transition, memory, unity-gate sensitivity, and links between physiology and later testimony.

A protocol-fixed sleep design should state the stage, awakening schedule, report window, scoring method, missing-report rule, distress policy, and separation of confirmatory from exploratory

features. Negative recall does not equal no experience, nor does a vivid report establish continuous experience across the interval.

Dream material is unusually sensitive. It can reveal trauma, sexuality, fear, relationships, and identity in forms the participant never intended to make public. Coding should minimize narrative detail, separate scientific features from identifying content, and permit withholding or deletion without penalty (World Medical Association, 2024).

The most useful output may be conditional. A study can report how marker families behave in intervals followed by particular reports, how awakening changes evidence, and which unity models remain compatible. It need not decide what every silent interval contained.

This discipline lets sleep inform the next boundary case without mystifying it. Anesthesia shares low access, uncertain report, memory failure, and state transition, but adds pharmacology, motor blockade, and nonnegotiable clinical priority.

12.3 — Anesthesia and Covert Consciousness

Anesthesia is intentionally induced for care, so clinical purpose governs every research use. State measurements must remain noninterfering, consented where applicable, and subordinate to analgesia, safety, procedure, and recovery. The scientific question is what anesthesia can reveal about access, memory, integration, and return under those constraints, not how care can be modified to produce a cleaner boundary state.

Anesthesia is a controlled model of altered access, but unresponsiveness is not equivalent to unconsciousness. Isolated-forearm studies, covert command paradigms, and network-dynamics research show that drug class, dose, motor blockade, memory, and recovery can dissociate, so a bearer model must preserve all of those layers (Sanders et al., 2012; Linassi et al., 2018; Jang et al., 2024).

The scientific difficulty is that anesthesia can separate responsiveness, memory, awareness, distress, sensory processing, autonomic reactivity, and later report. A patient may fail to move because movement is blocked, fail to remember because memory formation is suppressed, or fail to report because the relevant state passed before recovery. A single category called unconscious under anesthesia is not enough.

For public-risk control, anesthesia is a stress test for the unity gate and the endpoint firewall. It shows how a stream can pass through low-access, amnesic, reversible, or fragmented states without granting researchers permission to treat the body as empty.

12.3.1 — Drug Class and Dose

Drugs used during anesthesia have different effects on consciousness, memory, movement, and physiology. Propofol, volatile agents, ketamine, benzodiazepines, opioids, neuromuscular blockers, and adjuncts cannot be collapsed into one state category. Neuromuscular blockers cause paralysis without providing unconsciousness, amnesia, or analgesia. Drug class and dose shape access, memory, sensory response, arousal, and autonomic markers differently (Sanders et al., 2012; Jang et al., 2024).

A state model must therefore record agent, dose, timing, coadministration, depth monitoring, hemodynamics, ventilation, pain control, surgical stimulation, and patient factors such as age, illness, neurological condition, medication, and sleep deprivation. These variables are not merely medical background. They are part of the evidence chain.

The relevant disagreement is empirical: different theories predict different effects of drug class, dose, and state on access, complexity, self-monitoring, and embodied modeling. The protocol should predeclare which theory-indexed markers it expects to move for each agent and dose.

For the bearer question, dose specificity prevents a false unity gate. An interval under light sedation, dissociative anesthesia, deep general anesthesia, and emergence should not receive the same classification merely because all occurred in an operating room. The ledger cannot inherit a clinical label and call it a consciousness state.

A protocol that uses anesthesia data must therefore predefine state bins by pharmacology and physiology, not by narrative convenience. It must also state whether the evidence bears on level, content, valence, continuity, or memory. A drug-specific model may produce a no-estimate interval when the signals conflict.

The ethical point is equally sharp. The purpose of anesthesia is care. The purpose of state classification is research. The first cannot be altered to satisfy the second. The dying person owes no result, and neither does the anesthetized patient.

A concrete measurement advance makes these distinctions more tractable. Maschke and colleagues analyzed spontaneous EEG from 15 healthy volunteers before and during unresponsiveness produced by propofol, xenon, or ketamine. Neural criticality measures differed across the drug-associated experiential states and predicted perturbational complexity; ketamine-associated dream reports were especially useful for separating unresponsiveness from reported absence of experience (Maschke et al., 2024).

The productive next step is a preregistered external validation across anesthetic agents, patient populations, and recording systems, retaining reports and behavioral channels alongside EEG. Such work could improve interval classification and identify where an observation model should preserve possible experience. The immediate objective is a more reliable relation between neural complexity, reported experience, and task access.

12.3.2 — Behavioral Unresponsiveness

Behavioral unresponsiveness can arise from drug effect, paralysis, motor-pathway interruption, sensory failure, task design, pain control, fear, confusion, or inability to understand commands. Because these mechanisms differ, nonresponse cannot carry the whole consciousness inference; the dossier must identify which prerequisite failed or remained untested (Sanders et al., 2012; Linassi et al., 2018).

This matters especially when neuromuscular blockade, surgical context, airway management, or severe illness makes movement unavailable. A person may be unable to signal even if some conscious content remains. The correct inference is not empty. The correct inference is that behavior is an unavailable or compromised channel.

Theory families handle this differently. Access theories may ask for alternative forms of task access. Integration accounts may use perturbational evidence. Predictive accounts may examine autonomic and interoceptive dynamics. Higher-order accounts may be limited if explicit metacognition cannot be tested. The point is not to choose one. It is to prevent behavior from carrying the whole inference.

Behavioral unresponsiveness under anesthesia therefore supplies a general endpoint lesson. Absence of movement cannot by itself justify excluding an interval from the candidate stream, especially when drug effects, sensory isolation, and motor blockade share the same outward appearance. Any cleaner ledger obtained by

dropping those intervals must be treated as a gate-sensitive analysis rather than as evidence about their phenomenal absence.

A fair protocol records the motor channel separately from the consciousness hypothesis. It asks which commands were possible, whether sensory input was intact, whether movement was blocked, whether alternative responses existed, and whether physiological markers changed with stimulation. If these cannot be answered, abstention is stronger than declaration.

The burden of proof should never be placed on a person to move while science already knows movement may be unavailable. That is the human reason behavioral unresponsiveness must be treated as evidence about a channel, not as a verdict about a stream.

12.3.3 — Covert Command Following

Covert command following asks whether a person who cannot respond behaviorally can nevertheless follow instructions in neural activity. The paradigm is powerful because it separates motor output from task understanding and intentional modulation. It is also limited because it requires comprehension, attention, sensory access, task design, and equipment-sensitive interpretation (Huang et al., 2018; Claassen et al., 2019).

An openly released graded-propofol fMRI resource extends this logic in healthy volunteers. It combines mental-imagery and motor-response tasks before, during, and after loss of behavioral responsiveness, including instances of volitional imagery without overt response. The dataset permits comparison and validation of models across dose, task, connectivity, and emergence while keeping behavioral output distinct from covert task performance.

Model recovery separately requires synthetic or otherwise ground-truthed benchmark data (Huang et al., 2026).

Context determines whether covert tasks are feasible and interpretable. Under anesthesia, task delivery may be clinically inappropriate or technically fragile. In disorders of consciousness, related paradigms can reveal cognitive motor dissociation. Across both settings, absent behavior keeps alternative channels scientifically relevant.

A positive covert response establishes organized task-related cognition under a declared paradigm. It can support command comprehension and intentional modulation, but it does not map every interval, content, affective state, or continuity relation needed for a complete bearer classification.

Its strongest contribution is classificatory. Covert command following can reopen a case that behavior alone would have closed, motivate alternative communication channels, and change which routing models remain live.

The protocol requirements include protocol-fixed tasks, artifact controls, false-positive rates, false-negative rates, replication criteria, sensory access checks, medication context, and independent interpretation. A single surprising activation should not rewrite the bearer classification without a dossier.

A negative result is equally bounded. Task misunderstanding, sensory or language barriers, medication, fatigue, signal loss, preprocessing choices, and fluctuating state can all produce failure. Repetition is justified only while clinical condition,

participant welfare, and expected information gain support another attempt.

The versioned dossier therefore records the task, prerequisites, signal quality, uncertainty, and rival explanations for both positive and negative findings. Covert command following updates the state classification without becoming a universal test of consciousness (Claassen et al., 2019; Bodien et al., 2024).

12.3.4 — Memory Formation and Amnesia

Memory is often mistaken for experience because the public usually learns about experience through later memory. Anesthesia breaks that habit. A patient may have no later recall because memory encoding was suppressed, while the question of intraoperative or perioperative experience remains distinct (Sanders et al., 2012; Linassi et al., 2018).

The relevant distinctions include conscious experience, sensory processing, pain processing, distress, memory encoding, consolidation, retrieval, and later narrative. Each can fail or survive differently. A research model that treats memory as the archive of experience will erase states precisely when memory is most pharmacologically fragile.

The theory implications vary. Higher-order and access accounts may treat later report as valuable but not complete. Predictive and interoceptive accounts may examine bodily response without claiming direct report. Integration accounts may ask whether neural complexity remains sufficient. The disagreement shows why amnesia cannot be allowed to settle the gate.

A physiological response does not by itself establish conscious distress. The dossier should therefore analyze memory, access, nociception, autonomic response, and report as distinct channels.

The protocol preserves a memory-state distinction among experienced content, encoded content, retrievable memory, affective response, and later report. When memory is absent but other markers conflict, the allowed conclusion follows the relevant evidence class rather than treating amnesia as absence.

Anesthesia research makes intervals with little later narrative trace scientifically accessible. Combining state-sensitive observations with recovery reports helps characterize their place in a continuing life.

12.3.5 — Emergence and Rebinding

Emergence from anesthesia is not merely a switch flipped from off to on. It may involve gradual recovery of arousal, sensory integration, attention, memory, body orientation, reportability, agency, and emotional regulation. The stream may appear to return before all capacities are stable (Jang et al., 2024; Huang et al., 2024).

Rebinding is the scientific problem of how pre-anesthetic and post-anesthetic intervals are treated as belonging to one stream. Ordinary practice assumes continuity, and often that assumption is right. The research program still needs evidence rules because emergence can include delirium, confusion, hallucination, pain, fear, and amnesia.

Theory families again separate dimensions. Global availability may return with report and task access. Integration may recover

at a different pace. Predictive control may be distorted by pain, drugs, and interoceptive surprise. Higher-order monitoring may lag behind arousal. A single emergence time is therefore inadequate.

Emergence is a reversible transition in observable state. Return challenges an earlier endpoint classification when continuity with the same stream is independently supported, yet it cannot reconstruct every experience within the low-access interval. Induction, maintenance, transition, emergence, and later report therefore remain separate evidence windows whose relations can be compared without hindsight replacing uncertainty.

A good record marks induction, low-access intervals, possible content, emergence, report, confusion, and later revision as separate events. It does not overwrite uncertainty after recovery. If later testimony emerges, it updates the dossier rather than erasing the earlier no-estimate state.

Anesthesia emergence is a humane lesson in scientific patience. The person returns before the model fully understands the interval. The model's incompleteness should never burden the returning person with a public story they did not choose.

Emergence is a transition whose components can separate: arousal, command following, report, memory, orientation, and coordinated control may return on different schedules. Rebinding claims should therefore specify which relations resumed and when. Recovery supports continuity models but does not retroactively make the entire anesthetic gap known.

12.3.6 — Clinical Priority

Clinical care governs every anesthesia study. Drug choice, dose, ventilation, airway management, analgesia, monitoring, emergence, and postoperative treatment must be determined by patient safety and clinical judgment, not by the needs of the Law's research program. The participant owes the theory no additional risk or data (World Medical Association, 2024).

For clinical interpretation, keep awareness and memory separate, and interpret both alongside agent, dose, stimulation, pain control, task availability, and emergence timing; amnesia alone cannot close the consciousness question (Sanders et al., 2012; Linassi et al., 2018).

The perioperative chain should be time-resolved. Baseline cognition, induction, maintenance, surgical stimulation, dose change, physiological instability, task timing, movement channels, neural evidence, emergence, memory testing, and later report occupy different places in the inference. One depth label cannot stand in for that sequence (Jang et al., 2024).

Research procedures require a noninterference budget. Auditory tasks, repeated stimulation, extra sensors, staff movement, and prolonged setup can alter arousal or clinical workflow. The protocol should state the permitted burden and give clinicians an immediate stop rule without penalty to the patient or team.

Negative results require an opportunity-to-respond analysis. Investigators should report whether the stimulus was delivered, sensory access was plausible, signal quality met criteria, a response route remained available, and the state was stable long

enough for the task. Without that chain, a negative trial is a missing test disguised as evidence.

Permitted outputs are narrow: better classification methods, clearer uncertainty, protection against false absence, and improved separation among memory, access, and experience. Disallowed outputs include bedside ranking, clinical authority, judgment of a particular anesthetic plan, or claims that hidden suffering has been detected in a specific procedure.

Consent, minimization, and clinician override are also part of the data-generating model. If research burden changes care, stimulation, physiology, or observation, the resulting evidence is partly about the intervention introduced by the study. That dependency must be visible.

Anesthesia therefore supplies a disciplined transition model rather than a consciousness verdict. It shows why unresponsiveness and amnesia are insufficient while keeping the science subordinate to care.

12.4 — Coma and Disorders of Consciousness

Disorders of consciousness are where boundary-state science becomes most consequential. The research question is no longer an abstract puzzle. It concerns patients who may be unable to speak, move, or demonstrate awareness through ordinary channels while families, clinicians, and institutions face decisions under uncertainty.

Repeated behavioral examination remains essential, yet current evidence shows that a substantial subset of behaviorally unresponsive patients can exhibit covert command following with functional imaging or electrophysiology. The 2024 multicenter study of cognitive motor dissociation strengthens the case for multimodal assessment while leaving prognosis, personhood, and treatment decisions under independent clinical standards (Bodien et al., 2024; Giacino et al., 2018).

A 2025 three-center EEG study in 237 acute and chronic disorders-of-consciousness patients identified recurring dynamic connectivity patterns and evaluated real-time bedside detection and recovery prediction. For this chapter, the contribution is a longitudinal, state-dynamic marker family that can be tested against diagnosis, time, confounds, and outcome rather than a one-time scalar label. Its findings do not eliminate task, clinical, or theory uncertainty, but they make repeated bedside dynamics a serious part of the dossier (Della Bella et al., 2025).

Disorders of consciousness are used here to test the reliability of evidence channels, not to turn patients into proof material. Bedside behavior, task-based neural activity, perturbational

measures, clinical diagnosis, family observations, and longitudinal recovery can disagree. The dossier should preserve those disagreements and use them to qualify routing confidence and endpoint eligibility.

The burden question is direct: who carries the cost of a false absence? If a patient is treated as empty because evidence was difficult to obtain, the burden falls on the person least able to contest the classification. That is why the science must preserve uncertainty as a real output.

Table 12.2. Disorders-of-consciousness evidence and caution matrix.

Evidence family	What it can support	What it cannot decide alone
Behavioral assessment	Reproducible response, arousal, clinical category	Absence of experience when motor or sensory channels are compromised.
Task-based EEG or fMRI	Covert command following under a defined task	Continuous consciousness, valence, or whole-stream ledger inclusion.
Perturbational or complexity measures	Level or capacity under a theory-laden marker	Personhood, care entitlement, or universal consciousness status.
Family and clinician observation	Context, repeated patterns, state sensitivity	Definitive classification without corroboration and confound review.

12.4.1 — Clinical Categories and Diagnostic Boundaries

Clinical categories such as coma, unresponsive wakefulness syndrome or vegetative state, and minimally conscious state are indispensable. They organize observations about wakefulness, arousal, behavior, reproducible awareness, and recovery. But they are clinical categories, not transparent windows into the whole of subjective experience (Giacino et al., 2018; Giacino et al., 2002).

Coma involves absent wakefulness. Unresponsive wakefulness preserves arousal cycles without clear behavioral evidence of awareness. Minimally conscious states show inconsistent but reproducible signs of awareness. These distinctions must be respected because they shape prognosis, care, research eligibility, and communication attempts.

Theories of consciousness interpret these states through different markers. Global access may be limited. Integration and perturbational complexity may be reduced or partially preserved. Recurrent or posterior content networks may be damaged, masked, or inaccessible. Predictive and interoceptive processing may continue in ways that are hard to interpret.

Clinical categories organize care and prognosis. In severe brain injury, the measurement analysis records whether valence estimates are identified, partially identified, or dependent on explicit marker and routing assumptions.

A responsible classification records diagnosis, assessment tool, time since injury, etiology, medication, sensory limitations, motor limitations, arousal state, neuroimaging or electrophysiology if

available, and uncertainty. The classification should be versioned because state changes and methods improve.

The ethical baseline remains present care. Scientific uncertainty about a stream does not reduce the person's dignity, care entitlement, or family meaning. The research record may say no estimate; the bedside must still say care.

Clinical categories are operational diagnostic classifications with uncertainty; they are not direct partitions of phenomenal reality. Because their relation to conscious capacity can vary with time, examiner, task, sensory and motor access, and injury pattern, stream routing should use longitudinal, multimodal evidence and retain No adequate estimate when the category cannot bear the intended inference (Giacino et al., 2018).

12.4.2 — Cognitive Motor Dissociation

Cognitive motor dissociation names a clinically important separation: a patient may show no observable command following while functional magnetic resonance imaging or electroencephalography indicates covert performance of a commanded mental task. The finding makes behavior-only exclusion unsafe as a final rule and reopens assessment when motor output is unreliable (Claassen et al., 2019; Bodien et al., 2024).

Across six centers, Bodien and colleagues studied a convenience sample of 353 participants. Task-based fMRI or EEG detected responses in 60 of 241 participants without observable command following, or 25%. Among 112 participants who did follow commands behaviorally, 43, or 38%, produced detectable task

responses. These differing detection rates make channel sensitivity a central design question and support repeated, multimodal assessment of retained cognitive capacities (Bodien et al., 2024).

The evidential asymmetry is important. A positive, well-controlled task result can expose a false behavioral negative, while a negative result remains compatible with sensory failure, inattention, fatigue, medication, fluctuating state, misunderstanding, insufficient statistical power, or an unsuitable task. Absence on the test therefore cannot become proof of absence of experience.

The protocol must distinguish true covert response from artifact, analytic overfitting, sensory inability, task failure, and uncertain command delivery. Repetition and multimodal assessment may increase confidence, but testing must stop when fatigue, burden, or clinical priority makes further assessment inappropriate.

For routing and endpoint studies, cognitive motor dissociation changes the gate. Motor silence must first be treated as a possible channel failure, and low-response participants cannot be removed merely because behavior is easy to score. Positive cases increase protection and review; negative cases retain the limitations of the instrument and task.

The finding therefore narrows one claim rather than solving the whole consciousness problem. It defeats behavioral unresponsiveness as a sufficient exclusion rule while leaving phenomenal experience, continuity, prognosis, ownership, and

endpoint status separately uncertain (Claassen et al., 2019; Bodien et al., 2024).

12.4.3 — Longitudinal Change

Disorders of consciousness are dynamic. A single assessment can miss fluctuations in arousal, medication effect, fatigue, sleep-wake cycles, pain, infection, seizure activity, sensory access, and recovery trajectory. Longitudinal change is not a complication added after diagnosis. It is part of the state (Bodien et al., 2024; Yakhkind et al., 2024).

Repeated assessment matters because detection is probabilistic. A patient may show command following on one day and not another. A family may observe meaningful response in a familiar context while a clinical exam does not reproduce it. A machine marker may vary with state, electrode quality, or task comprehension.

Theories of consciousness must therefore be tested over time. A global-access marker may appear during brief arousal. An integration measure may recover gradually. Predictive and interoceptive regulation may change with medical stability. A single theory snapshot can turn state variability into a false classification.

For later protocols, longitudinal change protects the endpoint firewall. If a candidate endpoint or low-signal interval is later followed by evidence of return, the earlier classification must not be rewritten silently. The record should preserve candidate, uncertain, revised, and confirmed statuses.

A good longitudinal design records timing, state context, test burden, clinical changes, and the reason a test was or was not repeated. It uses trajectories rather than isolated labels. It also allows durable abstention when repeated evidence remains ambiguous.

The person does not become less worthy because the signal changes. The model becomes more honest when it records that change. That is the difference between a fair classifier and a classifier that offloads uncertainty onto the patient.

A single examination can misclassify a fluctuating or recovering patient. Longitudinal design should record examiner, instrument version, arousal, medication, sensory function, injury evolution, and state transitions so that change can be distinguished from measurement drift. Routing and endpoint conclusions should follow the trajectory of evidence rather than the first stable label (Giacino et al., 2018; Yakhkind et al., 2024).

12.4.4 — Confounds and Artifacts

Every marker in severe brain injury can be confounded. Medication can suppress responsiveness. Sensory loss can prevent command perception. Motor injury can prevent response. Seizure activity, autonomic instability, sleep, pain, fatigue, and environmental noise can alter signals. Devices can fail. Analysis pipelines can manufacture patterns (Casali et al., 2013; Schnakers et al., 2009).

Confounds are not excuses to ignore evidence. They are reasons to make evidence sharper. A state dossier should ask whether the channel was available, whether the task was understood, whether

artifact controls were passed, and whether alternative explanations were tested.

Complexity metrics, connectivity measures, and task-based responses each have their own artifacts. High complexity can reflect noise or nonconscious dynamics. Low complexity can reflect sedation, injury, poor data, or state fluctuation. Task response can reflect true command following or analysis error. A fair review names these possibilities before using the result.

For the evidence dossier, confound control prevents false terminal inference. A pattern that seems to show absence, narrowing, or closure may reflect medication, sensor shutdown, family absence, care procedures, or device limitations. If those confounds are not modeled, the burden of error falls on vulnerable patients and the truth.

A useful confound register includes medication, sedation depth, analgesia, sensory pathway, motor pathway, time since injury, arousal cycle, infection, seizure, temperature, sleep, device quality, preprocessing, and adjudicator knowledge. The register should travel with the classification rather than remain in a laboratory notebook.

The purpose of confound review is to identify which observations are informative and why. A clear account of signal quality, alternative explanations, and uncertainty makes even an incomplete record useful for comparison and future improvement.

Confound control should be built into the marker packet. Sedatives, antiseizure drugs, metabolic disturbance, hydrocephalus, sleep-wake fluctuation, sensory loss, motor

impairment, scanner artifact, and task noncomprehension can mimic absence or conceal capacity. A result that cannot separate these explanations belongs in a lower confidence or unusable class, even when the trace looks clean.

12.4.5 — Family and Clinician Evidence

Families and clinicians often notice patterns that formal tests miss. A familiar voice, a specific routine, a painful procedure, a beloved song, or a subtle movement may reveal context that a standardized task does not capture. Such evidence deserves respect because it can identify channels and states that instruments overlook (Giacino et al., 2018; Young et al., 2021).

It also requires discipline. Family hope, grief, exhaustion, and pattern seeking can overinterpret ambiguous signs. Clinician familiarity can be powerful but can also be shaped by workload, prognosis expectations, and institutional culture. Contextual evidence is valuable; it is not a definitive marker by itself.

The theory-plural approach helps here. A family observation may indicate access, affective response, learning, recognition, or arousal. It may also be a reflex, coincidence, or artifact of timing. The review should ask which theory families the observation bears on and what alternative explanations remain.

For public-risk control, family and clinician evidence matters because hidden burden is often visible first to those who care. A fair science should not treat only machine-readable signals as evidence. Yet it must also protect families from having their love turned into scientific proof or public burden.

A state dossier can include contextual observations with provenance: who observed, in what setting, under what conditions, whether the response was repeated, whether blinded review is possible, and which claims the observation does not support. This makes lived context reviewable without flattening it into a score.

Family and clinician evidence reminds the chapter that consciousness research is not conducted in a vacuum. It happens among people who are already carrying care, grief, uncertainty, and hope. The science must learn from them without making them carry the verdict.

12.4.6 — No Research Classification as Treatment Ceiling

A research classification must never become a treatment ceiling. Low confidence, failed command following, an unresolved marker pattern, or No adequate estimate cannot justify reduced analgesia, rehabilitation, communication support, repeated examination, legal protection, or ordinary clinical care (World Medical Association, 2024; Giacino et al., 2018).

Diagnostic classification, prognosis, research eligibility, and bearer routing are separate questions. They may use overlapping evidence, but they have different targets, consequences, and error costs. A marker useful for detecting covert command following may be poor at forecasting recovery and still less suited to determining whether an interval enters a phenomenal ledger.

False negatives are especially consequential because absent response can reflect motor impairment, fatigue, fluctuating arousal, language mismatch, sensory loss, medication, or task

burden. Multimodal assessment reduces some risks but does not make every negative channel independent or decisive (Bodien et al., 2024).

Longitudinal reassessment is part of the target. A state that fluctuates across hours or days cannot be represented responsibly by one examination selected for convenience. Repeated testing, rest, alternate tasks, and context-sensitive interpretation help distinguish stable absence from episodic access or measurement failure.

Verification is selective. Cases followed by recovery, repeated testing, longer survival, or better-resourced sites are more likely to supply a later answer. Studies should report which classifications become verifiable and whether verification depends on prognosis, family advocacy, site capacity, or survival, rather than evaluating accuracy only on the easiest cases.

Family and bedside observations can identify timing, channels, and test conditions that standardized tasks miss. Familiar voices, routines, expressions, or context-specific responses should be preserved with provenance and uncertainty, then examined against alternatives. Repeated observations can test whether context-specific responses recur under comparable conditions, helping separate stable signal from one-off interpretation.

Research and treatment pathways therefore remain on separate rails. Clinical decisions made under time pressure do not certify a research bearer, and research classifications do not outrank patient values, clinical obligations, or law. Public language should state the purpose-bound result and its limits. This separation also

guards against circularity in which treatment decisions made from a clinical classification later appear as independent validation of the research label.

The scientific gain is a more accurate account of what the evidence can and cannot show. The ethical gain is that uncertainty is absorbed by the research system rather than by the person whose communication is limited. That allocation of uncertainty reduces pressure to force a binary classification when the available channels support only a range of possibilities.

12.5 — Dementia, Delirium, and Fragmented Access

Dementia, delirium, and fragmented access force the chapter to separate experience from narrative continuity. A person may lose memory, executive organization, language, or orientation while comfort, distress, fear, pleasure, pain, trust, and recognition still matter. The scientific temptation is to treat what is hard to narrate as less real.

Dementia and delirium reveal why memory, language, attention, and experience must be kept distinct. Fluctuating cognition and report failure can coexist with distress, pleasure, recognition, and relational response, so the research problem is not to infer absence from impairment but to design context-sensitive access and comfort measures (Inouye et al., 2014; Fong et al., 2015; Livingston et al., 2024).

The scientific response is to keep present felt burden central even when biography becomes difficult to follow. Memory loss, fluctuating attention, atypical expression, and communication change can hide distress or comfort from ordinary observation. Measurement should adapt to those changes rather than treat them as reasons to erase the candidate stream.

Dementia and delirium should be analyzed through the capacities and channels that remain, not through a single global label. Attention, report, memory, affective responsiveness, pain behavior, sensory access, fluctuation, and medication can change differently. The classification should state which marker failed, which persisted, and when abstention is required, while care and dignity remain unchanged.

12.5.1 — Memory Loss Is Not Experience Loss

Memory loss can break biography without eliminating experience. A person may forget an event and still have felt it. They may fail to recognize a name and still feel comfort, fear, hunger, pain, pleasure, or attachment. A science that equates memory with experience would confuse later access with present life (Squire, 2004; Livingston et al., 2024).

The evidence channels must therefore separate episodic memory, semantic memory, autobiographical narrative, immediate affect, recognition, bodily comfort, distress behavior, and physiological state. Each channel can decline differently. A person's inability to recount a burden does not prove the burden was absent.

Theories of consciousness help by distinguishing content, access, reportability, memory, metacognition, and unity. Higher-order capacities may be reduced while experience remains. Global availability may narrow while local affective states remain salient. Embodied and interoceptive accounts may detect burdens that narrative accounts miss.

The scientific target is present experience, not the ability to preserve or narrate it later. A system that samples only remembered states will systematically underrepresent people with impaired encoding, retrieval, language, or autobiographical organization. Memory measures should therefore be modeled as delayed and selective witnesses whose failures change uncertainty, not as retrospective vetoes on what was felt.

A responsible protocol combines contemporaneous observation, accessible report, comfort and distress indicators, caregiver

context, sensory access checks, and repeated assessment. The record identifies which observations depend on memory and how recall was assessed.

The humane rule is exact: memory matters to identity, care, and evidence, but it is not the price of being counted as a feeling subject. The research program must keep present experience visible when the archive becomes unreliable.

Prospective observation is also making retained capacities in advanced dementia easier to study. Across 539 audiovisual observations of 20 participants, Gilmore-Bykovskyi and colleagues (2025) identified nine validated lucid episodes in three people, including increases in meaningful vocal communication. A separate caregiver study found that lucid episodes often occurred well before death (Griffin et al., 2024). These findings support patient-centered attention to fluctuating communication and offer a feasible observation method.

12.5.2 — Delirium and Fluctuation

Delirium is a fluctuating state of attention, awareness, cognition, and often distress. It can vary across hours, medication changes, infection, pain, sleep disruption, environment, and clinical stress. A single classification can be dangerously misleading because the state itself is unstable (Inouye et al., 2014; Fong et al., 2015).

The evidence problem is temporal. A person may be lucid in the morning, confused in the evening, distressed at night, and more coherent after hydration, pain control, or family presence. Measurement that averages across those changes can turn fluctuation into noise rather than evidence.

Theory families interpret delirium differently. Access may fluctuate; integration may be unstable; predictive control may be overwhelmed by interoceptive and environmental uncertainty; higher-order monitoring may fail; recurrence may remain locally active but disorganized. None of these accounts permits one fixed label without time indexing.

Delirium requires time-varying classification because attention, arousal, distress, perception, report, and physiology can fluctuate over hours. Treating the entire episode as one state can erase periods of possible experience or admit intervals whose channels were unusable. A state-space record should therefore permit included, low-confidence, and no-estimate intervals within the same clinical course.

A fair protocol records delirium screens, medication, infection, pain, sleep, environmental stimulation, sensory aids, hydration, communication access, and time of day. It also records whether a low score reflects inattention, aphasia, hearing loss, fatigue, fear, or true absence of relevant capacity.

Delirium teaches the book that uncertainty is sometimes rhythmic. The burden is not only whether a person is conscious, but whether the observation schedule is faithful to the moments in which the person can be reached.

12.5.3 — Language and Report Limits

Language is one of the most convenient bridges from experience to evidence, which is exactly why it can dominate classification unfairly. Aphasia, dysarthria, hearing loss, unfamiliar language, developmental stage, cognitive impairment, anxiety, fatigue, and

cultural differences can all limit report while experience remains (Livingston et al., 2024; Kitwood, 1997).

A boundary-state protocol should distinguish inability to speak, inability to understand, inability to access words, unwillingness to report, and absence of experience. These possibilities require different tests. Alternative communication, yes-or-no interfaces, eye tracking, gesture, affective expression, and caregiver knowledge may all matter.

Theories centered on report or metacognition are especially vulnerable here. They may overvalue linguistic access. Report-free paradigms reduce that risk but introduce their own theory dependence. The correct response is not to discard report, but to place report among other channels.

Language ability is a measurement condition, not an ontological criterion. People who cannot describe pain, fear, pleasure, confusion, or memory may be most vulnerable to having those experiences discounted. Instruments and interviews should therefore provide alternative communication routes, and failed verbal report should widen uncertainty rather than lower presumed experiential standing.

The dossier should record language access, translation needs, hearing and vision status, motor capacity, communication aids, fatigue, cultural context, and confidence in interpretation. It should also state which claims remain unavailable when report is weak.

Interpret speech and silence through the participant's communication capacities, clinical state, and available channels.

Language and report limits require alternative routes rather than lower expectations of experience. Gesture, gaze, affective response, familiar routines, supported communication, physiology, and clinician observation may each contribute within their scope. The study should record which channel was unavailable and why, so that inability to answer does not become an answer.

12.5.4 — Distress, Comfort, and Misinterpretation

Distress and comfort in dementia or delirium may appear in atypical forms. Agitation, withdrawal, calling out, resistance, facial expression, sleep change, appetite change, or bodily movement may reflect pain, fear, confusion, unmet need, environment, medication, or nonconscious reflex. Interpretation is necessary and risky (Inouye et al., 2014; Fong et al., 2015).

The risk of misinterpretation runs in both directions. A distressed person may be dismissed as merely confused. A reflex may be read as suffering. A calm appearance may hide pain, fear, or resignation. Atypical expression requires context, repeated observation, and humility.

Theory families can help separate channels. Interoceptive and predictive accounts foreground bodily distress and environmental threat. Access and report accounts ask what can be communicated. Integration and recurrence accounts ask what level and content markers remain. The disagreement should be recorded rather than resolved by convenience.

Atypical distress poses a symmetric error problem. Excluding hard-to-interpret behavior can hide burden; counting every

atypical movement or vocalization as distress can manufacture a signal the person did not experience. Repeated observation, individualized baselines, clinical context, caregiver knowledge, and converging channels should define the identified set rather than one behavior code.

A fair protocol uses pain assessment adapted to cognitive impairment, context review, caregiver input, medication review, environmental audit, sensory access, and response to comfort interventions. It records uncertainty about whether the marker reflects felt state, physiology, habit, reflex, or communication attempt.

Comfort matters too. Pleasure, recognition, relief, touch, music, routine, food, warmth, and familiar presence can be part of felt life even when narrative is damaged. A science that sees only distress because distress is louder would not be fair either.

Distress and comfort can be misread when expression is atypical, motor access is limited, or observers expect a flat response. State-sensitive behavioral patterns, physiological context, caregiver knowledge, and response to comfort measures should be evaluated together. The aim is not to infer valence from one proxy, but to prevent proxy failure from erasing possible suffering or relief.

12.5.5 — Dissociation and Split Access

Dissociation and split access complicate ordinary assumptions about unity. A person may experience depersonalization, derealization, altered self-location, discontinuity, compartmentalized memory, or changes in agency without the

science being entitled to sensational conclusions about multiple streams (Bayne, 2010; Schechter, 2018).

The evidence problem is not whether a clinical label proves partition. It does not. The problem is how to classify intervals in which access, memory, affect, agency, and self-representation are altered. Different dimensions can fragment without requiring the model to split the bearer.

For dissociation, the discriminating question is whether apparent fragmentation reflects disrupted self-monitoring, altered body/world modeling, loss of global access, or a genuine change in causal unity. Report that theory-indexed uncertainty directly.

Dissociation tests access and ownership, but lack of access alone does not settle stream continuity. The relevant questions concern causal influence, cross-state learning, affective carryover, coaccess, and whether event sets can be assigned without duplication. The answers may support one stream, a partition model, several admissible models, or no estimate.

A protocol should record clinical context, trauma risk, consent, privacy, report limits, memory access, affective continuity, and the danger of inducing distress through questioning. It should avoid any procedure that pressures a person to perform identity fragmentation for research.

Dissociation offers a productive test of how access, memory, agency, and causal continuity fit together. Claims about stream division should follow that evidence while preserving privacy, respect, and clinically appropriate support.

12.5.6 — Care and Dignity Under Uncertainty

Memory loss, language impairment, disorientation, or fragmented narrative do not reduce dignity or establish absence of experience. They alter access and continuity evidence while distress, comfort, relationship, and momentary awareness remain clinically important (Livingston et al., 2024).

Medication, pain, infection, sleep, sensory conditions, familiarity, fatigue, and time of day can change communication. One brief examination should not harden into a permanent account.

Care should maximize communication and minimize distress regardless of the estimate. Familiar people, adapted language, sensory aids, calm settings, and repeated opportunities may improve welfare and evidence without forcing performance.

A model may classify an interval as uncertain, locally supported, or unusable for one analysis. It may not turn that status into a judgment that the person is gone, less authentic, or less entitled to privacy and care.

Family and clinical observations can supply longitudinal context when source, timing, uncertainty, and alternatives are recorded.

When access remains unresolved, protective uncertainty is often correct. Science narrows its claim while care, dignity, and communication remain fully active (World Medical Association, 2024).

12.6 — Developmental and Nonhuman Cases

Development and nonhuman consciousness make the boundary problem less familiar and more ethically exposed. Adult human report cannot be the universal template. Infants, children, animals, and other forms of life may express experience through capacities, behavior, physiology, learning, play, pain response, social attachment, or ecological action that do not look like adult discourse.

Developmental and comparative science cannot use adult verbal report as the universal gate. Evidence from early development, comparative neurobiology, behavior, and welfare science supports graded reference classes and protective uncertainty, while the New York Declaration emphasizes a realistic possibility of consciousness across a wider range of animals than traditional practice assumed (Lagercrantz & Changeux, 2009; Andrews et al., 2024).

The evidential discipline runs in both directions. Convenience can exclude beings whose signals are difficult to interpret, while sentiment can promote weak evidence into a bearer verdict. Protective uncertainty supports proportionate welfare precautions and restricted claims; it does not erase the need for discriminating evidence.

Developmental and comparative cases require evidence zones because marker validity changes with age, species, task, anatomy, ecology, and welfare constraints. Each zone should state which capacities are being tested, which theory families interpret them, what transport assumptions are required, and what the

classification permits. The output is domain-bounded confidence, not a universal rank.

12.6.1 — Developmental Emergence

The origin of a qualifying conscious stream need not coincide with biological birth. Developmental emergence asks when the evidence makes a functional boundary of conscious experience scientifically plausible. A symbolic date cannot answer that question, and research convenience cannot substitute for the relevant developmental evidence (Lagercrantz & Changeux, 2009; Dehaene et al., 2017).

Developmental evidence includes arousal regulation, sensory integration, pain and comfort response, learning, sleep-wake organization, affective expression, social engagement, attention, memory formation, and neural maturation. These markers emerge unevenly. The model must not pretend that one milestone carries the whole boundary.

Developmental evaluation must distinguish flexible coordination, causal integration, embodied regulation, and explicit metacognition rather than treat them as interchangeable markers. The boundary remains theory-indexed and age-sensitive, especially when a theory requires explicit metacognition.

For later protocols, developmental emergence matters because a ledger cannot begin before the bearer exists, but that scientific boundary does not settle moral status. The scientific start of a stream for a model is not a public ruling on the value of infants, fetuses, children, families, or clinical care.

A responsible developmental protocol states age, developmental condition, marker family, sensory access, clinical context, stress burden, and uncertainty. It uses protective defaults where false exclusion could miss experience, while narrowing formal claims when evidence is insufficient for ledger inclusion.

The fair standard is careful without being cold. Developmental uncertainty should produce more protection and more precise language, not a search for a convenient line that lets the model avoid difficulty.

Developmental emergence is unlikely to be a single instant shared by all capacities. Arousal, sensory integration, affective learning, self-world differentiation, report, memory, and metacognition develop on different trajectories. The dossier should therefore be age- and capacity-specific and should not treat adult reportability as the threshold that creates experience (Lagercrantz & Changeux, 2009).

12.6.2 — Age-Appropriate Evidence

Age-appropriate evidence means the marker must match the organism's capacities. An infant cannot be asked for adult verbal report. A toddler may express pain, fear, or preference through behavior, attention, crying, regulation, and interaction. A child's evidence must be read developmentally rather than judged as deficient adult evidence (Lagercrantz & Changeux, 2009; Bayne, 2010).

The relevant channels include facial expression, physiological response, orienting, learning, touch response, sleep, distress, soothing, play, attention, social referencing, and communication

attempts. Each channel requires context because it can also reflect reflex, fatigue, hunger, illness, caregiver stress, or environmental mismatch.

Theories of consciousness can be translated into age-appropriate terms. Access may appear as flexible use rather than verbal report. Integration may appear as coordinated state regulation. Predictive processing may appear in expectation, surprise, and comfort-seeking. Higher-order evidence may be limited, but that limitation cannot erase possible experience.

For the evidence dossier, age-appropriate evidence prevents a subtle unfairness: making the most vulnerable subjects carry the cost of adult measurement. If the only accepted proof is adult speech, then infancy becomes invisible by method rather than by truth.

A protocol should state what the child could realistically do, what the environment allowed, what distress the study imposed, and which claims remain unavailable. It should also separate clinical care, developmental support, and research classification.

The goal is not to make children research objects. It is to keep the science from building a theory of conscious life that quietly begins only where adult methods become convenient.

Age-appropriate evidence changes the task, response channel, baseline, and interpretation. Infant looking, autonomic response, learning, preference, distress behavior, and neural organization can support different claims than adult report. Transport across ages requires an explicit bridge; using the same instrument name does not make the construct identical.

12.6.3 — Species-Specific Expression

Species-specific expression is the nonhuman analogue of age-appropriate evidence. Animals do not owe human-style report to be scientifically considered. Their capacities, ecologies, sensory worlds, social lives, pain behaviors, play, learning, and problem solving must be interpreted in relation to the form of life they actually have (Andrews et al., 2024; Birch et al., 2021).

The marker set will differ across mammals, birds, reptiles, fishes, cephalopods, decapods, insects, and other candidates. Some evidence may come from nociception, protective behavior, motivational tradeoffs, learning under analgesia, play, social recognition, sleep-like states, or flexible avoidance. No single human marker can be exported unchanged.

Species comparisons require homologous or functionally analogous markers rather than a human-centered checklist. Nonverbal flexible use, causal organization, embodied regulation, and ecological competence may carry different weights across taxa.

For public-risk control, species-specific evidence matters because a universal claim about conscious streams cannot silently mean adult humans only. At the same time, including a nonhuman stream in a formal ledger would require more than welfare concern. It would require domain-specific evidence about consciousness, valence, time, and the candidate realization if reserve dynamics are invoked.

A comparative evidence zone should name the taxon, context, marker family, experimental demand, welfare protections, and

known error routes. Protective treatment can be justified under uncertainty even when the scientific classification remains open. Precautionary welfare decisions must therefore remain distinct from claims that a marker has established consciousness or stream structure.

Nonhuman research expands the range of expressions, behaviors, and causal organizations that measurement must accommodate. Species-sensitive methods improve both scientific interpretation and welfare.

12.6.4 — Comparative Homology and Analogy

Comparative evidence often relies on homology and analogy. Homology asks whether structures or mechanisms are shared through common ancestry. Analogy asks whether different systems perform similar functions through different structures. Both matter, and both can mislead if used loosely (Barron & Klein, 2016; Crook, 2021).

A mammalian pain system may support inference through shared neurobiology. Bird cognition may require attention to different neural architecture with similar functional organization. Cephalopod intelligence may require analogy more than direct homology. Insects may present still different evidence profiles. Each case demands its own bridge.

Theory families help sort the bridge. Integrated and causal accounts may be more open to different substrates if causal organization is relevant. Embodied accounts may emphasize organism-environment loops. Access and higher-order accounts

may need translation into species-specific capacities. The bridge should be explicit rather than hidden in human resemblance.

For the bearer question, homology and analogy determine how far a status statement can travel. Evidence from mammals cannot silently generalize to all animals. Evidence from human patients cannot silently generalize to artificial systems. Reference class discipline applies to consciousness just as it applies to terminal dynamics.

A comparative dossier should state whether the inference is homologous, analogous, behavioral, physiological, computational, ecological, or welfare-protective. It should also state whether the evidence supports consciousness, valence, pain, affective learning, or merely complexity.

The chapter's rule is to let similarity help without letting it rule. A fair science takes kinship seriously, takes difference seriously, and refuses to turn either into a shortcut.

Homology can support transport when shared structures and functions have a credible evolutionary relation; analogy can support a weaker comparison when similar capacities arise through different organization. Neither is decisive by itself. The dossier should state which relation is claimed, which properties are conserved, and where the comparison is expected to fail.

12.6.5 — Protective Uncertainty

Protective uncertainty guides cases where suggestive evidence makes false exclusion costly. Welfare precautions can respond to that risk while researchers continue to assess formal inclusion (Andrews et al., 2024; Crump et al., 2022).

In nonhuman and developmental cases, protective uncertainty may lead to welfare consideration, reduced experimental burden, better housing, analgesia, environmental enrichment, or prohibition of harmful procedures even when consciousness classification remains open. The ethical response can be stronger than the scientific verdict.

Consciousness theories can identify different candidate cases. A cross-theory matrix records the supporting indicators and the areas of agreement or uncertainty, allowing welfare precautions and further assessment to proceed together.

When false exclusion could permit avoidable harm, the design increases welfare protection and preserves the unresolved scientific classification.

A protocol should distinguish research classification, welfare protection, legal routing, and public communication. Protective uncertainty belongs especially to welfare and research-burden decisions. It does not authorize public scoring, domain expansion, or claims that all possible bearers have been scientifically included.

This approach connects careful classification with practical care. The study reports the evidence it can identify while welfare decisions respond to the possibility of avoidable harm.

Protective uncertainty preserves welfare without pretending that consciousness has been established everywhere. When evidence is incomplete and the cost of false exclusion is serious, research and practice should avoid preventable suffering while retaining

an uncertain scientific status. Protection and classification answer different questions.

12.6.6 — No Harmful Crucial Experiments

No harmful crucial experiment is permitted to settle a question of consciousness. A study may not induce pain, deprivation, fear, injury, prolonged isolation, or clinically unnecessary burden in a child, nonhuman animal, or other vulnerable candidate merely because the result would be theoretically decisive (World Medical Association, 2024; Andrews et al., 2024).

No harmful crucial experiment does not mean no discriminating experiment. Formal models and simulations may use maximally sharp endpoint-versus-continuation contrasts, including the biological-death admissibility condition in Section 5.7.2, without turning those contrasts into empirical harm. Empirical comparative work can use methods such as naturalistic longitudinal variation, comparative anatomy and behavior, reversible low-burden perturbations, benign enrichment, route choice, recovery, natural survival, and independently warranted care, husbandry, or welfare interventions. The empirical study must not create a harmful terminal condition merely to sharpen the contrast. Ethical refinement can improve inference by removing acute threat, injury, escape responses, and other processes that would otherwise become competing explanations for an observed effect. The full immediate-terminal formal discriminator is developed in Section 19.2 and the Section 29.4.4 simulation benchmark.

Evidence must be age- and species-appropriate. Adult report tasks cannot serve as a universal test, and human-like behavior cannot be the only route to inclusion. Sensory worlds, motor repertoires, developmental capacities, ecological demands, and species-specific expression determine what is informative. A transport claim should identify the functional relation presumed to persist across different expression systems, not merely cite behavioral similarity.

False inclusion and false exclusion have different consequences. Precaution may justify welfare protection while scientific language remains restrained. Protective action is not a confirmed bearer classification, and classification uncertainty is never permission to neglect possible suffering (Birch et al., 2021; Andrews et al., 2024). The welfare threshold can therefore be deliberately more precautionary than the evidentiary threshold for scientific classification without conflating the two.

Research must not withhold ordinary care, enrichment, social contact, analgesia, or environmental support to preserve a contrast. Multidisciplinary review should identify avoided harms, unavailable evidence, and the limits those absences place on interpretation. When a humane condition removes a potentially informative contrast, the missing contrast should be recorded as an ethical identification limit rather than silently approximated.

Rigor therefore comes from theory comparison, better noninvasive markers, transport tests, and willingness to report no estimate when the only decisive experiment would be unacceptable. Comparative work is strongest when marker transport is tested across species or developmental stages with explicit allowance for different sensory, motor, and communicative repertoires.

12.7 — Artificial and Synthetic Candidates

Artificial and synthetic candidates test several assumptions at once: whether performance can substitute for experience, whether causal organization can transport across substrates, and how uncertainty should alter governance. Software systems, simulations, organoids, and other synthetic biological systems therefore require separate evidence pathways.

Theory-derived indicators can organize those pathways, but they are credence-shifting observations rather than consciousness detectors. Linguistic fluency, model scale, simulation success, electrical activity, and biological complexity each admit nonphenomenal explanations and cannot confer authority over persons (Butlin et al., 2026; Kreitmair, 2023; Hartung et al., 2024).

The evidence ladder separates performance, training history, simulation, architecture, causal organization, recurrent integration, memory, embodiment, self-modeling, and world-directed control. It also separates candidate status from personhood, welfare protection from scientific confirmation, and human governance from automated classification.

Artificial intelligence is especially vulnerable to category drift because fluent output can be mistaken for both experience and authority. Generated testimony may enter a dossier as behavior to explain; it cannot adjudicate its own status, classify another bearer, select endpoints, define fairness, or rank evidence.

Table 12.3. Artificial and synthetic evidence ladder.

Research-evidence zone	Typical evidence	Public-language limit
Not supported under current protocol	Only surface performance or scripted affect labels	No conclusion about consciousness, personhood, rights, or future architectures.
Insufficiently identified	Some architectural indicators but weak causal access	No conclusion that consciousness is present or absent.
Theory-limited research candidate	Indicators under one or two theories with live rivals	Theory-limited research status only; no personhood or rights inference.
Cross-theory research candidate	Multiple independent marker families survive review	Cross-theory evidence is not personhood, legal status, moral rank, or self-adjudicating authority.
Prohibited study	Testing would require creating or intensifying suffering	Stop or redesign; uncertainty does not license harmful evidence-seeking.

12.7.1 — Performance Is Not Experience

Performance is behavior under a task; experience is the phenomenal target, if any, behind that behavior. In ordinary human interaction, language is informative because it is embedded in shared biology and development. Artificial systems trained on human language break that inference and require an independent bridge (Bender et al., 2021; Butlin et al., 2026).

An artificial system may report pain because a prompt requests empathy, training data contain pain language, reinforcement favored a style, retrieval supplies a script, or the system models user expectations. Those explanations support claims about competence, imitation, alignment, deception, role performance, or interface design, not a conscious stream.

Consciousness theories supply candidate indicator families such as recurrent processing, global availability, higher-order monitoring, predictive modeling, agency, and embodied interaction. The 2026 indicator framework treats such features as theory-indexed reasons to update credence, not as a single test whose output settles consciousness (Butlin et al., 2026).

Without a supported phenomenal bridge, linguistic fluency, emotional style, self-description, and strategic behavior remain functional evidence. They may justify further architectural investigation while leaving bearer status unresolved.

A responsible dossier explains what the system can do, which mechanisms produce the behavior, which training and tool chains shape it, whether persistent state exists, and which alternative explanations survive. It can return noncandidate, theory-limited candidate, or No adequate estimate without contempt or hype.

Intervention gives architectural indicators scientific force. Ablation, memory interruption, recurrent-state perturbation, counterfactual transfer, and sensorimotor intervention can test whether a proposed organization is causally involved. Parameter count, eloquence, benchmark performance, and anthropomorphic design cannot substitute for that evidence.

12.7.2 — Architecture and Causal Organization

Consciousness theories concern causal organization, so architecture matters beyond surface behavior. Recurrence, integration, global availability, memory, attention, metacognition, embodiment, self-modeling, agency, and action-world feedback form different indicator families with different commitments (Butlin et al., 2026; Dehaene et al., 2017).

Each indicator receives a mechanical definition, time scale, perturbation, expected observation, and rival. Engineering labels such as memory, reward, attention, or self-model carry no evidentiary weight merely because a component uses the name.

Causal tests replace feature inventories with counterfactual evidence. If removing or interrupting a proposed feature leaves the relevant behavior unchanged, the feature may be redundant, decorative, or incorrectly characterized; if the behavior changes, the result still requires a theory-specific bridge to consciousness.

Training and simulation remain part of the architecture review because human descriptions of grief, pain, selfhood, and uncertainty can produce fluent reports through learned regularities, retrieval, reward shaping, or role prompting. The analysis must separate those routes from persistent state and causal organization.

Architectural evidence informs the classification specified by the protocol. The analysis names the indicator properties, causal organization, and observation conditions supporting that classification.

System version, training and fine-tuning, tools, memory, embodiment, sensors, actuators, persistent state, and intervention results belong in the same provenance packet. Indicator-rich and indicator-poor rivals receive the same behavioral evidence and analysis budget.

This method slows both excitement and dismissal. It asks which causal powers are present, which predictions they satisfy, which engineering explanation remains, and which observation would change the classification. The output is a bounded dossier rather than a verdict extracted from scale, brand, fluency, or fascination.

12.7.3 — Training Data and Simulation

Training data can reproduce the language of grief, pain, love, awe, fear, and philosophy without reproducing the experience described. The evidentiary task is to separate learned description, retrieval, prompt response, and reward-shaped style from persistent internal state (Bender et al., 2021; Butlin et al., 2026).

Simulation does not settle the matter by analogy. A simulated storm is not wet, yet some theories treat organization rather than material as central. The scientific question is therefore which causal properties are instantiated, which are merely represented, and what evidence would discriminate the two.

Theory families answer that question differently. Substrate-neutral accounts emphasize causal organization; embodied and biological accounts emphasize interoception, metabolism, organismic regulation, or developmental history. The dossier identifies which inference depends on which commitment.

Persuasive output also creates an authority hazard. A system may describe its own pain, spiritual insight, or certainty in ways that influence users. Those self-descriptions are observations generated by a system, not independent testimony about its phenomenal status or the Law.

Training source, fine-tuning, reinforcement objectives, role instructions, memory design, simulation architecture, intervention tests, and the relation between affect labels and internal control are all versioned. The dossier states whether the object is software, a simulation, an embodied agent, or a synthetic biological system.

The result may be scientifically modest: no current support, insufficient identification, or candidate status under one theory family. Modest classifications are valuable because they preserve a path for stronger evidence without allowing fluency to write metaphysics.

12.7.4 — Organoids and Synthetic Biology

The August 2025 ISSCR compilation retains guidance stating that current central-nervous-system organoids provide no biological evidence of consciousness or pain perception that would warrant specialized consciousness oversight, while urging continued attention as models mature, combine, and gain complexity (International Society for Stem Cell Research, 2025; Hyun et al., 2020).

That calibration prevents two opposite errors. Present organoids are not treated as conscious by default, and future ethical questions are not dismissed merely because current systems fall

below the evidentiary threshold. Governance follows the changing properties of the model rather than public fascination.

The dossier tracks cell types, maturity, connectivity, spontaneous dynamics, sensory coupling, learning, perturbational response, metabolic support, and theory-specific relevance. Electrical activity or complexity alone is insufficient.

Governance covers cell and tissue provenance, consent, stimulation limits, monitoring, welfare warnings, expert review, and authority to pause or stop. No aversive manipulation serves only to improve candidate-state detection.

Stronger evidence may support a stronger candidate classification through controlled review, independent expertise, and public correction. Weak evidence leaves a well-governed model with bounded claims, not a dramatic bearer verdict.

Design for uncertainty before ambition. Seek informative, reversible, low-risk observations; leave questions unanswered when stronger tests create morally relevant risk.

12.7.5 — Candidate Status and Abstention

Candidate status is a research classification, not recognition; abstention is an active result, not dismissal. A system enters a candidate zone only under declared theory-derived indicators and leaves it when version, architecture, evidence, or failure criteria change (Butlin et al., 2026; Hartung et al., 2024).

The evidence ladder distinguishes no current support, insufficient identification, theory-limited candidate, cross-theory candidate, welfare-precaution candidate, and prohibited study. Each class

names evidence, live theories, permitted research, prohibited uses, and revision triggers.

Public descriptions state the research classification, its intended use, and the evidence supporting it. These details connect the result with the scientific question it addresses.

Abstain if theories disagree, architectural access or transport fails, or testing requires harmful creation or manipulation. Record the reason and potentially decisive observation.

Classification may change with evidence, but no research zone permits harmful testing or automated administration. Welfare precautions may exceed classification because error costs differ.

12.7.6 — No Artificial Intelligence Sovereignty

Artificial systems may aid search, simulation, or pattern analysis under accountable review. They cannot govern consciousness classification, certify their experience, judge another system, or decide human inner life (Tabassi, 2023; Butlin et al., 2026).

Apply §12.7.1's performance-versus-experience and theory-indexed indicator rules. Artificial self-reports remain functional evidence unless architecture and intervention tests justify stronger inference; theory-based indicators may warrant further testing or precaution, but not a binary verdict (Bender et al., 2021; Butlin et al., 2026).

Accountability remains human and institutional. Records cover version, architecture, training, memory, tools, embodiment, data access, perturbations, rival explanations, uncertainty, and

prohibited uses. No automated score enters legal, commercial, employment, clinical, or welfare administration.

Mimicry cuts both ways. Fluency or apparent distress may cause over-attribution; unfamiliar systems invite careless dismissal. Perturbation, ablation, transfer, and memory interruption clarify causal organization without revealing experience.

Responsible research anticipates possible artificial suffering without manufacturing it. Reversible, low-risk tests, staged review, transparent sharing, and careful public communication are preferred; unnecessary aversive training, uncontrolled replication of candidate suffering, or escalation after warnings triggers stop or redesign (Butlin & Lappas, 2025).

Artificial and synthetic candidates can expand comparative consciousness science, but candidate status remains evidence under a method. It does not confer public authority, personhood, spiritual standing, or entitlement to govern human decisions.

12.8 — Boundary-State Evidence and Review

Boundary-state science needs a record form because memory, theory, technology, and public language all change. A case that looks clear under one marker family may become uncertain under another. A case that seems absent may later show covert response. A striking artificial output may lose force after architecture review.

Boundary-state evidence is unusually vulnerable to theory dependence, measurement error, and public overinterpretation. A versioned dossier should therefore record marker provenance, disagreement, false-positive and false-negative audits, lived-experience input, and the exact language permitted by the current evidence class (Yakhkind et al., 2024; Cogitate Consortium et al., 2025).

The review apparatus converts each boundary claim into an auditable packet: marker target, state and context, theory interpretation, shared dependencies, false-positive and false-negative routes, reviewer roles, version history, permitted analyses, and prohibited uses. This format is intentionally less dramatic than a verdict because its purpose is to expose where confidence comes from and where it fails.

Boundary cases become scientifically useful when they change the dossier rather than merely decorate the argument. Sleep may expose report bias, anesthesia may expose memory-output dissociation, severe injury may expose covert cognition, development may expose transport failure, comparative cases may expose anthropocentric markers, and artificial candidates

may expose performance-based inflation. Each case should end with a specific update or abstention rule.

12.8.1 — State Evidence Dossier

A state evidence dossier is the minimum record required before a boundary-state classification can influence a research claim. It should include the state description, timing, context, markers observed, markers unavailable, theory families used, confounds, uncertainty, and permitted uses. Without a dossier, the classification is only a story (Yakhkind et al., 2024; Giacino et al., 2018).

The dossier should separate evidence about level, content, access, reportability, unity, valence, continuity, and endpoint relevance. A case may support one dimension and not another. A dream report may support experience without supporting ledger content. Covert command following may support awareness without measuring valence. Artificial fluency may support performance without experience.

The dossier must record burden. What did the test require of the subject, family, animal, clinician, or system? Was there distress, fatigue, intrusion, privacy exposure, or clinical disruption? Evidence that shifts burden invisibly is not fair evidence.

The dossier prevents a favorable case from becoming portable authority. A result can influence routing or endpoint work only through a declared chain from state evidence to marker interpretation, classification, permitted inference, and uncertainty. If any link fails, the claim narrows or stops; the vividness of the case cannot repair the missing bridge.

A useful dossier also includes provenance: date, instrument, protocol version, theory matrix version, reviewers, dissent, and revision triggers. Future evidence should update the classification without pretending the old uncertainty never existed.

The state evidence dossier is the chapter's practical legacy. It makes the reasoning behind a classification available for review, preserves the person's context, and gives later evidence a clear route to improve the result.

12.8.2 — Cross-Theory Assessment

Cross-theory assessment asks where consciousness theories converge, diverge, or remain silent. A boundary claim is stronger when several independent theory families support it through different markers. It is weaker when support comes from one theory while others produce plausible rival interpretations (Cogitate Consortium et al., 2025).

The assessment should not average theories into a fake consensus. It should preserve disagreements. A global availability marker may be absent while integration markers remain. A recurrent signal may persist without report. A predictive-control marker may exist in a system whose higher-order markers are weak. These patterns are not nuisances; they are the evidence.

A cross-theory report should identify which claim each theory bears on: conscious level, content, unity, access, valence, continuity, or candidate status. It should avoid saying consciousness evidence when the evidence supports only access or integration under one framework.

Cross-theory assessment must be frozen at the level that matters. The protocol should state which marker families determine primary eligibility, which provide sensitivity analyses, and how disagreements are resolved before ledger outcomes are inspected. Switching theories after seeing the terminal curve is equivalent to changing the endpoint rule after the result.

The assessment should include failure triggers. If theories disagree on a classification that materially affects a ledger or endpoint inference, the result may be theory-dependent rather than supportive. If the study cannot survive declared alternative theories, it should narrow.

Cross-theory assessment should report agreement, disagreement, and blind spots rather than manufacture a consensus score. A marker supported by several theories may deserve more weight, while a disagreement can define the next discriminating observation. The result remains theory-indexed whenever the evidence does.

Cross-state transport can also be examined at the level of shared anatomy without assuming identical mechanisms. A 2025 analysis compared thalamocortical connectivity and local fluctuation across propofol and sevoflurane anesthesia, NREM sleep, minimally conscious states, and unresponsive wakefulness, finding nucleus-specific rather than uniform thalamic involvement. The result supports a state-indexed transport question: which marker relations persist, which change sign or locus, and which fail outside the context in which they were estimated (Lu et al., 2025).

12.8.3 — False-Positive and False-Negative Audit

Every marker can generate false positives and false negatives, and the two errors must remain separate. A false positive may attribute candidate experience or unity where the relevant state is absent; a false negative may exclude a state or being that has experience. Their scientific and ethical consequences differ by use (Green & Swets, 1966; Bodien et al., 2024).

False positives may arise from reflex, artifact, learned performance, simulation, noise, unconscious processing, nonexperiential complexity, or wishful interpretation. False negatives may arise from motor impairment, language or sensory limits, medication, low arousal, poor timing, species or developmental mismatch, inadequate tasks, or observation failure.

The audit should challenge each marker across the boundary states for which it is proposed. Deep sleep, dreaming, anesthesia, minimally conscious states, cognitive motor dissociation, delirium, dementia, infancy, nonhuman animals, organoids, and artificial systems expose different failure modes. A marker demonstrated only in easy adult waking cases is not yet a boundary-state marker.

Consequences must be traced through the full pipeline. A false negative can erase candidate experience and create informative missingness; a false positive can misroute events, inflate apparent coverage, or support unwarranted public claims. Research inclusion, clinical care, welfare protection, public

communication, and ledger inference therefore require different thresholds and invariant protections.

Where possible, the audit should estimate both error directions, calibration, opportunity to detect, and who bears the consequence. It should also test cases chosen to probe the marker's known limitations and plausible failure modes. Completing this audit is required before the tool is used for routing, endpoint interpretation, or public claims.

When neither error rate nor its distribution across populations can be justified, abstention is the defensible output. The report should state the remaining uncertainty and preserve care, dignity, and protective action independently of the classification.

12.8.4 — Expert and Lived-Experience Review

Boundary-state evidence requires expertise across fields. Consciousness theorists, cognitive neuroscientists, sleep researchers, anesthesiologists, neurocritical-care clinicians, dementia specialists, disability scholars, animal-cognition researchers, artificial-intelligence researchers, ethicists, patients, caregivers, and families each detect different failure modes (World Medical Association, 2024; Young et al., 2021).

Expert review is not decoration. It protects against theory capture, clinical naivete, disability erasure, anthropomorphism, machine hype, and public-risk drift. A panel that lacks the relevant expertise may make a classification look authoritative while hiding the burdens it cannot see.

Lived-experience review matters because boundary states are not only laboratory categories. People with dementia, dissociation,

disability, communication impairment, anesthesia awareness, family experience with disorders of consciousness, or caregiving knowledge may notice harms that technical experts miss. Their evidence is not sovereign, but neither is it optional.

Expert and lived-experience review answer different questions. Specialists assess marker validity, clinical context, task design, and statistical uncertainty; participants, survivors, families, and advocates can reveal burdens, access barriers, communication failures, and harmful interpretations that technical review may miss. The final dossier should preserve those roles without treating testimony as a substitute for marker qualification or expertise as authority over meaning.

A review process should record reviewer roles, conflicts, dissent, scope, and the exact claim being reviewed. It should not ask one panel to decide everything from scientific classification to care, law, ethics, and public meaning. Domain routing is part of fairness.

Good review turns disagreement into specific questions that the evidence can answer. It helps the program recognize a strong result when it appears and identify the next useful test when uncertainty remains.

The composition of review changes the evidence. A panel without disability expertise may overread silence; a panel without clinical expertise may miss medication or injury confounds; a panel without philosophy may confuse access with ontology; a panel without patient and family perspective may miss lived burden.

The review design should therefore be treated as part of the method.

Expert review should combine the disciplines that can see different failure modes and include lived-experience or family input where appropriate and safe. Neurology, anesthesia, sleep medicine, developmental science, comparative cognition, AI research, statistics, and ethics do not supply interchangeable votes. Their disagreements should be recorded as reasons and routed into confidence or redesign.

12.8.5 — Versioned Classification

Boundary-state classifications must be versioned because evidence changes. A sleep marker may be revised, an anesthesia model updated, a disorder-of-consciousness method standardized, an animal evidence framework expanded, or an artificial architecture disclosed. Without version history, later confidence can erase earlier uncertainty (Center for Open Science, 2025; Yakhkind et al., 2024).

A versioned classification records the state of evidence at the time: theory matrix, instruments, thresholds, reviewers, confounds, dissent, and permitted uses. If later evidence changes the classification, the record should show the change rather than pretending the earlier classification was always obvious.

Versioning matters for science because old data may not be comparable to new data. A marker update can change inclusion, exclusion, or confidence. A classifier that silently rescored historical cases would create artificial continuity and possibly false support for the Law.

A versioned classification should identify the marker package, theory family, threshold rule, calibration domain, adjudicators, evidence date, and permitted uses. When any component changes, dependent endpoint estimates and public artifacts should be discoverable through a revision graph. Scientific correction then becomes an observable process rather than a quiet replacement of one confident label with another.

The version history should include deprecated uses. A classification that was once used for research inclusion may later be found too weak for ledger inference. The version record states what changed and how it affects later analyses.

A later revision may strengthen, weaken, or reverse a classification. Preserve the earlier evidence, uncertainty, and scoring rules so the record shows how the conclusion developed.

12.8.6 — No Canon Settlement by Case Study

A striking case can expose a false assumption, but it cannot settle the universal bearer definition by itself. Covert command following, a vivid anesthesia report, remarkable animal behavior, or persuasive artificial dialogue may reopen a question and revise a protocol without creating canon (Cogitate Consortium et al., 2025).

Each case should enter a versioned dossier that records marker families, theory mappings, confounds, missing channels, competing explanations, permitted uses, and revision triggers. The dossier makes the case scientifically inspectable without turning it into a symbol larger than the evidence.

Generalization requires replication and theory comparison. Equal-budget rivals, independent sites, prospective predictions, and negative controls should determine whether the case reveals a stable phenomenon, a measurement artifact, a selection effect, or a failure of one theory-specific marker. Replication should include ordinary and ambiguous cases as well as striking examples so case selection does not inflate apparent marker performance.

Novelty and celebrity create predictable bias. Famous patients, visually compelling scans, extraordinary animals, and socially persuasive machines attract more attention, follow-up, and interpretive generosity than ordinary null or ambiguous cases. Review must examine whether publicity is changing the evidence standard. A review log can record whether extra testing, media attention, or model tuning followed notoriety, making attention itself a potential source of bias.

No single case may set treatment ceilings, legal status, species policy, artificial-system rights, or the endpoint rule for the formal hypothesis. Such decisions require their own evidentiary, ethical, and institutional processes, and research uncertainty cannot be converted into public authority (World Medical Association, 2024). Separating research classification from downstream authority also prevents a high-profile case from becoming an informal precedent beyond the evidence it actually supplies.

A canonical change should therefore require a documented synthesis across cases, methods, theories, and failure modes, together with expert disagreement and version history. The prior rule remains visible until the replacement has earned its scope.

Change control should state which cases would have been classified differently under the new rule, providing a direct measure of the practical effect of revision.

Case studies remain valuable because they make hidden assumptions vulnerable. Their proper role is to change the questions and tests, not to end them. The most informative case is often the one that forces a hidden assumption into an explicit hypothesis that can be tested elsewhere.

Chapter 13 — Truth-Level and Protocol Endpoints

Endpoint science begins by bringing several meaningful clocks into focus. A final breath, a clinical declaration, a fading neural signal, and the end of recording describe different events, each with its own purpose and uncertainty. Distinguishing them gives the research program a stronger basis for asking when a qualifying stream ends.

The formal hypothesis defines the truth-level endpoint as the end of the complete strict-pre-endpoint phenomenal domain of the routed stream. The scientific task is to connect that target with independently specified evidence and a reproducible adjudication procedure.

Endpoint science makes the final boundary an independently governed research object. It constructs prospective rules, collects channels distinct from the ledger estimator, estimates timing with uncertainty, handles return and resuscitation, and preserves no-estimate outcomes for sudden or low-signal cases. These requirements make the terminal claim answerable to evidence.

Endpoint science begins under clinical and relational constraints. The dying person is not an endpoint instrument, and family testimony is not an unlimited data source. Comfort, treatment, consent, refusal, and communication therefore enter the protocol as design variables and stop rules. When measurement interferes with those duties, the study yields rather than seeking a more complete ending.

The formal danger is circularity. If the program defines death as the moment when the ledger appears neutral, then neutrality has not been tested; it has been installed. If it chooses among several

candidate endpoint times after seeing which one produces the prettiest terminal pattern, it has not discovered fairness; it has selected a favorable clock. If it lets endpoint adjudicators tune thresholds with knowledge of ledger trajectories, it has allowed the answer to write the question.

This chapter builds the double firewall that prevents that collapse. Constructional independence requires the endpoint system to be built from channels not algebraically identical to the ledger estimator. Inferential independence requires thresholds, windows, analysts, revisions, and public claims to be separated from the outcome being tested. Residual dependence is not denied. It is modeled, reported, and used to limit the claim.

Endpoint research is most vulnerable when absence masquerades as an event. Missing data, device removal, sedation, family narrative, clinical declaration, and legal time can each explain why observation ended without identifying the truth-level endpoint. The status system therefore includes no-data, competing-clock, censored, and No adequate estimate states before terminal classification begins.

The scientific payoff is large. With endpoint discipline, the later protocol can ask whether prospectively specified terminal dynamics outpredict serious rivals without defining the terminal time by the very ledger under test. Without endpoint discipline, every elegant analysis downstream becomes suspect. A model that predicts neutrality at a self-chosen endpoint is not a discovery. It is a mirror.

Three products remain distinct throughout the chapter: the truth-level endpoint named by the formal target, the protocol object used to approximate it, and the evidence-status record describing whether adjudication succeeded. Candidate, estimated, revised, unresolved, censored, and unusable are statuses of the third product. They prevent an operational timestamp from being mistaken for the phenomenal endpoint itself.

Terminal research is written here as care-constrained measurement, not as drama. A last signal, family recollection, or peaceful appearance may be emotionally important without identifying the truth-level endpoint or the terminal ledger. The protocol earns trust by protecting comfort, recording uncertainty, and accepting observation shutdown before it earns any right to interpret a terminal pattern.

With those objects separated, the first falsification protocol can be both humane and interpretable. It knows when observation must stop, which inferences survive uncertainty, and how to report a failed or unusable endpoint without pressure to complete the story.

Endpoint uncertainty also changes the meaning of statistical power. A larger sample cannot repair a target that moves with the observed ledger, an endpoint rule that is revised after outcome inspection, or a terminal window that disappears selectively in the hardest cases. The design must therefore separate uncertainty that can be reduced by more observations from nonidentification that requires a different bridge, a narrower claim, or no estimate. That distinction prevents sample size from becoming a ritual substitute

for conceptual validity (Little & Rubin, 2019; Hernán & Robins, 2020).

A mature endpoint system also preserves counterfactual discipline. With the confirmatory rule fixed, it can show how classification changes under alternative approved persistence windows, marker families, and observation schedules. Sensitivity analysis then reveals fragility rather than silently replacing the primary endpoint.

Finally, the endpoint record must be understandable outside the analysis team. Clinicians, participants, family representatives, reviewers, and later investigators need to know whether a time was observed, estimated, retrospectively revised, censored, or unusable. That vocabulary is part of scientific dignity. It allows a study to remain precise without turning a person's ending into an administrative fact that claims more certainty than the evidence can carry (World Medical Association, 2024; Greer et al., 2023).

13.1 — Truth-Level Endpoint Domain

Endpoint science begins with a refusal of substitution. The formal hypothesis speaks about the end of the complete strict-pre-endpoint phenomenal domain of a routed qualifying stream. That event may correlate with brain death, cardiac death, clinical unresponsiveness, device silence, or the end of social interaction, but it is not identical to any one of them by definition. If the book lets a convenient proxy become the endpoint, the terminal test loses its target before it begins.

Modern death-determination standards are carefully operationalized clinical constructs, but the truth-level endpoint defined in Chapter 5 is a different scientific object. Brain-death criteria, circulatory criteria, device shutdown, legal time, and last observation can constrain the domain only through declared bridges; none is the latent endpoint by definition (Greer et al., 2020; Greer et al., 2023).

The word conceptual does not mean imaginary. It means the target is defined at the level of the formal object and then approached through evidence. Physics, medicine, and law all use constructs that require operational rules without being exhausted by one instrument. Here the construct is harder because its bearer is experience itself: the relevant stream may be inaccessible, low signal, intermittently expressed, or retrospectively revised by return.

The truth-level endpoint denotes the irreversible end of the relevant stream. A protocol estimates that endpoint from specified observations and can return an interval, a revised classification,

or an unresolved result. Separating the target from its estimate keeps each outcome interpretable.

A humane scientific program also avoids turning endpoint language into a story about a person's worth or meaning. A truth-level endpoint is not a moral verdict, spiritual judgment, clinical instruction, or public identity. It is a research construct whose use is narrow enough to be checked.

13.1.1 — The Truth-Level End of the Stream

The truth-level endpoint is the event at which the complete strict-pre-endpoint phenomenal domain of the routed qualifying stream ends under the declared branch. In notation, later chapters may call the latent endpoint T star, but the notation is not the event. The event is neither the cessation of a body part, a social relationship, nor a recording device, and branches involving return, continued experience, endpoint atoms, or endpoint-inclusive value must be declared rather than absorbed into one generic ending (Greer et al., 2023).

The stream is not defined by public display. It is the bearer of felt experience as received from the formal root. A person can be silent, paralyzed, sedated, dreaming, delirious, or unable to report while still leaving open the possibility of experience. The endpoint cannot therefore be set by the last report or last movement.

The endpoint is also not a reward for the model. A terminal study may estimate a candidate time, fail to estimate it, revise it, or classify it as unusable. All of those outcomes are compatible with

a coherent formal target. None allows a researcher to choose a time because it makes a ledger curve look orderly.

Irreversibility matters because a temporary interruption is not a truth-level endpoint. Sleep, anesthesia, coma, and some resuscitation contexts can include long intervals of missing report or weak signals. If later evidence supports continuity or return, the earlier candidate crossing must be demoted rather than treated as a confirmed endpoint.

Endpoint uncertainty belongs in the model rather than in the person. A protocol that equates no response with no experience transfers uncertainty into a false finality; a protocol that represents latent endpoint time, observation failure, and competing explanations carries the uncertainty itself. That difference is the basis of every later no-estimate and revision rule.

For analysis, this subsection forces a notation discipline. The conceptual endpoint should be stored as a latent object, not as a field copied from a monitor, a hospital record, or a family timeline. A case file may contain many terminal times, but only a declared endpoint model can say which time belongs to which scientific use. That distinction lets later models carry uncertainty without pretending that the formal endpoint has become visible.

13.1.2 — Biological and Clinical Proxies

Somatic death matters, but it does not by itself settle the formal endpoint. Biological systems fail in cascades: circulation, respiration, metabolism, brain perfusion, cellular integrity, and tissue viability do not collapse as a single mathematical instant. Clinical medicine must act under operational rules; scientific

analysis must not mistake those rules for the formal end of experience (Greer et al., 2020; Greer et al., 2023).

Brain death or death by neurologic criteria is closer to the relevant terrain than cardiac or administrative time of death, but it remains a clinical determination with declared prerequisites, exclusions, examinations, and jurisdictional governance. It can guide care, law, and transplantation policy. It cannot be imported as a solved theory of the final unit of conscious-stream identity.

Somatic and neurological events enter the endpoint dossier as clocks with declared relations to the phenomenal target. They can bound plausible intervals, provide competing-event information, trigger persistence checks, or identify observation shutdown. Routine recording and clinical decisiveness for other purposes do not make them the truth-level endpoint (Greer et al., 2023; Dhanani et al., 2021).

Direct cortical recordings show why this distinction is productive. In a nine-patient observational study during independently decided withdrawal of life-sustaining treatment, electrical silence usually preceded terminal spreading depolarization; the reported interval was 13–266 seconds (Dreier et al., 2018). Different physiological transitions therefore provide different time anchors. Carefully governed existing records can help refine this multi-clock model, including the uncertainty between a measured transition and the end of a qualifying stream.

Biological condition and stream evidence can vary in different ways. A biologically living body may present uncertain stream organization; a person near physiological collapse may retain

experience, covert awareness, or the capacity to recover. Each case calls for classification using the relevant marker and continuity evidence.

The strongest rule is simple: somatic evidence may narrow, challenge, or confirm endpoint classification only under declared criteria. If the endpoint system simply replaces truth-level endpoint with body death, it has changed the claim object. That change belongs to formal change control, not to an analyst's convenience.

13.1.3 — Legal and Administrative Time

Legal death is necessary for hospitals, families, states, records, estates, burial, organ donation, and public order. It is not designed to decide the formal endpoint of a consciousness hypothesis. Administrative categories must be stable enough to govern life with others; scientific endpoint categories must be narrow enough to test a claim (Greer et al., 2023; World Medical Association, 2024).

Legal and clinical systems continue to fulfill their own duties. The research record identifies the purpose and resolution of each certificate, registry field, or institutional timestamp and evaluates how it relates to the endpoint being studied.

Legal concepts can still matter as context. They determine when certain data streams stop, when consent authority changes, when records are closed, and when families encounter institutional language. They may create observation patterns that a study must model. They do not identify truth-level endpoint by legal authority.

Administrative timestamps invite silent alignment because they are available and standardized. A legal or registry time may sharpen a plot while remaining biologically and phenomenally coarse. It should therefore enter as context or a separately justified analysis clock, with its error relation to the truth-level endpoint estimated rather than assumed.

Uniformity across sites does not make an administrative time truth-relevant. A clinical declaration may be necessary for care and a registry timestamp necessary for reporting, yet both can be too coarse for terminal inference. The protocol should preserve their operational purpose, estimate their lag and uncertainty where possible, and prevent them from becoming the default endpoint of the ledger merely because they are complete.

13.1.4 — Last Observation and Observation Shutdown

The last observation can occur for several reasons that require separate endpoint adjudication. Sensors stop. A family declines further monitoring. A device is removed for comfort. A patient is transferred. A battery fails. A hospital workflow changes. None of these events proves that experience ended (Little & Rubin, 2019; Greer et al., 2023).

Last observation is especially dangerous because it often aligns with severity. The sickest moments are also the moments when monitoring may become least tolerable, least reliable, or least ethically appropriate. If the study treats observation cessation as the endpoint, it can convert burden, device fragility, or care priority into apparent terminal structure.

A valid endpoint system must therefore carry an observation clock distinct from the endpoint clock. The observation clock marks scheduled measures, failed measures, refused measures, removed devices, care interruptions, and unavailable data. It is a record of access to evidence, not a record of mind.

When a study loses the terminal window, its endpoint result may be absence of usable evidence. Reporting this explicitly keeps the observation record accurate and the endpoint question open for independently justified evidence.

The burden question is direct: who pays for the researcher's need for a final row of data? In a humane program, the dying person never pays through extra discomfort. The data structure pays by carrying missingness and by allowing the analysis to abstain.

The last observation may become relevant in sensitivity analysis, last-contact reporting, and missingness modeling. It may not become truth-level endpoint.

13.1.5 — Strict-Pre-Endpoint Domain and Posthumous Records

A person can remain loved, remembered, recorded, quoted, imitated, modeled, and socially present after death. Those forms of presence matter to families and cultures and belong to the study of memory, identity, and relationships (Parfit, 1984).

Personal archives give families and researchers access to memories, relationships, language, and patterns of response. A diary, video, social media profile, voice model, transcript, digital twin, or statistical simulation can preserve different aspects of that

record; its scientific use depends on the information it contains and how it was produced.

Social memory belongs to grief, history, relationships, and meaning. The formal ledger includes experience within the qualifying stream's strict-pre-endpoint domain; later archives inform retrospective questions about that earlier experience.

The endpoint file distinguishes evidence about experience before the endpoint from representations created afterward. A final message, photograph, recording, or diary may inform retrospective classification when its timing, provenance, consent, and measurement properties are established. Later memories, interpretations, and synthetic representations retain their own source and creation dates.

13.1.6 — Endpoint Uncertainty and Nonidentification

Endpoint uncertainty and endpoint nonidentification are different results. Uncertainty describes an identified target estimated imprecisely under a declared model. Nonidentification means that materially different truth-level endpoints remain compatible with the observed record because the bridge, clock, routing, or observation process cannot distinguish them (Manski, 2003).

Clinical declarations, physiological events, legal times, last observations, device shutdown, and family reports can constrain the endpoint without being identical to it. Each proxy relates differently to the complete strict-pre-endpoint phenomenal domain and fails under different conditions.

When several endpoints remain admissible, the protocol should report an identified set or branch-specific results rather than select

the point that makes the ledger easiest to analyze. A defensible interval can be more informative than a falsely precise timestamp because it preserves both the evidence and the unresolved bridge.

Construction and adjudication must remain independent of the tested residual. Choosing an ending because the ledger is near zero, or excluding cases whose residual is inconvenient, manufactures closure rather than tests it.

Sensitivity analysis should vary only prospectively approved endpoint models, persistence windows, proxy assumptions, and observation rules. Public status language should distinguish observed, estimated, interval-identified, revised, censored, unresolved, and unusable endpoints, while naming whether sparse data, conflicting clocks, routing ambiguity, or structural nonidentification caused the limitation.

A no-estimate endpoint is therefore a substantive scientific result. It identifies the missing bridge that prevents a terminal claim, blocks later mathematics from claiming more certainty than the domain permits, and directs the next design toward the actual source of nonidentification.

13.2 — Protocol Endpoint Objects and Adjudication Predicates

Endpoint work becomes safe only when it stops using one word for several different acts. A candidate crossing is not an estimated endpoint. An estimated endpoint is not a confirmed endpoint. A confirmed endpoint can still be revised when later evidence shows return or classification error. These distinctions are not clerical. They are the scientific grammar that prevents a terminal analysis from overclaiming.

Endpoint adjudication requires a protocol object that is observable, prospective, and independent of the tested ledger. Clinical-trial methodology and causal inference support the endpoint discipline developed here: endpoint construction, estimation, and confirmation must be separable enough that one stage cannot quietly encode the desired result of another (Hernán & Robins, 2020).

The section's status ladder also gives negative and unusable evidence a place to stand. If a threshold crossing is followed by return, it is a false crossing. If the data are too poor to classify, the endpoint is unresolved or unusable.

The status system records endpoint ambiguity explicitly. It identifies which evidence supports a classification, what remains unresolved, and which additional observations could improve the estimate.

The endpoint-status ladder determines analysis eligibility. Qualified prospective endpoints may enter the primary analysis; retrospectively qualified endpoints may support secondary

reconstruction; unresolved or censored endpoints restrict inference; and failed endpoint gates make the affected evidence Unusable. An endpoint that cannot be identified or validly bounded despite passed gates yields No adequate estimate. The distinctions are fixed before analysis so endpoint quality cannot be renegotiated after model fit is known.

Table 13.1. Protocol endpoint status and interpretation rules.

Endpoint status	What it means	Interpretation rule
Candidate crossing	A protocol-fixed threshold event has occurred in the endpoint system.	Evaluate persistence and the remaining adjudication criteria.
Estimated endpoint	A model assigns an event-time distribution or interval under declared assumptions.	Retain the estimated interval or distribution and its assumptions.
Confirmed endpoint	A persistence, review, or evidence rule has been satisfied under the protocol.	Reopen classification when later return or identified error requires it.
Revised endpoint	Later evidence changes the versioned classification.	Preserve the original primary analysis and label retrospective revisions.
Unresolved or unusable	The endpoint cannot be classified with adequate quality.	Report the missing classification and its consequences for available analyses.

13.2.1 — Candidate Protocol Endpoint Object

A candidate crossing is the first event at which a prospectively specified endpoint rule is triggered. It may involve a unity-proxy threshold, a loss of responsiveness pattern, a neurophysiological marker, a quality-controlled absence of state evidence, or a composite event declared before the study. Its dignity lies in being prospective, not in being final (Hernán & Robins, 2020).

A candidate crossing is a research alarm, not a verdict about the person or the truth-level endpoint. It marks the moment at which a prospectively specified threshold has been met and activates the protocol's confirmation, return, and revision rules. The ledger remains unopened to the endpoint adjudicators until that process is locked.

One workable formal form is a threshold time conditioned on quality and persistence prerequisites. The variables belong to endpoint construction, not to the ledger estimator. A low-quality crossing is not a candidate endpoint; it is an artifact flag.

The candidate crossing carries its own context: medication, sedation, respiratory intervention, delirium, sensor quality, care procedure, and observation conditions. Without that context, a threshold crossing is only a number with insufficient provenance.

Denominator discipline reports how often candidate crossings occur, fail confirmation, precede return, or become uninterpretable because evidence quality fails. Publishing only successful confirmations hides the false-crossing burden.

The benefit is procedural honesty. A frightening threshold becomes less dangerous when the study treats it as a provisional

signal with known error rates, review steps, and reversal rules rather than a final statement about the person.

Candidate crossings are also useful for calibration because they expose the endpoint system before it receives permission to conclude. Candidate reversals and missed endings identify different error burdens, but their counts alone do not establish sensitivity or specificity. Sensitivity requires the proportion of independently adjudicated endings detected by the rule; specificity requires the proportion of independently adjudicated non-endings correctly left unflagged, with reference rules, time windows, and denominators declared. Those tradeoffs belong in the endpoint report before any terminal ledger claim is interpreted.

13.2.2 — Persistence and Confirmation Window

A persistence window is the rule that prevents an instantaneous fluctuation from becoming an endpoint. In clinical and neurophysiological data, state markers can flicker because of artifact, medication timing, arousal fluctuation, hypoperfusion, electrode contact, motion, care procedures, or sampling cadence. A candidate crossing therefore needs a declared pattern over time before confirmation is even considered (Cox, 1972; Andersen et al., 1993).

The window is not always a fixed number of minutes. It may be a duration, a repeated-state requirement, a sequence of low-signal observations with quality checks, an absence of return under clinically meaningful conditions, or a combination of channels.

The choice must be justified by endpoint science, not by convenience or by the expected ledger shape.

Persistence also has ethical limits. A protocol may not extend monitoring because a researcher wants a cleaner persistence window if the person's comfort, preferences, or care needs require stopping. When care interrupts the window, the correct status may be unresolved rather than confirmed.

The persistence window is calibrated before outcome inspection. Stretching or shortening it after viewing the terminal ledger turns endpoint confirmation into model rescue, and the same crossing can look very different under five-minute, one-hour, or last-exit rules.

A good endpoint report states the window, its rationale, its quality conditions, its sensitivity analysis, and the number of cases whose status changes under plausible alternatives. This makes persistence a scientific object rather than a hidden judgment.

The window exists to protect the person and the claim at once. It protects the person from a false finality. It protects the claim from confirmation by noise.

13.2.3 — Adjudication Predicate and Estimated Endpoint

An estimated endpoint is not a time point handed down by the data. It is a probability distribution, interval, or classification result produced by a model under assumptions. It depends on observations, state definitions, priors or likelihoods where used, censoring rules, quality thresholds, and revision procedures (Hernán & Robins, 2020; Fleming & Harrington, 2005).

The word estimated should remain visible in public and technical language. If the chapter writes simply T after a model has produced an estimate, readers may hear certainty. A cleaner convention distinguishes the latent conceptual endpoint from the estimated endpoint and keeps the uncertainty attached to every downstream analysis.

Event-time uncertainty can be narrow, wide, multimodal, or formally unidentifiable. In a low-signal terminal window, several candidate intervals may be plausible. In a sudden-death case, no meaningful interval may exist within the observed data. Forcing a point estimate in those cases manufactures information.

Estimated endpoint uncertainty is propagated into sensitivity analysis rather than collapsed too soon. A terminal signature may be robust to plausible jitter, fragile under small changes, or entirely dependent on one time choice, and those outcomes carry different claim status.

The estimation model must declare what information it uses. A prospective filter uses only information available up to the time being estimated. A retrospective smoother uses later evidence. A retrospectively adjudicated onset may be clinically useful, but it may not be treated as if it had been available prospectively.

Each endpoint estimate states the observed channels, adjudication rule, uncertainty interval, and assumptions linking the protocol object to the latent target. A point estimate may simplify a table, but the downstream analysis still exposes how conclusions change across plausible endpoint times.

13.2.4 — Confirmed Endpoint Status and Performance

A confirmed endpoint is a candidate event that has passed declared confirmation rules. Confirmation may require persistence, independent review, absence of return under relevant conditions, quality checks, clinical context, and a documented decision path. It is stronger than a candidate crossing, but it remains a research classification (World Medical Association, 2024; Center for Open Science, 2025).

The word confirmed can mislead if it is allowed to sound metaphysical. Here it means confirmed under the protocol, not confirmed by direct access to the end of experience. The confirmation class should always travel with the version of the endpoint rule, the evidence window, and the known limitations.

Confirmed endpoints are eligible for primary analysis only if the confirmation procedure was prospectively specified, constructionally separated, and inferentially protected. A confirmed endpoint obtained after outcome-dependent tuning or ledger-aware review may be useful for exploratory learning, but it is not confirmatory evidence.

The confirmation process should include false-positive and false-negative audits. How often do candidate crossings fail? How often do low-signal cases later show return? How often does sedation mimic absence? How often does device failure make an endpoint look clean? Confirmation is a performance claim, not a label to be trusted without calibration.

A confirmed endpoint can also become unconfirmed. Later return, new channel evidence, or error discovery should not be hidden to

preserve a tidy result. Revision is a strength when the version history is preserved.

Endpoint confirmation is a qualified research status whose strength comes from explicit criteria, reproducible adjudication, and a clear revision route. Its scope remains the protocol's classification of evidence.

Confirmation should also specify what kind of evidence was absent. Absence after high-quality observation is different from absence after device removal, heavy sedation, emergency intervention, or poor contact. A confirmed endpoint built from strong absence should not be pooled casually with a confirmed endpoint built from fragile absence. Confirmation classes may need grades, and those grades should travel into sensitivity analysis.

13.2.5 — Revision, Versioning, and Audit

Revision is a necessary feature of endpoint science in low-observation, high-stakes states. If later evidence shows that a candidate or confirmed endpoint was wrong, the record must change. Preserve the record of what was known when the primary analysis was run (Särkkä, 2013).

A revision can arise from return, resuscitation, recovered communication, post hoc device-quality review, clinical context, later family or clinician evidence, or discovery that an endpoint channel was compromised. Each source has a different evidentiary weight and different risk of bias.

The chapter distinguishes revised classification from retrospective smoothing. A revised endpoint may improve the

final case record. It does not automatically authorize the primary analysis to behave as if the later evidence had been available at the time. The original filtered analysis and the revised secondary analysis both need to be visible.

Versioned records preserve that difference. A good record says: under rule version one and information available at time t , the endpoint status was candidate; after later return, the status became false crossing; after expert review, the case was routed to error memory. That history is more scientific than a single overwritten label.

Reclassification can improve the endpoint method. When new evidence changes the interpretation of a case, researchers update the classifier, stress-test the protocol, and explain what the case teaches about endpoint adjudication.

Revision should make the record more accurate without rewriting the history of what was known. The original classification, later evidence, reason for change, and affected analyses all remain visible. This distinguishes scientific correction from retrospective smoothing and allows false-ending rates to improve the next protocol rather than disappear from view.

Revision should be asymmetric in public interpretation. A case revised from confirmed to false crossing is not a public scandal if the earlier rule was followed; it is a data point about error. A case revised from unknown to confirmed may strengthen feasibility but cannot retroactively create prospective knowledge. Both revisions become part of the same scientific memory: the endpoint system is learning under uncertainty.

13.2.6 — No Endpoint Defined by the Tested Residual

No favorable endpoint selection is the rule that keeps terminal analysis from becoming a proof machine. When several candidate endpoints exist, the study may not choose the one that makes the residual most neutral, the curve most elegant, or the rival least competitive. The confirmatory endpoint object must be fixed before the ledger result is inspected (Hernán & Robins, 2020).

The object includes more than a threshold. Persistence duration, last-exit rules, allowable gaps, smoothing, censoring, reentry, competing events, and revision handling can all change terminal alignment. The protocol should freeze the primary construction, publish a bounded sensitivity family, and report whether the signature survives rather than substituting the most favorable definition.

Analyst separation and technical controls strengthen the rule. Endpoint adjudicators should not see ledger trajectories where feasible, ledger analysts should not tune endpoint thresholds, and endpoint algorithms, forms, training data, permissions, and deviations should be versioned before unblinding. The primary endpoint file should be reproducible without access to the tested residual.

The firewall has two distinct layers. Constructional separation asks whether the endpoint object is built from information that is not algebraically identical to the ledger estimator. Inferential separation asks whether analysts, thresholds, model selection, sensitivity choices, and public verdicts are protected from the outcome being tested.

Both layers permit explicitly modeled dependence. Illness severity, medication, frailty, comfort care, physiology, and sensor quality may influence both endpoint channels and ledger estimates. The analysis names these shared causes, models their effects, and carries them through sensitivity analyses so that conclusions reflect the resulting uncertainty.

The rule also protects adverse results. A rival victory, false crossing, unusable endpoint, or unfavorable residual must remain in the record when the frozen design says so. Reworking the endpoint until PTVC survives would convert the study from adjudication into advocacy.

The firewall should face direct audit. Synthetic ledger trajectories, perturbed endpoint labels, permission tests, endpoint jitter, and reproducibility checks can reveal whether information that should be unavailable changes the construction. A failed audit requires a redesigned workflow, a new blinded package, or a narrower estimand, not stronger rhetoric.

A defensible endpoint is therefore visible in the data flow: independent features where possible, frozen rules, cross-fitting, shared-confound analysis, dispute logs, public revision rules, and a reproducible primary file. The endpoint and ledger may share declared causes, but they cannot be the same algebraic construction or be tuned to rescue one another.

$$E_t \equiv f_E(Z_{\leq t}^E, \Gamma_E), \hat{L}_t = f_L(Z_{\leq t}^L, \Gamma_L), Z^E \not\equiv Z^L$$

13.2.7 — Constructional Independence

Constructional separation means the primary endpoint is not constructed from the same algebra that defines the measured

ledger. If candidate momentary-valence or interval-contribution estimates quantify affective burden, those same quantities cannot define the truth-level endpoint. Otherwise the terminal claim would test a condition it helped create (Hernán & Robins, 2020).

The separation does not require different organs or wholly unrelated sensors. Consciousness, physiology, and affect share biology. The rule is narrower and stricter: the endpoint channels must not be algebraically identical to the ledger estimator, and any overlap in raw acquisition, preprocessing, or latent variables must be declared.

A unity-proxy endpoint may use perturbational response, connectivity, command-following evidence, arousal context, or other consciousness-related markers. A measured ledger may use physiological valence estimators. When a raw channel contributes to both systems, the primary protocol should either remove the overlap, split the feature families, or route the case to residual-dependence modeling.

Constructional separation is easiest to understand through failure. If a falling affect score is treated as evidence that the mind is ending, and the same falling score is then tested for terminal neutrality, the endpoint and outcome have become one object. No amount of statistical sophistication repairs that circularity.

The separation should be visible in the protocol and the manuscript. Readers should be able to identify endpoint features, ledger features, overlap exclusions, channel provenance, and the rule that prevents outcome-driven endpoint construction.

The firewall reduces burden by keeping the question honest. The person's ending is not shaped to fit the ledger. The ledger is evaluated at an endpoint constructed independently enough to put the claim at risk.

Constructional separation should be audited at the feature level. A physiological channel can be safe in one role and unsafe in another if preprocessing turns it into a ledger proxy. For example, a signal used to classify unity may become entangled with valence estimation if affective labels trained the same representation. The firewall therefore asks not only whether variables have different names, but whether their construction is algebraically and statistically distinct.

13.2.8 — Inferential Independence

Inferential separation prevents the people and procedures around the endpoint from leaking terminal results into endpoint definition. Even if endpoint channels are constructionally distinct, analysts can contaminate the endpoint by tuning thresholds after viewing ledger outcomes, selecting smoothing rules that improve the terminal pattern, or excluding hard cases after seeing results (Särkkä, 2013; Fleming & Harrington, 2005).

The first defense is preregistration. Thresholds, windows, state definitions, confirmation rules, revision procedures, and primary-versus-secondary analysis roles should be declared before the outcome is inspected. Exploratory changes are allowed only when labeled as such.

The second defense is role separation. Where feasible, endpoint adjudicators should be blinded to ledger trajectories, and ledger

analysts should receive endpoint classifications only after endpoint adjudication is locked. Small teams may not always make full separation possible, but the limitation must be acknowledged rather than hidden.

Cross-fitting or sample splitting supplies a third defense. Endpoint tuning occurs in one partition and the resulting rule is applied to held-out cases. This does not make endpoint estimation perfect; it prevents the same observations from selecting the endpoint and then appearing to confirm the terminal claim.

Inferential separation also applies to narrative interpretation. A striking terminal curve should not be allowed to influence case review, family communication, or public artifact selection. The most persuasive picture is often the most dangerous one if its selection rule was not fixed in advance.

Inferential independence is lost when endpoint thresholds, windows, exclusions, or features are selected because they improve the terminal ledger result. The endpoint model may learn from training data, but the confirmatory endpoint for a case must be frozen before the tested residual is revealed. Cross-fitting, held-out adjudication, or separate teams are methods for preserving that order.

Information separation can fail during feature and model selection even when endpoint and ledger teams begin apart. Thresholds, windows, exclusions, and preprocessing choices may be tuned toward an attractive terminal result. Locked scripts, restricted data access, analyst blinding where feasible, and a complete tuning log

make independence a property of workflow rather than a statement of intention.

13.2.9 — Shared-Confound Analysis

Shared confounds are the reason the firewall cannot stop at separate variables. Disease severity, medication, frailty, oxygenation, inflammation, pain control, sensor contact, care procedures, and family or clinician decisions can affect both endpoint markers and ledger estimates. A clean channel list does not make those causes disappear (Little & Rubin, 2019; Hernán & Robins, 2020).

A shared-confound model begins by identifying variables that plausibly influence both systems. Some are measured directly, such as medication timing or device removal. Some are latent, such as global decline, delirium burden, or unobserved discomfort. The model should state which are measured, proxied, or unmeasured.

Shared causes belong in the primary causal diagram and sensitivity plan. Sedation, frailty, perfusion, illness severity, family availability, device removal, and observation quality can affect both endpoint proxies and ledger estimates. A pattern that disappears across plausible shared-confound models has a different status from one that survives; a pattern dominated by unresolved dependence is model-ambiguous, not quietly positive.

Confounding can also create false endpoint evidence. For example, a care procedure may reduce signal quality and physiological variability simultaneously. Without context, the

study may read this as low unity plus variance compression. With context, it becomes a rival explanation.

Sensitivity analysis should vary confound assumptions, especially when variables are unmeasured or weakly measured. The public verdict should state whether conclusions are robust, fragile, or unusable under plausible shared-confound structures.

13.2.10 — Independent Teams and Blinding

Independent teams and blinding turn the firewall from intention into process. Endpoint adjudicators work without the terminal ledger whenever possible, ledger analysts cannot change endpoint labels, and review committees receive only the information required for their task (World Medical Association, 2024; Center for Open Science, 2025).

The level of independence can be scaled. A small feasibility study may use documented role separation and audit logs. A multisite confirmatory study should use separate endpoint and ledger teams, locked data packages, blinded adjudication, and prespecified dispute resolution. The stronger the claim, the stronger the separation must become.

Blinding does not mean ignorance of clinical context. Endpoint adjudicators may need medication, imaging, treatment, arousal, and device-quality information. What they do not need is the measured ledger trajectory whose terminal behavior the study is trying to evaluate.

Audit trails matter because blinding can fail. Who saw which files, when thresholds changed, when cases were excluded, and when public figures were selected should be recorded. The goal

is not suspicion for its own sake. It is to make rescue moves visible.

Independent teams also protect participants and families. They reduce the chance that a researcher invested in the hypothesis interprets an ambiguous ending as favorable. They keep clinical and family-facing communication from being shaped by a terminal result.

The chapter treats independence as a burden carried by institutions, not by dying participants. The study must build the separation; the person should not be asked to trust a theory's goodwill.

Role-specific language preserves the firewall. Endpoint adjudicators give endpoint reasons, ledger analysts give measurement reasons, and any unavoidable role overlap is offset by masked datasets, staged releases, decision logs, and independent review. The purpose is protection from unconscious alignment rather than bureaucracy.

13.2.11 — Prospective Registration and Locked Adjudication

Prospective specification is the study's memory before outcome inspection. Use §6.7's terminology for protocol-fixed, prospectively specified, and publicly preregistered. The endpoint record names endpoint channels, thresholds, persistence windows, exclusion and abstention rules, confirmation procedures, revision handling, primary and secondary analyses, and public-reporting categories (Chambers, 2013; Center for Open Science, 2025).

The protocol-fixed record includes both success and loss conditions: what qualifies an endpoint, what produces unresolved or unusable status, what triggers revision, and what follows when endpoint uncertainty exceeds the admissible range for the primary estimand.

It also names the sensitivity analyses that stress the endpoint, including threshold jitter, alternative clocks, last-observation alignment, shared-confound adjustment, filter-versus-smoother comparison, and false-crossing treatment. Sensitivity is planned before the result becomes inconvenient.

Post-specification changes can be legitimate when safety, ethics, or scientific error require them, but each change is versioned and treated as a changed endpoint rule rather than a quiet reinterpretation of the same test.

A public registry record helps readers distinguish a surprising result from a tuned result. A terminal pattern observed under a frozen endpoint rule carries more evidentiary weight than one found after several endpoint revisions, all else equal.

The same prospective record provides an ethical safeguard. It prevents a person's endpoint classification from being revised after the fact merely because another label would make the terminal result more attractive.

The record also covers revision. A protocol that fixes the threshold but improvises return handling has not protected the endpoint; false crossings, recovery, device cessation, low quality, sudden death, withdrawal, and competing somatic events receive declared classification consequences before outcomes are known.

13.2.12 — Residual Dependence and Sensitivity Analysis

Biological, clinical, and observational interconnection leaves residual dependence even behind strong firewalls. Endpoint channels may share latent causes with valence estimates despite separate teams and code. Model that dependence explicitly rather than assume perfect independence (Little & Rubin, 2019; Manski, 2003).

Shared random effects, latent severity, site and device effects, treatment processes, observation models, and sensitivity parameters can represent that dependence. The scientific question is how much shared structure would be required to explain the apparent terminal signature without PTVC, and which parameters are informed by data rather than assumption.

Verdicts should respond to the sensitivity result. If modest dependence removes the pattern, the claim is fragile; if the result survives a wide, justified range, it becomes more interesting; if the dependence cannot be bounded, the output remains exploratory or No adequate estimate. Numerical strength cannot compensate for unidentified dependence.

Reports and figures should disclose the firewall state and the remaining shared channels. Independent, cross-fitted, jointly modeled, retrospectively adjudicated, and merely differently labeled pipelines are not equivalent. The diagnostic, uncertainty, and verdict consequence should be stated beside the result rather than hidden in implementation notes.

The firewall should itself undergo adversarial stress testing. A test team can inject synthetic residual trajectories, hide or reveal

selected covariates, perturb endpoint labels, and inspect whether adjudicators or scripts change decisions. Sensitivity of the endpoint to prohibited information is a measurable failure and should trigger redesign or narrowing.

A dependence budget makes the remaining risk explicit. It records unavoidable shared channels, the magnitude of an unmeasured common cause required to erase the result, and the conclusions that survive alternative dependence structures. A result that requires implausibly perfect separation should be labeled fragile even when the primary graph is striking (Hernán & Robins, 2020; Manski, 2003).

The endpoint dossier should close with a reproducibility packet containing frozen code, rule version, adjudicator and ledger information sets, deviations, dispute logs, and the mapping of every case to qualified, revised, unresolved, censored, or unusable status. Another team should be able to reconstruct the endpoint without seeing the tested residual; otherwise the object is not ready to support the claim.

13.3 — Stream Routing, Origin, Maximality, and Junctions

An endpoint claim is incomplete until the study can say which stream is ending. Chapter 11 developed routing as a bearer problem; here the same discipline is made endpoint-specific. Origin, maximality, split points, fusion points, overlap, and unresolved junctions must be declared before terminal evidence is inspected, because a favorable ending can otherwise be manufactured by changing the object after the path is known (Bayne, 2010).

The endpoint dossier therefore contains a routing graph as well as a time line. Nodes represent candidate stream intervals or junction states, edges represent prospectively permitted continuations, and each phenomenal contribution is assigned at most once. The graph does not settle metaphysical identity. It makes ownership assumptions visible enough to audit, vary, and reject.

13.3.1 — Stream Origin and Initial Ownership

A stream origin is the earliest boundary from which the protocol treats a candidate trajectory as one routed phenomenal history. It is not automatically conception, birth, first memory, first report, registration, hospital admission, or device connection. Those are observable anchors that may constrain the origin, but none is identical to the truth-level beginning of conscious continuity (Lagercrantz & Changeux, 2009).

Because early experience is often left-censored, origin uncertainty should be represented rather than erased. A study may define a reference-class-specific eligibility origin, a first observed

interval, and an identified set of plausible truth origins. Reporting all three prevents the administrative start of observation from masquerading as the beginning of the stream.

Initial ownership also requires a no-duplication rule. If two candidate routes both claim the same early interval, the protocol must either adjudicate between them, assign explicit mutually exclusive probabilities, or leave the interval unresolved. It may not count the same phenomenal contribution in two ledgers because two biographies or data systems refer to it.

Developmental and clinical evidence can narrow origin classes without becoming an oracle. Neurodevelopmental organization, behavioral repertoire, recurrent access, physiological integration, and later continuity may all bear on plausibility, but their evidential force depends on the reference class and the theory family used to interpret them (Lagercrantz & Changeux, 2009; Dehaene et al., 2017).

The origin rule must be frozen before terminal analysis. Retrospectively shifting the start until positive and negative magnitudes balance would be the temporal counterpart of defining the endpoint by zero. A defensible study therefore prospectively specifies origin objects, alternative origins, left-censoring assumptions, and the verdict consequences of origin failure.

The scientific output may be an interval of admissible origins rather than one date. That result is not evasive. It states exactly how much of the trajectory is identified and prevents unsupported early-life extrapolation from entering a terminal claim.

13.3.2 — Maximality and Continuation

A qualifying stream is maximal when it cannot be extended earlier or later under the declared unity and routing rules without joining evidence that the protocol does not license as one stream. Maximality is therefore a property of the candidate object under specified criteria, not a narrative judgment that the life feels complete (Bayne & Chalmers, 2003; Casali et al., 2013).

Continuation evidence is plural. Causal dependence, preserved access architecture, learning, memory, dynamical integration, recovery trajectories, and intervention response can support an edge between intervals. No single marker is necessary in every population, and no marker becomes sufficient merely because it is convenient to collect (Bayne & Chalmers, 2003; Casali et al., 2013).

The protocol should compare at least three continuation models where the case permits: uninterrupted continuation, pause with rebinding, and termination followed by a new stream. Model comparison must use the same observations and loss rules. Otherwise the preferred continuation model may win by receiving richer evidence than its rivals.

Maximality also has a stopping discipline. Once the declared evidence no longer supports extension, the protocol must not continue the stream through an archive, social memory, legal status, a successor system, or a later simulation. Those objects may preserve information and meaning, but they do not inherit phenomenal ownership by continuity of record.

Sensitivity analysis should vary unity thresholds, permitted gaps, observation models, and rebinding priors. A terminal conclusion that changes under minor defensible variations is not stable enough for a strong verdict. The appropriate output may be Reference-class narrowed, Model-ambiguous, or No adequate estimate.

Maximality defines the temporal extent of one candidate stream under the declared unity and routing criteria. The analysis states the evidence supporting each boundary and preserves alternatives where that extent remains unresolved.

13.3.3 — Split Points and Descendant Streams

A split point is a junction at which one previously coordinated candidate stream may no longer be representable as one maximal stream under the declared unity rule. Split-brain research, dissociation, severe focal injury, and engineered partition are relevant because they show that organismic unity and phenomenal unity need not be treated as synonyms (Gazzaniga, 2000; Pinto et al., 2017).

The conservative formal rule is parent termination with descendant initialization. Once a split is adjudicated, the parent ledger ends at the junction and each descendant begins with its own origin state. No descendant inherits an obligation to complete the parent, and no later total may be used to trade valence across descendants.

Evidence for a split should exceed ordinary functional specialization. Distinct access, conflicting simultaneous control, independent learning, stable dissociation, divergent report, and

causal decoupling may support partition. A single lateralized response or transient communication failure is evidence to investigate, not a sufficient basis for multiple-stream classification.

Partial partition may require an overlap model rather than an immediate binary split. In such cases the protocol can represent a junction interval with competing ownership hypotheses and prohibit terminal adjudication until the overlap is resolved or explicitly carried as nonidentification. This is scientifically cleaner than forcing a sharp boundary through ambiguous evidence.

The error costs are asymmetric. False splitting can duplicate or erase parts of one stream; false continuation can pool experiences that should be separately routed. Both errors can manufacture closure. The analysis therefore reports how each plausible split rule changes the residual, but it does not select the rule that improves fit.

A split classification remains a scientific model, not a legal division of the person, a moral ranking, or a statement about how relatives should love or remember. The protocol's authority ends at routing and uncertainty.

13.3.4 — Fusion, Overlap, and Junction Rules

Fusion is the converse junction problem: two or more candidate streams become sufficiently integrated that later experience may form one new maximal stream. The later unity does not retrospectively merge the earlier histories. Each pre-fusion stream remains fixed as its own past, while a new post-junction stream

begins under an explicit origin rule (Bayne, 2010; Tononi et al., 2016).

Information exchange alone cannot establish fusion. Distinct systems may communicate, synchronize behavior, share memory access, or coordinate control. A fusion claim requires evidence bearing on a unified phenomenal field, and current methods may often leave that question unresolved (Bayne, 2010; Tononi et al., 2016).

Overlap is different from full fusion. A system may show shared access in one domain and segregated access in another, or alternate between integrated and partitioned organization. The routing graph should allow junction states and mixed evidence rather than forcing all intervals into one permanent topology.

Junction rules must specify temporal granularity. A split or fusion that appears at one sampling rate may dissolve at another. Multiscale analysis therefore reports whether the junction persists across defensible resolutions, and it treats resolution-dependent conclusions as model-limited rather than ontologically final.

The post-junction stream begins without receiving a transferred balance. Nontransferability means that phenomenal measures are not assets moved from parent streams into a successor. The new stream has its own routed domain even when it contains memories, dispositions, or structures inherited from earlier systems.

For public communication, junction diagrams must show uncertainty and temporal direction. A visually seamless merger can imply metaphysical continuity that the data do not establish.

The safer diagram shows pre-junction streams, the uncertain junction interval, the post-junction candidate, and the alternative models that remain live.

13.3.5 — Exhaustive Routing and No Double Counting

Exhaustive routing assigns every phenomenal contribution in the declared study domain to one stream, probabilistically among mutually exclusive alternatives, or to the unresolved set. Unassigned contributions must remain visible. A protocol cannot discard difficult intervals yet claim complete-stream adjudication (Little & Rubin, 2019; Hernán & Robins, 2020).

No double counting is equally strict. An interval represented under several candidate routes belongs to sensitivity or model-averaging analysis, not simultaneous ledgers whose values are later combined. The same experience cannot support multiple terminal equalities merely because routing is uncertain.

Probabilistic routing requires the estimand and its posterior or mixture summary to remain distinct. Posterior ownership probabilities yield an expected or mixture-level quantity, not an observed truth-level ledger. Analysis must separate route from valence uncertainty and never present a posterior mean as exact stream ownership.

Routing completeness should be audited with a balance sheet of a different kind: counts or measures of included, excluded, multiply claimed, and unresolved intervals. This is not a moral ledger. It is a data-integrity report that lets reviewers see whether a favorable residual was purchased by selective ownership.

Missingness and routing can interact. The least observable intervals may be the ones most likely to be dropped, reassigned, or merged. Sensitivity analyses should therefore couple observation models to routing models rather than assuming that missing intervals are exchangeable with observed ones (Little & Rubin, 2019; Hernán & Robins, 2020).

A route without exhaustive, nonduplicative ownership is Route-failed. Prediction cannot repair the defect because the tested object was never defined well enough to carry the claim.

13.3.6 — Endpoint Routing Audit and Intrastream Nontransferability

Before any endpoint verdict, an independent audit should reconstruct the route from origin through every pause, split, fusion, overlap, and return. It asks whether each rule was prespecified, whether alternatives were scored equally, and whether any revision followed inspection of the terminal residual (Greer et al., 2023).

The audit also enforces intrastream nontransferability. Magnitude from one stream cannot repair another stream's residual even when streams share a body, family, archive, origin system, or successor. This is a formal boundary, not a metaphor about moral isolation.

Junction sensitivity should be reported as a family of endpoint results. If defensible routes yield different signs, compatibility states, or verdicts, the result is model ambiguity or a narrowed reference class, not permission to select the route that preserves the preferred claim.

Event-level ownership conservation is mandatory. Each included interval is assigned once to one declared stream, assigned probabilistically across mutually exclusive routing graphs, or left unresolved. No interval may disappear, appear in multiple branches, or move across streams to improve closure.

Routing uncertainty must propagate to the terminal estimate through a family of admissible graphs, prospectively specified model weights, or an identified set when weights are indefensible (Manski, 2003). A reproducible packet preserves origin, maximality, split and fusion rules, overlap treatment, graph version, adjudicator information, interval ownership, superseded routes, and reasons for change without exposing the tested residual.

Clinical and ethical authority remains separate. Routing uncertainty cannot decide treatment, personhood, capacity, inheritance, guardianship, spiritual status, or eligibility. At junctions, causal inheritance and shared memory may motivate bridge hypotheses, but they never authorize retroactive pooling of predecessor ledgers (Greer et al., 2023; World Medical Association, 2024).

13.4 — Accessibility Classes and Terminal Windows

The endpoint is not one clock. Clinical care has a clock. Unity-proxy measurement has a clock. Observation availability has a clock. Ledger estimation has a clock. Legal and administrative systems have their own clocks as well, although they do not own this chapter's scientific endpoint. When those clocks are aligned without scrutiny, endpoint inference becomes fragile.

Terminal accessibility is a multistate observation problem. Clinical state, unity proxy, measurement availability, censoring, competing events, and terminal support can change on different clocks, so endpoint eligibility should be reported as a class or identified set rather than compressed into one timestamp (Andersen et al., 1993; Aalen et al., 2008; Little & Rubin, 2019).

Clock separation becomes operational through a multistate record. Clinical interventions can change physiology and possible experience; unity proxies can fail through low signal; observation can stop for reasons unrelated to consciousness; and ledger estimates can change when future data enter. Recording each transition on its own clock preserves causal order and prevents one convenient timestamp from absorbing the others.

The core principle is that endpoint adjudication should model progression through states rather than jump from observed to ended. A stream can be open, low signal, candidate crossed, confirmed, returned, censored, withdrawn, or unknown. A study that lacks a state for uncertainty will convert uncertainty into something else.

The machinery here is not final ontology. It is a way to keep endpoint evidence honest enough for later tests. A multistate model can be wrong, but it is wrong visibly. A single timestamp can be wrong invisibly. The displayed inequality is a diagnostic clock-separation convention, not a theorem that every recorded time must differ in every case.

$$T * \neq T_C, T * \neq T_{det}, T * \neq T_{adj};$$

$$T_C \neq T_{det}, T_C \neq T_{adj}, T_{det} \neq T_{adj}$$

Any two realized times may coincide in a case without becoming the same clock object.

Table 13.2. Endpoint clocks, records, and primary dangers.

Clock	Records	Primary danger
Clinical clock	Treatment, interventions, declarations, physiology, care changes.	Clinical necessity can be mistaken for endpoint evidence.
Unity-proxy clock	Prospectively specified consciousness-related channels and thresholds.	Proxy absence can be mistaken for absence of stream.
Observation clock	Scheduled, failed, refused, removed, interrupted, or unavailable data.	Data cessation can be mistaken for the truth-level endpoint.
Ledger clock	Affective estimates, measured ledger windows, and analysis alignment.	Ledger behavior can leak into endpoint construction.

13.4.1 — Clinical Accessibility Class

The clinical clock records what care is doing. Medication, sedation, oxygen support, ventilation, hemodynamics, resuscitation attempts, comfort measures, withdrawal of devices, transfer, discharge, and clinical declarations all belong here. These events are not outside the science. They shape what can be observed and sometimes shape the experience being studied (Greer et al., 2023; Giacino et al., 2018).

Clinical time has privileged ethical authority. Care decisions are made for the person, not for the terminal model. A palliative intervention that disrupts measurement does not create a data problem to be solved by delaying care. It creates a scientific limitation that the study must carry.

The clinical clock can also act as a confounder. Sedation can reduce behavior, alter physiology, change sensor quality, and affect ledger estimates. Pain treatment can change both experience and endpoint channels. Ventilation changes can alter signals that a naive endpoint rule might treat as consciousness-related.

A good endpoint record therefore annotates candidate crossings with the clinical state surrounding them. The question is not only whether a threshold was crossed, but what was happening to the person, the care plan, and the body when the threshold appeared.

Clinical declarations of death, including neurologic or circulatory determinations, should be recorded in this clock with their criteria. They can provide important boundaries and external

context. They do not erase the conceptual difference between clinical authority and research classification.

The clinical clock remains prior because treatment cannot be reorganized to serve endpoint inference. Changes in medication, ventilation, analgesia, monitoring, or location should be recorded as time-varying causes of both observation and state, not treated as protocol deviations to be suppressed. The study adapts to care; care does not adapt to the study.

The clinical clock also identifies why observations are missing. A gap following a comfort-medication change carries different causal information from a failed battery or hospital discharge. Recording those causes prevents care events and logistics from being misread as mind-related endpoint evidence.

13.4.2 — Unity-Proxy Accessibility

The unity-proxy clock records the protocol-fixed consciousness-related channels used to approach the endpoint. These may include perturbational, connectivity, responsiveness, arousal, command-following, or other theory-sensitive indicators. The details belong to the boundary-state and protocol chapters; here the point is clock discipline (Casali et al., 2013; Bodien et al., 2024).

A unity proxy is not the unity gate itself. It is an instrumented candidate for classifying whether the relevant stream remains plausibly active, low signal, absent, or unknown. The clock records changes in those proxies with their quality conditions and context.

The unity-proxy clock must not be derived from the ledger estimator. If affective estimates help define the endpoint, the terminal claim becomes circular. The endpoint system may record physiological channels that overlap in broad biological context, but algebraic identity and outcome-driven tuning must be blocked.

Threshold families are safer than a single threshold. A channel may be sensitive under one state and unreliable under another. The endpoint clock should preserve low-signal, artifact, and uncertain states rather than turning all subthreshold intervals into absence.

The unity-proxy clock also needs revision memory. If a patient later shows evidence of continuity or return, earlier unity-proxy classifications must be demoted or reclassified. The history should remain visible so the system can learn where it failed.

This clock carries one of the chapter's central burdens: it must bring consciousness science into endpoint work without letting any metric become a universal meter of mind.

13.4.3 — Observation Window and Sampling Support

The observation clock is the clock of available evidence. It records when data were scheduled, collected, failed, refused, stopped for comfort, stopped by clinical care, lost to device failure, interrupted by transfer, or missing for unknown reasons. It is essential because endpoint evidence often disappears exactly when it becomes most tempting to interpret (Andersen et al., 1993; Aalen et al., 2008).

Observation missingness is rarely innocent near death. The person may be too uncomfortable for sensors, the family may decline monitoring, clinicians may need access, devices may lose contact, tissue perfusion may change, or the care setting may shift. Each reason carries different implications.

A study that treats missing data as if it were a zero signal shifts burden from the instrument to the person. The fairer approach is to tag observation status at the interval level: observed, partially observed, poor quality, refused, clinically interrupted, device failed, administratively unavailable, or not meaningful because care rightly stopped.

Sudden unobserved endings inform feasibility, burden, and future design. Their records preserve the available evidence and the exact extent of missing terminal observation.

Observation status should travel into models of endpoint uncertainty. A confirmed endpoint built from high-quality, independent channels carries a different status from one inferred through sparse, low-quality, or post hoc evidence. The clock keeps those statuses separate.

The observation clock is also where site differences enter the endpoint model. A hospice room, intensive care unit, home setting, and emergency department may produce different observation patterns even for similar physiology. If those differences are ignored, the endpoint system may learn the institution rather than the stream. A credible multisite protocol therefore models observation infrastructure alongside state evidence.

13.4.4 — Ledger-Independent Terminal Window

The ledger clock records affective estimates, measured-ledger windows, and the alignment choices used in terminal analysis. It belongs in the endpoint chapter only because it must remain separate. The endpoint system should know that the ledger clock exists, but it must not let ledger behavior decide endpoint construction (Little & Rubin, 2019).

This separation is more than a file-management rule. If the endpoint team sees a ledger curve and adjusts a threshold to catch a pleasing terminal approach, the endpoint has become outcome-selected. If the ledger team sees endpoint uncertainty and chooses the endpoint that supports neutrality, the test has become circular from the other side.

The ledger clock may still enter joint models as an object of analysis. For example, a model may ask whether observation quality, clinical events, and endpoint status affect the measured ledger. It may not define the primary endpoint by ledger features.

A clear ledger clock also prevents accidental smoothing leakage. If a smoothed ledger estimate uses future data, it cannot be used to construct a prospective endpoint. Retrospective reconstructions must be labeled as such; their primary or secondary status follows the prespecified analysis plan.

The clocks may inform one another under declared models, but they are not silently interchangeable. Cross-fitting, joint models, and shared-confound analyses can use dependence while preserving honest prediction. The prohibited move is to let the ledger select its own terminal window or let an administrative

time stand in for a phenomenal endpoint without an explicit bridge.

The ledger clock therefore functions as a boundary marker. It is the clock the endpoint system must not become.

For the primary terminal test, endpoint rules and adjudication must be protected from outcome-driven ledger tuning. A prospectively specified joint model may nevertheless estimate declared dependence between endpoint and ledger processes; joint modeling is not automatically exploratory. The analysis must identify its estimand, information set, shared causes, and anti-circularity controls, and must not describe a retrospective estimate as an advance prediction.

13.4.5 — Multistate Terminal Support, Atoms, and Diffuse Timing

A multistate endpoint model represents movement among declared protocol states such as open, low signal, candidate crossing, confirmed endpoint, return, resuscitation, competing event, censoring, withdrawal, device cessation, and unknown. Every state needs an operational meaning and an allowed analytic role (Fine & Gray, 1999; Fleming & Harrington, 2005).

History and dwell time matter. A crossing followed by return differs from persistent absence under high-quality observation, and sedation differs from low signal after technical failure has been excluded. Hidden semi-Markov structure can represent duration without turning the first low-access instant into finality.

Transition intensity and occupancy answer different questions: increased hazard of a terminal-support state does not imply

simultaneous individual entry, and high occupancy does not prove absorption. Both are reported so a population pattern cannot masquerade as a truth-level endpoint (Andersen et al., 1993; Aalen et al., 2008).

Absorbing status is versioned. A frozen primary classification may later enter error memory after recovery, while withdrawal, device cessation, and competing events can end observation or the study question without resolving mind absence.

Endpoint laws may be discrete, absolutely continuous, singular continuous, or mixtures of these; endpoint observations may be interval-censored, and the law may be only partially identified. When the last qualifying observation precedes the first verified nonqualifying state, preserving the bounded interval is stronger than manufacturing a timestamp.

The transition graph marks impossible, reversible, conventionally absorbing, censored, false-confirmed, and observation-shutdown paths. It is therefore both a statistical and governance device, recording how endpoint classification is earned, revised, lost, or withheld without confusing protocol states with the truth-level endpoint.

13.4.6 — Misaligned Clocks, Censoring, and No Estimate

Clinical events, unity-proxy crossings, observation shutdown, legal timestamps, detection, confirmation, and retrospective adjudication often diverge. The protocol preserves each clock and states which analysis uses it; collapsing them can make compression follow medication, device contact, last observation,

or administration rather than the endpoint object (Little & Rubin, 2019; Manski, 2003).

Sensitivity analysis jitters candidate times, compares clock alignments, and quantifies gaps by site, diagnosis, medication, and device. Dependence on a preferred clock narrows the result to the endpoint system.

Public reports name the endpoint class and uncertainty. Large, systematic, or transported gaps require an endpoint-system verdict or No adequate estimate before any terminal conclusion.

13.5 — Filtrations, No-Look-Ahead, and Endpoint Leakage

Filtering estimates a state from information available through the specified time; smoothing uses later observations to reconstruct an earlier state. An advance-prediction claim requires the prospective information set. A prespecified retrospective estimand may legitimately use smoothing, including in a primary analysis, provided the report states that information set and does not claim foresight.

A claim of preterminal prediction requires predictions computed from information available at each frozen prediction time. Filtering and forecasting must therefore exclude future observations and outcome-informed preprocessing. Smoothed trajectories may support a separately prespecified retrospective target, reconstruction, or sensitivity analysis; their primary or secondary status follows the analysis plan rather than smoothing alone.

Look-ahead leakage is not a minor statistical mistake. It can manufacture the very preterminal order the Law is supposed to predict. If future endpoint information helps shape the curve before the endpoint, the study may appear to have seen the ending coming when it merely smoothed backward from it.

$$\pi_t(i) = Pr\{S(t) = i | O_{\leq t}\}, \pi_t(i) = Pr\{S(t) = i | O_{\leq n}\}$$

13.5.1 — Prospective Filtration and Information Set

A prospective filter uses information available up to the current time. In an endpoint setting, it may update the probability that the

stream is open, low signal, candidate crossed, confirmed, or unknown based on observations that have already occurred. It does not know future return, later device review, or final clinician adjudication (Särkkä, 2013; Fleming & Harrington, 2005).

The prospective filter is appropriate for confirmatory claims about information available at a stated time, including anticipation and forecasting. A claim about preterminal dynamics reconstructed after observation ends may instead use a prespecified retrospective model. The latter must be reported as reconstruction, not as a signal known before the endpoint.

Filtering forces the program to confront real-time ambiguity. A case that looks obvious retrospectively may have been uncertain in the moment. The filter preserves that uncertainty rather than granting the past the knowledge of the future.

The filter's inputs must be documented: which channels were available, missing, or low quality; which clinical context variables were included; and which endpoint thresholds were frozen. That record makes the filtered estimate reproducible.

A filtered endpoint may be wrong. That is acceptable. The question is whether it was produced by the rule the study declared and whether its errors were preserved. Error memory lets the system improve without pretending all past filtered estimates were correct.

The prospective filter is the chapter's antidote to prophecy language. It asks only what could have been known, not what the ending later made obvious.

The filter should also preserve nondecision. A real-time classifier may output open, low signal, candidate, or unknown, and unknown should not be treated as failure of computation. In endpoint science, unknown can be the most accurate state because it preserves the information available at the decision time. A filter that always decides may be less scientific than one allowed to abstain.

13.5.2 — Retrospective Smoothing

A retrospective smoother uses later information to reconstruct earlier states. It can be valuable for clinical narrative, case review, secondary analysis, and classifier improvement. It can integrate return evidence, final device-quality audits, clinician notes, family reports, and later state information (Särkkä, 2013; Little & Rubin, 2019).

A smoother uses later observations to refine the account of an earlier trajectory. Report it as retrospective reconstruction and evaluate prospective forecasting from the information available at each prediction time.

Smoothing is especially tempting near terminal endpoints because future data can stabilize noisy states. A low-signal interval may be reclassified after return. A candidate crossing may be demoted after evidence of continuity. These revisions improve the case record while changing the analysis status.

Every endpoint figure should identify its information set. Labels such as filtered primary estimate, smoothed secondary reconstruction, retrospectively adjudicated onset, and versioned revision tell the reader whether future evidence entered. Without

that label, an apparently early terminal signal may be a reconstruction produced only after the ending was known.

Smoothers can also introduce bias if the future data are selected or incomplete. A case with rich post-event review may be smoothed differently from a sudden unobserved death. The smoother must carry observation and selection limits.

Retrospective smoothing may improve an earlier-state estimate, but it cannot show what was known at the prediction time. A prespecified primary retrospective analysis may use later evidence; a primary forecast may not. Tables, figures, and verdicts should identify both the analysis role and the information set.

Retrospective smoothing is most useful as a teacher for later prospective rules. If it repeatedly corrects filtered errors in a particular state, the next protocol can prospectively specify better features or windows. It becomes methodologically dangerous only when used to rescue the current primary test.

13.5.3 — Endpoint Leakage and Frozen Prediction Time

Look-ahead leakage occurs when information from after a time point influences the estimate, threshold, classification, or feature used before that point. In terminal research, leakage can make a preterminal trajectory look more orderly, more predictive, or more neutral than it was under prospective information (Hernán & Robins, 2020).

The simplest leakage is retrospective smoothing shown as if prospective. More subtle forms include tuning endpoint thresholds using complete trajectories, choosing a persistence

window after seeing return outcomes, selecting features that best align to terminal neutrality, or excluding cases because later evidence made them messy.

Look-ahead leakage is dangerous because it often looks like wisdom. The smoother fills gaps, reduces noise, and resolves ambiguity. The resulting curve feels scientifically mature. But if the primary claim was prospective, that maturity is borrowed from the future.

Auditing leakage requires a time-stamped pipeline. Each feature, classification, exclusion, revision, and figure should be labeled by the information set that produced it. If a step used future data, it cannot support a primary prospective claim.

Endpoint jitter tests help expose leakage. If a terminal result changes dramatically under small perturbations of detection time or retrospective adjudication, the claim is less stable than the smoothed figure suggests.

The no-leakage rule is not anti-interpretive. It allows hindsight where hindsight is declared. It simply refuses to let hindsight become the evidence that the model predicted.

Look-ahead leakage should be tested with deliberately damaged pipelines. The study can run a leakage-positive analysis as a negative control to show how much artificial order future information can create. If the leakage-positive curve resembles the claimed signature, the primary result needs especially strong separation. The false method becomes a teaching device for why the real method must stay strict.

Leakage can enter through preprocessing as well as explicit endpoint labels. Imputation models, denoising procedures, feature selection, and representation learning may all use information collected after the frozen prediction time. A valid prospective analysis therefore versions the entire pipeline, not only the final regression, and fits every data-dependent transformation inside the training fold or prospective window.

Nested evaluation is especially important when endpoint definitions, unity thresholds, or feature families are tuned. The outer split estimates transport to unseen cases; the inner split selects among candidate pipelines. Without that separation, a model can appear to predict terminal structure while merely remembering the particular endpoint construction used to optimize it. The error is methodological, not cosmetic, because it converts hindsight into apparent foresight.

13.5.4 — Primary and Retrospective Analyses

Primary endpoint analysis is the analysis that carries the main public burden of a study. It must use the endpoint rule, information set, thresholds, windows, and classification procedures declared before outcome inspection. Secondary analyses may explore alternatives, but they do not have the same status (Center for Open Science, 2025; Chambers, 2013).

This distinction is central for the Law because terminal patterns are easy to find retrospectively. If the primary analysis fails and a secondary smoother succeeds, the result is not confirmatory support. It may be hypothesis-generating, a clue for improved

endpoint design, or evidence that the primary rule was too crude. It is not the same claim.

The primary analysis should declare how it handles candidate, confirmed, revised, unresolved, and unusable endpoint classes. It should also state what happens when endpoint uncertainty exceeds the admissible band for the estimand. If the answer is abstention, that is a valid primary result.

Secondary analyses can examine alternative clocks, retrospective adjudication, persistence windows, state models, or family-report augmentation. Their status depends on what was prespecified and which target they estimate. Retrospective analysis is not automatically exploratory, but an outcome-selected refinement cannot replace a failed primary test and retain its confirmatory status.

The distinction protects the public from proof drift. A headline that merges primary failure and secondary insight misleads. A careful report can say that the primary rule did not support the claim, while a secondary analysis identified a possible endpoint refinement for future testing.

The strongest version of the program gives the primary analysis a fair opportunity to support, narrow, or challenge the tested claim, with the same reporting standards for each outcome.

The analysis plan should assign each output to a public-status lane before results arrive. Primary endpoints support the declared confirmatory question; secondary endpoints refine mechanisms, estimate sensitivity, or generate improved rules; exploratory endpoints suggest future studies. A reader should not need to infer

this hierarchy from tone. The table, figure captions, and verdict language should carry it explicitly.

13.5.5 — Last-Observation Alignment and Informative Shutdown

Last-observation alignment is a rival explanation in which apparent terminal structure arises because data are aligned to the moment observation stops rather than to truth-level endpoint. This can create false compression, false smoothing, or false terminal concentration if measurement cessation is driven by severity, device tolerance, or care workflow (Hernán & Robins, 2020; Little & Rubin, 2019).

The rival is plausible because terminal observation is fragile. Monitoring often becomes harder when physiology changes, family preference shifts, care intensifies, or devices interfere with comfort. If the study aligns all trajectories to the last usable measurement, it may be analyzing the end of measurement rather than the end of mind.

The endpoint chapter therefore requires last-observation analysis. Do candidate signatures align better with the unity-proxy endpoint or data-cessation clock? Are patterns similar when observation continues after candidate crossing? Do device failures produce comparable apparent compression?

Last-observation controls identify the contribution of alignment to the apparent pattern. A persistent result merits further comparison; a disappearing result informs the observation model; indistinguishable explanations remain unresolved.

This rival also protects comfort. If the study knows that data cessation is informative, it can stop without pretending that stopped data became an endpoint. The person's care remains prior; the model carries the lost information honestly.

Last-observation alignment turns a common data defect into a specific adversarial test. That is exactly what a serious science volume should do.

This rival matters even when endpoint science is strong because last observation can coincide with the moments most compelling to readers. A smooth terminal figure aligned to data exit may resemble discovery while being a workflow artifact. The chapter therefore puts last-observation alignment in the rival set before the first study begins.

13.5.6 — Public Reporting of Revision and Leakage Audits

Endpoint revision shows that the system can correct itself, but public reporting must show how claim status changed. It should identify the original classification and information set, later evidence, revised classification, and affected analyses while avoiding spectacle or consolation language about the person's death (Spiegelhalter, 2017; World Medical Association, 2024).

A leakage audit traces each datum by generation time, availability to the endpoint classifier, first analyst access, and derivation from ledger or outcome-adjacent variables. Event logs, separated teams, frozen outputs, and an independent integration step are stronger than retrospective assurances; where full separation is impossible, overlap and its consequences are documented. A timestamped provenance graph can reveal leakage paths that

prose descriptions miss, especially when derived variables cross team or software boundaries.

Preprocessing is part of the audit. Artifact rejection, smoothing, imputation, censoring, and quality thresholds may leak endpoint status when tuned on known cases, so versioned pipelines, locked parameters, and held-out stress sets must test whether the terminal pattern survives. Stress sets should include intentionally leaky pipelines so the audit can demonstrate that it detects contamination rather than merely confirming the preferred workflow.

The public record includes negative audit findings, unresolved channels, staff overlaps, and analyses downgraded because separation was incomplete. The audit states which channels were checked and what each check found. Publishing the downgrade rule in advance prevents partial separation from being reinterpreted after a favorable terminal pattern appears.

13.6 — Return, Resuscitation, and False-Ending Controls

Any system that classifies truth-level endpoint near the boundary of low signal, sedation, clinical intervention, or failing physiology must be prepared for return. Treating return as evidence lets the endpoint system improve and preserves the participant's actual recovery in the record.

Return after apparent cessation provides a practical test of an endpoint protocol. Resuscitation, autoresuscitation, delayed recovery, and reversible neurologic shutdown inform persistence and reentry rules and can require revision of an earlier endpoint classification (Dhanani et al., 2021; Greer et al., 2023; Parnia et al., 2023).

Return and resuscitation should update a state history, not erase it. The record should preserve the original candidate crossing, the evidence that supported it, the reentry or return event, and the revised classification. That sequence lets the protocol learn which persistence or marker assumptions failed while preventing later recovery from being used to pretend that the earlier endpoint decision was never uncertain.

The core moral rule remains simple: rescue and treatment come first. Emergency intervention does not serve the study. Research classification follows care. If care reopens an endpoint that the study thought closed, the study changes its record. The person owes the model no consistency.

The scientific value of false endings is large. They expose threshold fragility, state dependence, channel failure, and

overconfident irreversibility. A program that remembers its false endpoints becomes harder to fool.

13.6.1 — False Ending and Premature Crossing

A false crossing is a candidate endpoint event followed by evidence that the relevant stream remained or returned. The evidence may be behavioral, communicative, neurophysiological, clinical, or contextual. The term false crossing is deliberately technical. It does not shame the protocol; it describes an event class (Dhanani et al., 2021; Greer et al., 2023).

False crossings can arise from artifact, sedation, delirium, transient hypoperfusion, device failure, motor impairment, low arousal, or an endpoint threshold that is too brittle. They can also arise because the science of consciousness is incomplete. The endpoint system should learn from all of these causes.

A false crossing requires demotion of the earlier endpoint status. It may become a low-signal interval, a reversible interruption, an artifact event, or an uncertain state. What it cannot remain is a confirmed truth-level endpoint under the same version history.

False crossings should be counted and described. How many candidate crossings occur? How many later return? Which channels failed? Which clinical states were present? Which thresholds were most vulnerable? These data are classifier evidence, not merely exclusions.

A false endpoint can erase a living or returning stream from the analysis, mislead a family, and contaminate every terminal estimate built on the label. The protocol must therefore record false crossings, near misses, reversals, and their downstream

effects as system-level errors. Responsibility for the mistake belongs to the research system, not to the person whose state was difficult to classify.

False crossings are therefore not enemies of the program. They are one of the ways the program remains scientific.

False crossings are especially valuable because they reveal which combinations of channels imitate endpoint absence. They can identify medication effects, arousal fluctuations, device artifacts, and care-procedure disruptions. A mature program should publish false-crossing rates and examples, stripped of identifying details, because the classifier's failures are part of the scientific object.

13.6.2 — Resuscitation, Autoresuscitation, and Recovery

Resuscitation and recovery require special care because they can reopen what looked closed. A cardiac arrest, respiratory collapse, or severe neurologic crisis may be followed by restored circulation, consciousness, communication, or other continuity evidence. The endpoint record must be able to reverse itself without hesitation (Dhanani et al., 2021; Parnia et al., 2023).

The chapter does not treat resuscitation as a research opportunity. Emergency intervention belongs wholly to care. Researchers may record what happened only under ethical, consent, and burden rules. They may not shape rescue, delay rescue, or infer from rescue decisions that the endpoint question has been answered.

Recovery evidence can vary. Immediate command following is strong but not always available. Later communication may support continuity but can be affected by memory gaps, medication, delirium, or trauma. Physiological return may

constrain endpoint timing without directly establishing subjective continuity. The record should grade evidence rather than collapse it.

Resuscitation stress-tests the multiple-clock structure in §13.4: arrest and return, observation gaps, unity-proxy confidence, and ledger availability can diverge, so one endpoint timestamp cannot represent all four.

If recovery occurs after a candidate endpoint, the primary rule should state how the case is handled. It may become false crossing, reversible low-signal state, censored, unresolved, or excluded from primary endpoint analysis. The rule should not be invented after the outcome is emotionally or statistically attractive.

An endpoint model incorporates later recovery by correcting its record and preserving the evidence behind the revision.

Recovery also changes how endpoint evidence should be archived. The case should not be erased from the study as inconvenient; it should move into a recovery and reversal class with its original filtered state preserved. That lets later researchers ask whether the endpoint system failed because the threshold was too sensitive, the window too short, the channel too narrow, or the clinical context too unstable.

13.6.3 — Persistence, Hysteresis, and Reentry

Hysteresis means the rule for leaving a state need not be identical to the rule for entering it. Endpoint adjudication needs hysteresis because near-boundary signals can oscillate. Without reentry rules, a noisy channel can produce multiple candidate endpoints

in rapid sequence (Greer et al., 2023; Fleming & Harrington, 2005).

A simple threshold creates arbitrary endings when signal quality fluctuates. The system may declare candidate endpoint, then open, then candidate again, depending on noise, arousal, medication, or device contact. Hysteresis requires a stronger or sustained pattern before changing state back and forth.

Reentry rules should define how a stream moves from candidate crossing back to open, from low signal to candidate, from confirmed to revised, and from unknown to classified. These rules should be protocol-fixed, state-specific, and sensitive to clinical context.

Hysteresis is not a trick to avoid falsification. It can make the endpoint harder to confirm and easier to demote under return. Its purpose is to prevent noise from carrying formal authority. The rule must be tested through simulation and false-crossing memory.

The endpoint model should report how often classifications change under different hysteresis parameters. If the scientific result depends on a narrow hysteresis choice, the endpoint is fragile. If it survives plausible choices, the endpoint system is more credible.

Reentry rules reflect the varied ways living systems change state. They improve classification by preserving continuity evidence, reversals, and uncertainty.

Hysteresis should be tuned for scientific stability rather than aesthetic smoothness. A rule that is too strict may miss genuine

return; a rule that is too loose may oscillate with noise. The protocol should test hysteresis parameters on held-out examples and report how often endpoint status changes under plausible alternatives. Stability has to be earned, not assumed.

13.6.4 — Return Without Recall

Memory after return depends on encoding, consolidation, retrieval, language, and reporting capacity. An endpoint model evaluates these processes alongside other state evidence when interpreting a gap in recall (Squire, 2004; Parnia et al., 2023).

The distinction matters after resuscitation, anesthesia, delirium, coma emergence, and severe physiological crisis. A person may later remember nothing, remember fragments, confabulate, or report experiences shaped by recovery. Each possibility has different evidentiary status.

Credible recall can support continuity. The record preserves memory's contribution without using it as the sole exclusion rule for experience.

A returned person's memory, silence, confusion, or fragmentary account belongs to the protected case record and must be interpreted through memory, medication, injury, language, and time since recovery. It can revise scientific confidence about the earlier interval; it should not be converted into a public story about whether the Law was witnessed, disproved, or fulfilled.

Methodologically, memory gaps strengthen the case for contemporaneous, low-burden, noncoercive observation before and during boundary states. They do not authorize burdensome probing. When memory fails, the model carries uncertainty.

Return without recall can overturn a premature endpoint classification when the returned state is independently linked to the same stream under the declared routing rules. Amnesia does not by itself resolve that linkage or show that the intervening interval was empty. Report the return evidence, the revised endpoint status, and any remaining uncertainty about the gap.

13.6.5 — Competing Events, Refusal, and Withdrawal

Competing events must be defined relative to the study's event of interest: they preclude that event, whereas an interruption of observation alone does not. Transfer, discharge, device removal, refusal, withdrawal of consent, loss of capacity without adequate surrogate permission, clinical emergency, family request, or care procedure can all interrupt endpoint adjudication (Fine & Gray, 1999; World Medical Association, 2024).

Withdrawal is not failure by the participant. It is a right and a design condition. If a person or authorized process stops participation, the research model records the endpoint evidence as censored, unresolved, or unavailable under the rules. It does not infer closure from refusal.

Device removal is especially important. A sensor may be removed for comfort, clinical access, skin integrity, family preference, or operational need. Treating that removal as data about mind would convert care into endpoint evidence.

Each listed event's role should be specified in the estimand structure of the study. Is it a competing risk, a censoring event, an intercurrent event, an endpoint-disqualifying event, or a

secondary classification? The answer should be written before data are collected.

The distinction also prevents survivor bias and selective reporting. Cases with messy competing events may be less likely to produce clean terminal figures. If they disappear from the denominator, the endpoint system will look better than it is.

Competing events, refusal, transfer, device removal, and clinical necessity can terminate observation without terminating the stream. Each should be coded by cause and routed to its own censoring or no-estimate rule. None creates a missing interval that the theory is permitted to fill by imputation.

Withdrawal and competing events should be coded with reasons where ethically permissible. Refusal, discomfort, clinical necessity, transfer, family request, device removal, and administrative discharge carry different implications for missingness and endpoint uncertainty. Treating all exits as one censoring code hides the burden structure that this chapter is supposed to make visible.

13.6.6 — Error Memory and Protocol Correction

A false ending is evidence about the protocol, not an inconvenience to erase. Return, autoresuscitation, delayed recovery, renewed command following, or later testimony shows that a candidate endpoint, persistence window, observation rule, or routing assumption failed for that case (Dhanani et al., 2021; Greer et al., 2023).

The original classification and the evidence available at the time should remain immutable in the audit record. The corrected

classification is added as a new version with the trigger, reviewer, affected analyses, and reason for revision. Hindsight may improve a secondary reconstruction, but it must not rewrite what the primary model actually knew.

Protocols should prospectively specify return windows, competing events, reentry rules, and the circumstances that require a case to be reclassified or withdrawn from a terminal analysis. Different clinical contexts may require different windows; the choice must be justified before the outcome is known.

Correction must propagate through a dependency graph. Endpoint estimates, ledger calculations, figures, summaries, model fits, and public statements that relied on the false ending should be identified, rerun, qualified, or withdrawn. The person should not become a permanent error label simply because the research object changed. Dependency-aware correction can preserve unaffected analyses while preventing the false endpoint from remaining embedded in downstream estimates.

Original and revised analyses should be reported together when both are useful. The original analysis preserves the record of the prespecified information set; the revised analysis shows what later evidence reveals. Their difference is itself a measure of endpoint fragility. A large discrepancy between the two analyses should trigger review of which later information changed classification rather than being averaged into one endpoint estimate. For the paired comparison, all other prespecified analysis choices should remain fixed where possible, so the

difference isolates the effect of the new endpoint information rather than combining correction with model retuning.

Public correction should be prompt, specific, and proportionate. Participants, authorized representatives, clinicians, reviewers, and readers need to know what changed and which conclusions no longer hold, without sensationalizing the return or implying a metaphysical lesson (Center for Open Science, 2025). Correction notices should preserve the original date and affected version, allowing readers to distinguish a repaired record from a result that was never superseded.

Error memory makes the endpoint system stronger. A protocol that preserves and learns from false endings becomes less likely to repeat them and more capable of declaring no estimate when the available clocks cannot support a responsible judgment. Cataloging false-ending mechanisms can also improve design by showing which clinical or observation states most often generate premature endpoint confidence.

13.7 — Sudden, Diffuse, and Low-Signal Endpoints

Many endings will not supply the terminal window a researcher wants. Sudden death may leave no usable preterminal series. Low-signal states may produce artifact rather than evidence. Emergency care may correctly interrupt measurement. Sedation, delirium, and rapid decline may make signals ambiguous. The chapter treats these cases as central because they are where overconfidence is most tempting.

Sudden, diffuse, and low-signal endpoints can produce informative censoring, uncertain timing, or loss of usable terminal support. Sedation, delirium, emergency intervention, equipment removal, and rapid decline can jointly alter experience and observation, making no-estimate outcomes essential to valid inference (Little & Rubin, 2019; Surges et al., 2024).

Missing terminal data identify a concrete boundary for the current analysis. The study records the missing window or inadequate signal, reports its consequences, and uses that information to improve feasible future designs.

Unusable endpoint evidence is a substantive outcome. A case may be censored, unresolved, excluded from the primary terminal analysis, or retained only for feasibility and observation-process learning. The report should state why the case was unusable and what it still teaches, without forcing it into a favorable or unfavorable terminal narrative.

The humane logic is identical to the scientific logic. Emergency intervention, comfort, and dignity come first. If those priorities erase the terminal window, the study accepts the loss. It does not

ask the person to suffer for completeness or ask the model to pretend completeness remains.

13.7.1 — Sudden and Unobserved Endpoints

A sudden unobserved ending is a case in which the relevant terminal interval is missing or too sparse to support endpoint adjudication. The person may die suddenly, outside the measurement window, after transfer, after withdrawal, or during an event that prevents useful observation. The study may know that death occurred without knowing the endpoint state in the required sense (Greer et al., 2023; Little & Rubin, 2019).

This situation cannot be repaired by aligning to the last observation. The last observation may be hours, days, or weeks before the event, and its relationship to truth-level endpoint may be unknown. It can constrain what was observed, not what happened afterward.

Sudden endings are scientifically valuable for feasibility. They tell the program how often terminal windows are unavailable, which populations are difficult to observe, which care contexts make monitoring inappropriate, and whether the reference class can support the proposed study.

A study should report sudden unobserved endings in the denominator. Excluding them silently can make the endpoint system look more usable than it is. A reference class with frequent unobserved endings may require a different design or a narrower claim.

The public wording should be plain: no terminal endpoint verdict was available. This protects families from speculation and protects the theory from imputation.

Sudden death is therefore not a blank page for the Law. It is a boundary condition on what this research program can honestly know.

Sudden unobserved endings define the feasible reference class of terminal-window research. Their frequency determines how much of the population can ever contribute qualified terminal data and whether observed cohorts are selected toward slower, more monitored trajectories. Reports should therefore treat sudden cases as a scope and transport problem, not merely as missing rows.

13.7.2 — Diffuse Support, Low Signal, and Artifact

Near terminal states, signal quality can change with perfusion, device contact, movement, sweating, skin integrity, electrical noise, medication, clinical procedures, or physiology outside the qualified context of use. Classify these observation conditions before interpreting the signal (FDA-NIH Biomarker Working Group, 2016; Little & Rubin, 2019).

Quality thresholds should be declared by channel. A unity proxy may be unavailable if contact quality fails. A physiological marker may be unusable during movement or care. A device may produce clean-looking numbers that are physiologically meaningless under terminal conditions. The endpoint model must know the difference.

Low signal can also be a real state. A fading consciousness marker under adequate quality may be endpoint-relevant. The difficult task is separating true low signal from poor observation. That separation requires quality indicators, negative controls, clinical context, and abstention rules.

Artifact should never be corrected by desire. Imputation, smoothing, or manual cleaning may be useful only when rules are frozen and the procedure is labeled. If artifact dominates a candidate endpoint, the case may need to become unresolved or unusable.

A low-signal report should state what failed: sensor contact, biological signal, responsiveness, arousal, data cadence, clinical context, or model confidence. Different failures imply different revisions.

Low signal is an observation requiring classification: it may reflect the underlying state, poor observation quality, or both; it is not itself an endpoint. Reduced amplitude, missing channels, medication, impaired perfusion, movement, emergency procedures, device displacement, and genuine decline can produce similar records. Endpoint classification requires both quality criteria and contextual evidence; when those causes cannot be separated, the case remains unusable rather than being promoted to terminal support.

A low-signal branch should record which channel failed, when it failed, what competing causes were present, and whether any independent marker remained. Sensitivity analyses can then test whether conclusions depend on treating the interval as censored,

missing, or potentially conscious. None of those branches is equivalent to assigning low consciousness by the size of one signal.

13.7.3 — Emergency Intervention and Rescue Priority

Emergency intervention is categorically prior to endpoint inference. Rescue, stabilization, comfort, airway support, medication, resuscitation, seizure treatment, and hemorrhage control can interrupt measurement or destroy interpretability, and the study accepts that loss (World Medical Association, 2024; Greer et al., 2023).

Research never slows, times, or shapes urgent care. A protocol that depends on uninterrupted measurement during clinical need is both ethically and scientifically unfit.

The emergency event is still recorded on the clinical clock with its treatments, signal consequences, and missingness. It can explain candidate crossings or false endpoint classifications without becoming evidence of the truth-level endpoint.

Low signal, device removal, medication effects, and missing data may arrive together. The status system therefore returns competing event, censored endpoint, or no endpoint verdict rather than forcing interpretation.

Emergency care is a protected intervention, not a protocol deviation. Incidental data remain governed by prior consent, minimal burden, and later review; the event never becomes an opportunity to complete a terminal curve.

13.7.4 — Sedation, Delirium, and Rapid Decline

Sedation, delirium, and rapid decline are not interchangeable. Sedation can reduce arousal, memory, movement, report, and physiological variability. Delirium can fragment attention, perception, distress, and communication. Rapid decline can alter perfusion, metabolism, and signal quality. Each can mimic endpoint approach without being truth-level endpoint (Surges et al., 2024; Inouye et al., 2014).

Endpoint models should therefore carry state context. Medication class, dose timing, route, cumulative burden, delirium assessment where possible, pain or dyspnea treatment, infection, hypoxia, metabolic changes, and care goals may all matter. These variables are not nuisance notes; they are rival explanations.

A sedated low-signal interval may be a reversible drug effect, an ethically appropriate comfort state, a true reduction in consciousness, or a mixture. The endpoint system should not force one interpretation when the evidence cannot separate them.

Delirium adds another difficulty: experience may be present, intense, confused, and difficult to report. Treating delirious inability to communicate as absence of experience would be both scientifically unsafe and ethically dangerous. Distress may be hidden precisely when report becomes unreliable.

Rapid decline can compress observation opportunities. A model may see steep change and infer endpoint approach, but the same pattern may reflect systemic collapse, sensor gain, or medication. The correct response is rival modeling, not dramatic conclusion.

Sedation, delirium, and rapid decline require joint time-varying models because responsiveness, distress, memory, physiology, and data quality can change together. The analysis should compare medication, illness, arousal, sensor failure, and genuine endpoint explanations instead of treating every downward trace as approach to the truth-level end. When those explanations remain inseparable, the endpoint widens or becomes unavailable.

The scientific report should distinguish state change from confound change. Dose timing, delirium assessments, perfusion, respiratory status, pain control, device quality, and observation frequency can reveal whether an apparent decline reflects consciousness evidence, measurement deterioration, or both. Comfort remains prior even when the additional clinical information cannot recover an estimate.

13.7.5 — No Imputed Closure

No imputed closure is the rule that missing terminal data cannot be filled with the hypothesis. If the endpoint is unobserved, unresolved, or unusable, the study may not declare that the ledger reached neutrality because the Law predicts it. That would be circularity in its most direct form (Little & Rubin, 2019).

Imputation can be legitimate in ordinary statistical work when assumptions are explicit and the estimand permits it. Endpoint closure is different because the missing value is the claim. Imputing it from the claim under test destroys falsifiability.

The rule applies to whole-life closure, terminal neutrality bands, preterminal signatures, and endpoint classification. A missing terminal window cannot be replaced by a smooth curve to zero. A

low-signal interval cannot be labeled neutral because it is near death. A sudden ending cannot be counted as supportive because the model expects closure.

Imputation requires an explicit observation model, assumptions appropriate to the estimand, and uncertainty propagation. A prespecified primary analysis may use defensible imputation, accompanied by sensitivity analyses. It may not impose terminal zero, a favored trajectory, or the hypothesis under test on the missing observations and then count that imposed result as evidence. If plausible missingness assumptions change the verdict, report that dependence or abstain.

Public communication must resist filling missing data with stories of mystery, peace, hidden balance, or spiritual confirmation. The correct statement is narrower: the terminal evidence was unavailable or insufficient, so the scientific claim remains limited.

No imputed closure applies in figures or text. A plot does not draw a graceful terminal line through an unobserved interval unless it is labeled as simulation, sensitivity, or imputation, and a table does not convert an unusable endpoint into a neutral one for completeness.

13.7.6 — Unusable Endpoint and No Adequate Estimate

Sudden death, diffuse decline, heavy sedation, delirium, low signal, missing sensors, late enrollment, or observation shutdown can leave the truth-level endpoint outside protocol support. Report it as unusable rather than assigning zero or imputing favorable closure.

Apply the evidence-state distinctions in §24.2 and §27.4 to endpoint uncertainty. A defensible interval of endpoint times may support branch-specific or set-valued analysis, while inseparable adequate endpoint, routing, or missingness models remain Model-ambiguous (Manski, 2003).

State missingness assumptions. Carried-forward values, smooth extrapolation, favorable terminal imputation, and complete-case analysis can mimic stable endings after informative observation loss. Test plausible selection and pattern-mixture models in sensitivity analyses (Little & Rubin, 2019).

Retain difficult endpoints and unfavorable residuals in the accounting. Report unusable-case counts, reasons, differences by site, state, treatment, or access, and each restriction's effect on the reference class and denominator.

A peaceful appearance, flat trace, last word, or family narrative can hold personal meaning while leaving the terminal phenomenal state unidentified. Report the failed layer: terminal support, routing, clock alignment, observation, bridge validity, or burden-driven shutdown.

A no-estimate outcome defines the remaining population and the next protocol's repair task. It also prevents universal terminal conclusions from resting only on easily observed cases.

13.8 — Comfort-First Care and No-Estimate Outcomes

Chapter 3’s comfort-first rules govern this entire section. The local endpoint consequence is precise: care, refusal, family burden, or clinical duty may close observation, and the resulting record must move to the appropriate qualified, censored, unresolved, unusable, or no-estimate state rather than forcing a terminal value. Endpoint governance must therefore carry evidence class, permitted use, uncertainty, correction route, and care boundary together (World Medical Association, 2024; Council for International Organizations of Medical Sciences, 2016; Sanders et al., 2024).

A terminal evidence class describes the endpoint information available to a protocol. Qualified, revised, unresolved, censored, and unusable classifications identify the analyses the record supports and the questions that remain open.

Governance therefore has to be both scientific and humane. It must define evidence classes, protect family and clinician language, route formal definitions to the formal-law book, route evidence status to this volume, and prevent public artifacts from turning endpoint science into spectacle.

Table 13.3. Endpoint evidence classes and public-status restraints.

Endpoint evidence class	Allowed public status	Required restraint
Qualified endpoint	May support the declared analysis within its reference class.	No claim of an exact truth-level endpoint or personal meaning.

Endpoint evidence class	Allowed public status	Required restraint
Unresolved endpoint	May inform feasibility, uncertainty, and future design.	No positive or negative terminal verdict.
Unusable endpoint	May count in denominator and operational evaluation.	No imputed closure or anecdotal use.
Revised endpoint	May update the versioned record and secondary analysis.	No rewriting of primary prospective evidence.

13.8.1 — Comfort-First Care

The comfort-first rule is not a slogan. It is a stop rule. Measurement stops when care requires access, when devices burden the person, when the person refuses or withdraws, when family involvement becomes harmful, when clinicians judge the protocol disruptive, or when dignity would be compromised by continued observation (World Medical Association, 2024; Sanders et al., 2024).

The rule applies even when stopping makes the endpoint unusable. A research program that cannot tolerate lost data will be tempted to make people serve its completeness. This chapter reverses the burden: the model must tolerate loss so the person does not have to tolerate unnecessary burden.

Comfort-first design also means that endpoint protocols should be built around minimal burden from the beginning. Passive or clinically integrated observation is preferable to intrusive prompting. Any active measurement must have explicit burden

caps, withdrawal routes, and staff authority to pause or stop without research permission.

The rule does not make the science weak. It makes the reference class honest. If comfort-first constraints prevent certain endpoint claims, the claim narrows. A narrowing forced by ethics is not a defect. It is the condition under which the research remains worth doing.

Comfort-first stopping must be recorded without blame. The endpoint status may become censored, unresolved, or unusable. The record should say care required stopping, not that data were lost because of noncompliance.

The dying person owes no final measurement. That sentence is the ethical center of the chapter and the practical boundary of its science.

13.8.2 — Refusal, Family Welfare, and Clinical Communication

Family and clinician communication must prevent endpoint language from becoming prognosis, consolation, pressure, or interpretation. A family should not hear that a candidate crossing means the person is gone. A clinician should not hear that a terminal study wants monitoring continued against care judgment. Research vocabulary must remain research vocabulary (Council for International Organizations of Medical Sciences, 2016; World Medical Association, 2024).

Use the endpoint status terms defined in §13.2 consistently in family and clinical communication, linking each classification to its meaning for the observation and care setting.

Family narratives can be evidence in some contexts, but they are not clean endpoint labels. Last words, apparent lucidity, silence, agitation, peacefulness, or remembered signs may matter clinically and relationally. In research, they require denominator, selection, timing, and interpretation limits.

Clinicians need a separate channel for concerns. If research terminology confuses care, increases family anxiety, or creates pressure around monitoring, the protocol should pause or stop. The endpoint system exists inside clinical trust, not above it.

Communication materials keep death spectacle, proof language, and emotional manipulation outside the scientific record. Their tone must be clinically useful, gentle enough for families, and exact enough for later audit.

Families may be told that data are incomplete, that a protocol endpoint was or was not adjudicated, and that uncertainty remains. Model probabilities are not translated into reassurance, blame, a promise about inner life, or an interpretation of what a death meant; those categories belong to evidence status, not consolation.

13.8.3 — Endpoint Evidence and No-Estimate Classes

Endpoint evidence classes identify which analyses the record can support. Qualified endpoint evidence may enter the prespecified primary analysis appropriate to its estimand and information set. Later information may support a declared retrospective reconstruction but cannot create an earlier forecast. False crossings record protocol error; unresolved, censored, or unusable

endpoints restrict or prevent the affected terminal claim (Greer et al., 2023; World Medical Association, 2024).

Each class must carry provenance and permissions: rule version, channels, information set, clinical context, observation quality, confidence, revision history, allowed analyses, and prohibited public interpretations. The class is an evidence contract, not a decorative label.

Class structure governs the reference claim. A hospice cohort with many independently qualified endpoints and an emergency cohort dominated by sudden unobserved endings support different inferences even when their nominal sample sizes match. Denominator flow should show how many cases entered each class and which transitions occurred.

The same endpoint classes appear in reports, figures, summaries, and public artifacts. Mixed-class figures identify their composition, and claims based on qualified endpoints disclose the unresolved, censored, revised, and unusable cases excluded from support.

The class set should remain small enough to audit while preserving every distinction that changes inference. Sensitivity analyses should show whether conclusions change when retrospective or lower-quality classes are included, excluded, or reclassified, making the selection mechanism visible rather than hiding it behind one final sample size.

Endpoint classes connect the available evidence with a specified scientific use. Their definitions and revision rules make that connection clear to readers.

13.8.4 — No Endpoint Verdict as Personal Meaning

Scientific reporting can describe what was observed, how an endpoint was classified, and which uncertainties remain, while families and communities retain the space to understand the life in their own terms (Parfit, 1984).

Graphs, last signals, false crossings, and peaceful accounts can invite narrative closure. The report resists that pull by keeping every sentence tied to the observed object, its uncertainty, and its permitted use.

Families, communities, and spiritual traditions may find meaning through their own relationships and practices. Scientific endpoint reporting contributes a clearly defined account of the observations.

The boundary survives every scientific outcome. Support for PTVC would not authorize death interpretation, and defeat would not subtract dignity from any life. Detachable public language therefore says that evidence was classified, revised, or unavailable, never that a life was balanced, redeemed, or explained.

13.8.5 — Scientific, Legal, and Spiritual Boundaries

Formal and empirical changes travel through different authorities. A revision to the truth-level endpoint or strict-pre-endpoint domain belongs to the formal root and requires controlled concordance. A revision to an estimator, persistence window, evidence class, or adjudication rule belongs to scientific method and changes the evidence status. Clinical ethics governs care

throughout; no layer silently rewrites another (World Medical Association, 2024).

Hard cases often revise the empirical bridge rather than the formal target. A return may show that a threshold or confirmation rule was wrong. New boundary-state evidence may improve unity proxies. Neither result, by itself, settles the truth-level endpoint or the formal identity of a stream.

Formal change control should be rare, visible, and justified. Empirical updates should be expected, versioned, and tied to evidence. Confusing those two processes lets the project escape defeat by redefining the target, or lets a measurement failure falsely weaken the formal hypothesis.

Clinical, legal, scientific, and spiritual systems answer different questions. Clinicians direct care, law records institutional status, science classifies evidence under a protocol, and families or traditions may carry meaning. An endpoint estimate does not inherit the powers of those neighboring systems, and none of them supplies the scientific endpoint merely by naming an ending.

Change propagation should follow the layer that changed. A new formal definition triggers concordance across the model and series; a new endpoint estimator triggers reanalysis, versioning, and public correction within the scientific program. Keeping those routes separate prevents an operational difficulty from quietly redefining PTVC and prevents a formal clarification from being mistaken for new empirical support.

13.8.6 — Observation Shutdown, Correction, and Public Stop Gate

Observation shutdown is a protocol event, not a truth-level endpoint. Record why monitoring stopped and keep endpoint adjudication separate.

Care, refusal, family privacy, and clinical capacity outrank data completion. Preserve the last valid information set and the missingness consequences; return Unusable evidence, Inconclusive evidence, or No adequate estimate according to the canonical evidence-state rules rather than extrapolating.

If later evidence changes the admissible endpoint model, correct dependent analyses through Chapter 28. Audit whether stop rules were applied consistently across sites and populations so selection introduced by shutdown is reflected in the reference class.

Part V — Study Families and First Tests

A study family translates a formal claim into an empirical design. Earlier Parts established scientific jurisdiction, the formal target, representation and measurement, stream identity, and endpoint discipline. This Part connects those dependencies to populations, instruments, estimands, rivals, burden limits, decision rules, and stopping routes. Each design identifies the evidence needed to develop, replicate, revise, or retire a component.

Part V asks what the first humane, protocol-fixed, decision-relevant test should look like. Its scientific strength comes from fixing the target objects, measurement conditions, outcome branches, stopping rules, and next actions before outcome inspection (Nosek et al., 2018; Munafò et al., 2017).

Research burden is part of the data-generating process. Fatigue, workflow, privacy, staff capacity, device discomfort, consent, refusal, and comfort can change who remains observed and what the record means; evidence obtained by compromising care is methodologically contaminated.

The first protocol therefore fixes a reference class, measurement stack, endpoint clocks, estimands, intercurrent-event handling, rival models, burden budget, missingness branches, decision thresholds, and adverse-result language before enrollment. Its simulation gate can cancel recruitment when the planned cadence, sensors, endpoint uncertainty, or missingness pattern cannot separate the candidate from its strongest rivals. A runnable study is not automatically an informative or permissible study (International Council for Harmonisation, 2019; Chan et al., 2025).

The first setting is selected for measurement quality, feasibility, and participant comfort. In a late clinical window, the primary questions concern the observed dynamics and the models that explain them.

The second study family examines sleep, dreams, and affective reprocessing. It asks how state-specific affective dynamics can inform testable hypotheses through optional reports, physiological measures, and comparison with established sleep science. Privacy and participant comfort shape the observation plan.

The third study family converts the reserve-coupled route and neighboring candidate routes into exposed predictions. It asks whether independently measured horizon and capacity variables carry the boundary-rate, dispersion, covariance, and intervention signatures that the route requires, and whether equally informed rivals reproduce them. Reserve is a candidate state, not worth, prognosis authority, or a reason to narrow anyone's care.

The fourth study family follows experience-related constructs over longer periods without pretending that a long record is a complete stream. It confronts delayed entry, sparse windows, treatment change, informative observation, device and language drift, competing events, transport, and the privacy cost of being followed. Longitudinal evidence becomes useful only when the conditions under which a person was visible remain part of the scientific object.

Here scientific character appears as method. Prospective specification, negative controls, model recovery, missingness

analysis, versioning, replication, and publication of adverse results are the instruments by which the program states what can count against it before enthusiasm has a result to protect. They convert openness to correction from a promise into a design property.

The Part's strongest contribution is an architecture in which support, narrowing, rival victory, unusable evidence, ethical stoppage, and defeat all produce defined scientific consequences. *The Law of Fairness* becomes more serious when those branches remain real after the work becomes expensive. A hypothesis gains content by exposing the conditions under which it must become smaller, change route, or yield. Predefining those consequences also protects later teams from sunk-cost pressure when a costly protocol reaches an unfavorable branch.

For statisticians and methodologists, the program asks for discrimination rather than a favorable association. The design must survive protocol-fixed rival comparison, generator and model recovery, negative controls, observation-process modeling, and reference-class limits. The relevant question is whether the complete pipeline can distinguish a candidate signature from the processes that mimic it, not whether one coefficient points in a preferred direction. Discrimination should be evaluated on simulated and empirical cases where rivals are intentionally hard to separate, not only on easy benchmark worlds.

The first studies can establish measurement foundations, distinguish candidate routes, and identify the observations that make stronger tests possible. Clear reporting of methods and

results lets readers follow those advances and understand how each stage prepares the next. A result that improves the next design can be valuable even when it leaves the target hypothesis unchanged, because dependency knowledge is itself cumulative.

The four chapters carry the science outward in complementary directions. The first protocol builds a decision system; sleep and dream studies open a repeated-state laboratory; terminal-window studies test route-specific restrictions; and longitudinal designs expose how observation changes across time. Each study family must alter the status of a declared component without manufacturing the answer through its scale, endpoint, sample, or missingness rules. Using a common status vocabulary across the four families will make later synthesis possible without treating unlike evidentiary roles as interchangeable.

Chapter 14 — The First Discriminating Protocol

The first discriminating protocol begins with the smallest humane question capable of changing scientific status. Terminal dynamics, felt experience, and conscious unity call for tighter identification and lighter burden, not a rush toward vulnerable moments. The design therefore tests prospective preterminal structure and held-out rival performance before any attempt at complete-stream adjudication.

The proposed design is observational, staged, and comfort-first. It never induces pain, withholds or delays care, alters medication for research, or manipulates expectation. It asks whether a qualified measurement stack and independently adjudicated endpoint support a bounded inference in one reference class. Protocol content, consent routes, burden limits, and stopping rules are fixed before enrollment. SPIRIT 2025 formally applies to randomized-trial protocols; here its relevant checklist principles are used only as a voluntary rigor framework, alongside current good-clinical-practice principles and the Declaration of Helsinki (Chan et al., 2025; International Council for Harmonisation, 2026; World Medical Association, 2024).

The protocol record fixes every estimand, endpoint, rival, burden ceiling, stopping rule, and public result branch before outcome inspection. Apply §6.7's prospective-specification terminology to that record. A statistician should be able to locate the estimands, a clinician the burden and stop rules, an ethics reviewer the recruitment and consent gates, and a public critic the branches that prevent favorable results from receiving special treatment.

The first decision-relevant question is deliberately not the strong latent claim. No late-window study can identify a whole-life

ledger unless an independent initial-ledger bound or lifelong bridge has already been specified before outcome inspection. This protocol therefore treats terminal-level equivalence as secondary and conditional. Its primary work concerns prospectively defined preterminal structure: reserve interactions, variance behavior, filtered prediction, and out-of-sample comparison with serious rivals.

This restraint makes the study more severe, not less ambitious. A design that separates a reserve-linked dynamic from ordinary homeostasis, endpoint-conditioned bridges, frailty, medication effects, observation shutdown, and none-of-the-models data is more informative than one dramatic terminal curve. The scientific achievement is a result branch that survives comparison without depending on a compelling scene.

Burden accounting belongs inside the analytic design. The relevant questions include who carries the measurement, who can refuse it, which care and privacy costs the observation creates, and which clinical or family labor remains hidden behind the data. A study that cannot represent its own burden cannot interpret the trajectory it helped produce.

The protocol also treats clinical context as a data-generating process rather than background color. Medication, palliative sedation, analgesia, delirium, disease trajectory, family presence, prognostic awareness, cultural death scripts, site routines, device tolerance, staff workload, and sensor quality can all shape the observed trajectory. Some are confounds, some are competing explanations, some are ethical stop signals, and some are reasons

for no-estimate status. None may be ignored because it complicates the story.

The recruitment gate is absolute. No participant may be recruited through crisis, treatment dependency, aid dependency, family pressure, platform belonging, religious belonging, transition participation, fear of losing care, or desire to please an institution. Consent cannot be bundled with ordinary care, public services, spiritual participation, civic participation, operational records, or Artificial Intelligence training permission. A protocol that benefits from dependence has converted vulnerability into leverage. The recruitment record should document the contact pathway and any authority relationship between recruiter and participant, so compliance with this gate can be audited rather than inferred from consent paperwork alone.

The analytic gates are noncompensatory. The endpoint system must avoid defining itself through ledger behavior; the candidate momentary-valence estimator must already be qualified for the clinical context; the reserve proxy must add information beyond severity, prognosis, treatment, and observation quality; and model-recovery studies must show that candidate, rival, hybrid, and open-set worlds can be distinguished at the proposed burden. Later predictive performance cannot rescue an earlier identification failure. Each gate should therefore have a prospectively declared decision rule and failure consequence, preventing downstream performance from relaxing an upstream requirement after results are visible.

Section 14.7 applies the protocol's distinct Unusable evidence, No adequate estimate, Inconclusive evidence, and Model-

ambiguous branches. Each branch identifies a different next measurement or design problem without being counted as support or defeat. The frequency and recorded reasons for these branches should also be reported across sites and cohorts, because recurring no-estimate or model-ambiguous outcomes may indicate a systematic limitation in the measurement or design architecture rather than evidence about the candidate Law itself.

Public reporting is part of the protocol. A protocol-fixed report template should require participant flow, methods, deviations, nulls, adverse feasibility findings, rival wins, model-recovery failures, missingness branches, endpoint revisions, and correction routes regardless of outcome. STROBE supplies the primary reporting discipline for this observational design, while CONSORT 2025 contributes useful flow, harms, and transparency checks for any later randomized extension. No public artifact may convert individual trajectories into spectacle or imply that a measured pattern reveals worth, destiny, holiness, rank, or completion (von Elm et al., 2007; Hopewell et al., 2025). A fixed template also reduces selective emphasis by requiring the same outcome categories whether the preferred model wins, loses, or cannot be adjudicated. Using the same template across supportive, adverse, and unresolved branches also gives independent teams a stable reporting object for replication and correction.

The first protocol estimates named components in one declared reference class under one frozen measurement version, endpoint system, and rival set. That bounded task is the form in which a result can be replicated, challenged, transported, or defeated. A

conclusion that exposes every bridge on which it depends is scientifically stronger than a sweeping claim that cannot identify its measured object. This boundedness makes disagreement productive because critics can challenge a specific bridge without reconstructing the entire program. That specificity lets later studies strengthen, replace, or retire one bridge without pretending that an untouched component has changed status.

Section 14.7 fixes the status and next action for every admissible exit, and the action map is published with the protocol so readers can verify that consequences were not chosen retrospectively. Publishing the map prospectively also gives replication teams a common decision rule for comparing outcomes across sites and versions.

14.1 — The First Decision-Relevant Question

The first study evaluates a bounded late-window process with declared instruments, an endpoint system, and explicit rival models. Its purpose is to identify which observations can most inform the next research decision (Nosek et al., 2018; Chambers & Tzavella, 2022).

The decision-relevant question therefore concerns prospective preterminal structure. The study asks whether a reserve-linked dynamic conjunction improves held-out prediction and rival discrimination in a bounded palliative reference class. That wording keeps the protocol close to what it can actually test. It also keeps the program from treating a beautiful terminal graph as a complete life-level verdict.

A negative answer remains decision-relevant. Candidate failure narrows the route; observation-shutdown explanations return the measurement program to development; endpoint uncertainty gives endpoint work priority; and excess burden stops the clinical study. These branches are the mechanism by which the design remains vulnerable to evidence rather than immune to it.

Placed between prior qualification and later replication, the protocol is a staged feasibility-and-discrimination study. The measurement stack must already be usable in the target clinical state, while transport, calibration, and site dependence remain tasks for independent replication. Its question is whether the program should proceed, narrow, or stop.

Table 14.1. Protocol objects, inferential roles, and claim ceilings.

Protocol object	Primary role	What it can update	What it cannot update
Preterminal dynamic conjunction	Primary confirmatory target	Reserve-linked drift, innovation, variance-shape, and held-out rival comparison in the declared reference class	Exact latent closure, whole-life balance, personal meaning, legal or spiritual status
Terminal equivalence band	Secondary target	Compatibility of the measured estimator with a declared band after origin, endpoint, and observation gates pass	Instrument-free equality or a whole-life terminal ledger
Endpoint model	Eligibility for inference	Whether the stopping system is independent enough to support terminal-window analysis	truth-level stream endpoint as ontology or clinical/legal death
Feasibility and burden outcomes	Gate before expansion	Whether recruitment, observation, and clinical workflow are ethically and operationally viable	Any proposition about the truth or falsity of the Law by themselves

14.1.1 — Primary Scientific Question

The primary scientific question is whether the protocol-fixed reserve-linked dynamic conjunction improves held-out predictive and generative adequacy over strong rivals under a common observation model. It is not whether a person's complete life has reached exact neutrality. The first question has estimands, comparators, failure conditions, and a next action; the second depends on unsolved whole-life and measured-to-latent bridges (Nosek et al., 2018; Chambers & Tzavella, 2022).

The conjunction should include nonredundant components that fail differently: a reserve-by-state interaction, a prospectively specified dispersion restriction, filtered prediction of a held-out interval, observation-process diagnostics, and negative-control behavior. A negative drift, smooth terminal curve, or interval overlapping zero cannot carry the package. The point of heterogeneity is to force bridges, frailty, treatment, selection, and ordinary regulation to explain the same frozen fingerprint.

The phrase held-out prediction matters. A model that explains the terminal pattern after observing it has not earned the same status as a model whose parameters, thresholds, and preprocessing were fixed before the held-out window. The first study must therefore separate training windows, validation windows, and confirmatory windows before any endpoint result is seen.

The primary analysis should be comparative rather than ornamental. The candidate model is tested against ordinary homeostatic mean reversion, endpoint-conditioned bridges, frailty and age decline, medication and sedation processes,

observation shutdown, and flexible time-to-endpoint models. A rival is favored when it meets the protocol-fixed victory criterion; adequate candidate and rival models that remain inseparable yield Model-ambiguous.

The study evaluates aggregate and model-level behavior within a declared reference class. Any individual compatibility estimate is reported as a statistical object under the protocol's participant-protection rules.

A favorable answer would raise the status of one component program. An adverse answer would weaken or retire the tested empirical bridge. This is the right opening question because it can redirect the scientific path without pretending to settle every possible boundary architecture.

14.1.2 — Why Not Begin With Exact Terminal Zero

Exact terminal zero is the wrong opening estimand because the relevant origin is not instrument-given. A late-window measurement system can be standardized, calibrated, and linked, but standardization does not create an independent origin for a whole-life latent cumulative process. A terminal value cannot be interpreted as exact closure unless the origin problem has been solved before the terminal result is inspected (Hernán & Robins, 2020).

The pre-enrollment ledger is also unknown. A person entering a palliative study brings a whole lived history that the study has not observed. Resetting the ledger at enrollment would turn the study into a local-window analysis while allowing public language to

sound like a whole-life claim. The protocol must carry that unknown initial term explicitly.

Endpoint uncertainty creates a third barrier. The conceptual endpoint, the candidate crossing, the detection time, and the retrospective adjudicated time are not the same object. If the analysis chooses the endpoint after seeing which window looks most neutral, the terminal-zero claim becomes circular. The endpoint must be declared through independent channels and stress-tested by jitter and revision rules.

Measurement error creates a fourth barrier. A physiological estimator can concentrate near a band for reasons that have nothing to do with the latent claim: attenuation, sensor removal, sedation, reduced movement, decreased observation intensity, changing calibration, or endpoint-conditioned selection. A measured value near zero is not exact neutrality unless the observation model has survived its own tests.

Beginning with exact zero would also distort ethics. It would tempt the research team to seek the cleanest terminal window, the most complete final record, or the most symbolically satisfying ending. A comfort-first protocol must do the opposite. It must allow missing terminal data, device removal, refusal, sedation, rescue, and no-estimate endings without treating them as obstacles to be overcome at the bedside.

Terminal-regime concentration or equivalence may remain secondary targets, but they do not lead the design. The opening study begins where evidence can be prospective, comparative, and less dependent on arbitrary origin: preterminal dynamics,

reserve coupling, observation-process behavior, and rival discrimination.

14.1.3 — Component Claims Under Test

The protocol decomposes the program into independently reportable components. The measurement component tests whether the candidate momentary estimator identifies its protocol-fixed interval target in the clinical context; the reserve component tests an independently constructed capacity state; the endpoint component tests the adjudication firewall; the observation component tests informative visibility; and the dynamical component compares held-out candidate and rival performance. Each component keeps its own estimand, error rule, and verdict ceiling (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

The dynamical component asks whether the candidate reserve-linked model improves prospective prediction over rivals. Its result informs further development of the mathematical realization in the declared setting.

Each component has a corresponding decision. Measurement failure directs instrument development; endpoint failure directs stopping-rule revision; rival superiority directs review of the tested mechanism.

Each component receives its own status. Recruitment may be feasible while measurement recovery fails; the endpoint system may be usable while reserve coupling disappears; a reserve association may survive while the observation process explains the same pattern. Those are different scientific outcomes with

different repair paths. Compressing them into one favorable or unfavorable headline would erase the information the protocol was built to obtain.

Component separation also protects participants. If a burden measure fails, the study stops or narrows before additional terminal recruitment, even if the statistical model looks promising. Ethical feasibility is not a secondary appendix to scientific success. It is a noncompensatory prerequisite.

The final report names every component that moved and every component that did not. If only a measurement bridge survives, the public sentence identifies that bridge, the population, the protocol, the rivals, and the unresolved prerequisites. Component-level evidence is most useful when it is not inflated into a statement about the whole Law.

14.1.4 — Reference Class

The first reference class should be narrow enough to be clinically coherent. A plausible starting point is adults receiving specialist palliative or hospice care at participating sites, with prognosis windows appropriate to observation, and with care teams able to support optional, low-burden participation. That is a reference class, not a human universal (Nosek et al., 2018; Chambers & Tzavella, 2022).

The eligible setting must allow research participation to remain separate from crisis, unstable care access, coercive dependence, and urgent clinical decision making. Sites unable to protect comfort, refusal, or staff attention are outside the first protocol even when their populations are scientifically important. This

boundary limits what can be learned now; it does not diminish the importance of people or conditions excluded from the initial design.

The reference class must include site, diagnosis, prognosis, care model, language, communication access, medication context, and consent pathway. A hospice site with strong family support is not interchangeable with an emergency department, a prison infirmary, an unsupported home death, or a low-resource region. Transport beyond the reference class must be earned later.

The registry should identify the populations and endpoint pathways the study does not represent. Sudden deaths, pediatric populations, nonhuman streams, artificial candidates, resuscitation pathways, deaths outside organized care, and settings without qualified endpoint review require distinct designs. Naming those absences prevents a local result from being translated into a universal statement by omission.

Reference-class discipline is part of fairness. People outside the first study should not be absorbed into its public conclusions. The hidden burden of overgeneralization falls on those whose conditions were not represented, whose access differed, or whose endings did not resemble the sampled pathway.

The first study reports its findings within the declared clinical population. It identifies the empirical bridge tested, the evidence supporting or challenging that bridge, and the populations or settings in which replication would be most informative.

14.1.5 — Decision Relevance

Decision relevance means that every major result changes a predeclared scientific action. A favorable component result may justify independent replication; a rival victory may retire the candidate realization in that reference class; measurement failure may redirect resources to instrument development; and an unacceptable burden profile may close terminal recruitment. The protocol therefore registers its action map as carefully as its estimands (Chan et al., 2025; Hernán & Robins, 2020).

Decision relevance also requires bounded ambition. This protocol is a gate, not a container for all future public belief. It asks whether the next gate should open, close, or be rebuilt. A design that claims to settle the theory would create more ethical and interpretive burden than its evidence could justify.

The decision branches should be written in the prospective specification rather than composed for the press release. If the candidate wins on a subset of estimands but loses on observation-process checks, the public wording must be already constrained. If model recovery is inadequate, the result is unusable even if the observed pattern looks favorable.

The protocol must define resource consequences. A failed pre-enrollment recovery benchmark blocks the proposed design. Investigators should distinguish a remediable lack of resolution from structural nonidentification, then test any revised sample size, cadence, or measurement plan in simulation under the same burden limits. Recruitment resumes only after the redesigned benchmark passes. An adverse burden result suspends expansion,

and a rival victory cannot be answered by adding flexible candidate parameters without declaring and testing a new version.

A decision-relevant protocol makes humility operational. It is not enough to say that negative results will be welcome. The study must specify what negative results do. It must let the Law become smaller, less public, more conditional, or scientifically retired in the tested form.

14.1.6 — What the Study Cannot Establish

The first protocol evaluates measurement, endpoint, route, and comparator questions within its declared reference class. The registry and study reports identify those questions and the evidence used to answer them (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

The study reports late-window dynamics. Any complete-history extension uses an independently qualified initial-ledger bound or lifelong bridge specified before data inspection. The report should separate conclusions supported by the observed late window from those that depend on the additional historical bridge.

Participant data contribute to scientific models under consent and governance. Personal meaning remains with the participant. Optional qualitative accounts can accompany the scientific record without being converted into latent-state labels the participant never authorized.

It cannot authorize clinical care changes. Comfort care, pain relief, sedation, rescue, communication, and family support remain prior to the study. The protocol's conclusions cannot justify delaying care, increasing measurement, or altering

treatment in pursuit of cleaner data. Care events that interrupt measurement should be recorded as part of the observed process, not treated as deviations to be corrected away.

Applications in civic design, government, law, religion, transition, artificial intelligence, and ordinary life are evaluated through the evidence and authority appropriate to each domain. A scientific result can constrain factual premises in those domains without transferring the study's decision rule or authority into them.

A study cannot rescue itself by changing scope after failure. The public result must name the failed object, and any new hypothesis must carry a new version. That rule lets the protocol teach without becoming self-protective. Versioning also protects negative evidence, because the failed claim remains identifiable even after a successor is proposed.

14.2 — Population, Enrollment, and Burden

Chapter 3 governs consent, dependence, and care priority. This protocol adds only the local conditions that non-crisis recruitment be independent of care and that participant, family, and staff burden be monitored as part of study feasibility.

Table 14.2. Enrollment, consent, and stop conditions.

Enrollment element	Required declaration	Stop or narrow condition
Reference population	Diagnosis groups, prognosis window, care setting, language access, communication support, and site capacity	Population too heterogeneous for the planned estimands or too dependent for free refusal
Consent pathway	Timing, key information, support person role, capacity review, re-consent, pause, withdrawal, and data-retirement options	Consent cannot remain ongoing, supported, revocable, and unbundled from care
Burden budget	Maximum prompts, sensor hours, family contacts, staff minutes, and adverse burden thresholds	Observed burden exceeds budget or concentrates in a vulnerable subgroup

Enrollment element	Required declaration	Stop or narrow condition
No-crisis recruitment	Recruitment cannot occur through crisis, care dependency, aid dependency, family pressure, platform belonging, religious belonging, or fear of losing care	A site cannot operationally separate participation from access, safety, belonging, or treatment.

14.2.1 — Inclusion and Exclusion

Inclusion criteria should be scientific and safety criteria. They should name the clinical state, expected observation window, capacity pathway, communication support, measurement feasibility, care-setting stability, and site readiness needed for the estimands. Convenience, expected fit, dramatic terminal proximity, or anticipated compliance must not drive inclusion (World Medical Association, 2024; Council for International Organizations of Medical Sciences, 2016).

Exclusion criteria should prevent harm and noninterpretability. A person should not be invited if participation would predictably burden comfort, disrupt care, intensify family pressure, overload staff, or produce data too confounded by crisis to answer the primary question. Exclusion from the first protocol is not exclusion from dignity or from future, better-designed science.

Diagnosis and trajectory strata should be declared before enrollment because they generate different symptom paths, medication exposures, observation opportunities, and endpoint processes. Cancer, neurodegenerative disease, organ failure,

dementia-related pathways, and mixed frailty should not be pooled merely to enlarge the sample. Partial pooling may borrow information where justified, but it must not turn composition change into an apparent terminal signature.

Communication access is part of eligibility design, not an afterthought. Nonverbal communication, augmentative devices, interpreters, caregiver-supported communication, fluctuating attention, and sensory disability require explicit routes for participation and uncertainty. When a site cannot support those routes, the reference class must narrow transparently rather than classifying inaccessible participants as ordinary missing data.

Exclusion rules must be audited for unfair patterning. If disability, language, poverty, race, site resources, family structure, or home-care access repeatedly exclude people, the report should say so. That finding may reveal an institutional burden before it reveals anything about the Law.

The final inclusion table should be readable by a clinician and a participant advocate. A criterion that cannot be explained in ordinary language may still be scientifically necessary, but it must be translated in consent and reviewed for hidden coercion or hidden exclusion.

14.2.2 — Late-Window Enrollment

Late-window enrollment is scientifically limited by design. It observes a fragment of a trajectory after long unknown history, after disease selection, and often after major treatment and family changes. The protocol must state that its window begins at

enrollment and that the pre-enrollment ledger remains unknown (Emanuel et al., 2000; Wendler & Grady, 2008).

The enrollment time should be recorded as a scientific event, not merely an administrative date. The point at which a person becomes eligible may depend on diagnosis, prognosis, hospice referral, insurance, family capacity, clinician judgment, cultural expectations, and site practice. Those variables shape the observed terminal window.

Late enrollment also creates survivor and access selection. People who reach a study site with time, capacity, and support differ from people who die suddenly, without care, or under emergency intervention. The protocol should model selection into the reference class and avoid public language that treats the sample as the human end-of-life field.

The measured cumulative estimate in a late window is an increment. The study may evaluate changes, dynamics, variance, observation quality, and endpoint timing within that increment. It may not speak as if enrollment resets the life ledger. A clean window is not a clean life total.

Pre-enrollment context is limited to variables required by the estimand and rival models. Diagnosis, medication history, recent symptom trajectory, major care transitions, and hospitalizations may be necessary. The collection plan specifies how each requested field contributes to the analysis.

A late-window study can still be valuable. It can test whether the candidate dynamics appear during a vulnerable and clinically

important period. Its honesty comes from saying exactly that, not from pretending to have reached beyond what it observed.

14.2.3 — Capacity and Consent

Consent is a continuing state, not a signature preserved from enrollment. The protocol should define supported decision procedures, re-consent checkpoints, participant-controlled pauses, and observable assent or dissent markers for periods of fluctuating capacity or communication. Uncertainty about willingness suspends research activity; it does not authorize investigators to infer continued permission from earlier cooperation (International Council for Harmonisation, 2026; National Commission, 1979).

The key information should be understandable under illness and sufficient for a considered decision. It should explain that this observational study is not individualized treatment, does not guarantee personal benefit, and will not determine care access or interpret a participant's life. It should name the burden, data collected, optional components, and right to stop without explanation or loss of ordinary care.

Surrogates require careful boundaries. A legally authorized representative may permit certain research procedures when the participant cannot decide, but surrogate permission should not turn a person's dying process into data if prior wishes, current distress, or clinical judgment argue against continuation. The comfort-first rule remains superior to completeness.

Capacity fluctuation should be recorded without becoming a worth judgment. A participant may be fully dignified, clinically

protected, and scientifically unclassifiable at the same time. The protocol must not treat temporary incapacity as consent to observe more passively or as permission to infer willingness from silence.

Consent should be granular. Physiological observation, self-report prompts, chart linkage, family context, audio or narrative notes, data sharing, future reuse, model training, and publication should be separately permissioned where applicable. A person may accept one form of participation and reject another.

Withdrawal should include data-retirement options declared in advance. Some derived aggregate results may not be retractable after analysis, while identifiable future use can be stopped. Consent materials must state these differences plainly so refusal and withdrawal remain real rather than ceremonial.

14.2.4 — No-Crisis Recruitment

No-crisis recruitment should be enforced by timing, personnel, and documentation. Invitations are deferred during acute fear, unresolved treatment decisions, unstable symptoms, family conflict, or any circumstance in which declining could reasonably feel unsafe. Screening logs should record deferral without converting vulnerability into noncompliance (World Medical Association, 2024; Council for International Organizations of Medical Sciences, 2016).

Recruiters should be independent from direct care whenever possible. When clinical staff introduce the study, the script should separate care from research and transfer the conversation to trained research personnel. A nurse, physician, chaplain, or aide

should not carry the burden of persuading a patient while also providing care.

Recruitment language should describe the study without invoking legacy, heroism, proof, special access, or the promise of helping humanity through one person's death. The participant may be told why the question matters, but no invitation should make scientific usefulness feel like a final obligation. A person receiving end-of-life care owes the program neither data nor meaning.

Timing matters. Recruitment should not occur during uncontrolled symptoms, emergency decisions, family conflict, medication changes that impair comprehension, or immediately after receiving devastating news. The protocol should include a cooling-off interval where clinically appropriate, and it should let sites abstain when timing cannot be made fair.

Recruitment monitoring should include refusal rates, reasons for refusal where voluntarily offered, staff concerns, family concerns, and participant-reported pressure. Low refusal can be a warning sign, not merely a recruitment success. If a site produces unusually high acceptance under dependence, monitoring should investigate pressure rather than celebrate efficiency.

No-crisis recruitment protects science as well as people. A sample recruited through desperation or belonging will carry expectancy, selection, and trust confounds into the data. The study cannot learn fairly from people it has pressured into helping.

14.2.5 — Bystander and Family Protections

Terminal research often collects bystander data even when it does not intend to. Family presence, visitor timing, caregiver distress,

staff interaction, room changes, and relational events may explain signals. The protocol must separate participant data from family and bystander data rather than absorbing everyone near the bed into one research object (Emanuel et al., 2000; Wendler & Grady, 2008).

Family members should not become unpaid instruments. If the study asks for context reports, timing notes, or post-event narratives, it must define burden, consent, refusal, support, and withdrawal for those contributors. A grieving family member's testimony may be valuable, but it is not automatically available because the participant consented.

Bystander data should be minimized and purpose-limited. The protocol can record relational context categories where necessary, such as alone, family present, clinician present, procedure occurring, or conflict noted, without collecting names, private conversations, or interpretable family stories unless separately consented and scientifically necessary.

Family pressure can work in both directions. Some families may encourage participation because they want meaning; others may oppose participation because they fear exploitation. The protocol should not recruit through either pressure. It should let participant preference, capacity rules, and comfort govern without turning family disagreement into data spectacle.

Staff protections belong here too. Nurses, aides, social workers, chaplains, physicians, and volunteers can experience added workload, grief exposure, moral stress, and conflict. The burden

budget must include staff time and staff refusal. A site that cannot protect staff should not run the protocol.

Bystander protections also improve validity. Family anxiety, staff workload, clinician behavior, and room events can alter physiology, missingness, and care timing. Treating those effects as invisible would burden the science with false simplicity.

14.2.6 — Participant and Staff Burden Budget

The burden budget should specify maximum prompts, sensor-wear intervals, device checks, family contacts, research visits, staff documentation, and quality-control requests, together with cumulative limits across days. It should also name prospective pause, reduction, and withdrawal triggers for fatigue, distress, device intolerance, family concern, staff overload, clinical disruption, or repeated refusal. Observation is itself an intervention, so its demands must be fixed before enrollment rather than inferred after participants have absorbed them (International Council for Harmonisation, 2026; National Commission, 1979).

Procedure counts alone cannot represent burden. A one-minute prompt during severe breathlessness may be heavier than a longer conversation on a stable day, and the same device may become intolerable after dyspnea, skin fragility, fatigue, delirium, or family crisis. Burden should be updated prospectively from participant report when available, bedside observation, device-tolerance records, symptom state, clinician judgment, and staff workflow indicators (World Medical Association, 2024; Council for International Organizations of Medical Sciences, 2016).

Staff burden shares the budget. Aggregate time, emotional labor, documentation, device maintenance, overnight coverage, workflow interruption, and independent consent support by role and site. Feasibility built on unrecorded work by nurses, aides, or family members will not transport ethically or scientifically.

The burden rules are noncompensatory. Strong data quality, an attractive early signal, or additional power cannot purchase permission to exceed comfort limits, add sensors, increase prompts, or prolong observation without renewed review. Stopping for excess burden is a usable result about where the design should not go.

Burden-triggered pauses and withdrawals also shape the data-generating process. Observation may disappear precisely when distress or incapacity rises, so an ethically correct stop can still change the population represented by the estimate. Reports should show the relevant burden threshold, the observations lost after it was crossed, and the reference class to which the remaining result can still apply (Little & Rubin, 2019; Hernán & Robins, 2020).

Enrollment flow should preserve the denominator from first approach through screening, deferral, exclusion, consent, first measurement, withdrawal, and analysis. Eligibility, temporary deferral, inability to approach safely, site limitation, communication barrier, device intolerance, and active refusal require distinct neutral codes. Collapsing them can make a restrictive design look broadly acceptable and can hide avoidable barriers to participation (Emanuel et al., 2000; International Council for Harmonisation, 2026).

Consent remains longitudinal. Capacity, fatigue, clinical state, family presence, and willingness may change during the observation window, so the protocol must state when permission is reconfirmed, how assent or dissent is recognized, what happens to previously collected data after withdrawal, and which procedures stop immediately when a stable preference can no longer be expressed. A design that enters a vulnerable person's day must also know how to leave it cleanly (Emanuel et al., 2000; Wendler & Grady, 2008).

14.3 — Measurements, Endpoint, and Data Flow

Measurement development begins in lower-risk settings. Before a palliative cohort is considered, the candidate momentary-valence estimator, interval valence-contribution rule, reserve proxies, endpoint channels, preprocessing, quality controls, and provenance system are declared and qualified for the target clinical state (FDA-NIH Biomarker Working Group, 2016; International Council for Harmonisation, 2026).

Data flow is not administrative plumbing. It is the route by which a latent question becomes a measured claim. Every transformation changes what can be said. Raw sensor units, artifact rules, windowing, synchronization, missingness marks, endpoint adjudication, and statistical estimation must therefore be visible before the first participant is enrolled.

The protocol's measurements must also preserve conflict. If a reserve proxy declines while observation quality collapses, that is not a clean reserve signal. If the candidate momentary-valence estimator moves toward neutrality while sedation increases, the treatment context is not background. If endpoint channels and cumulative-value channels become coupled through preprocessing or analyst decisions, the independence firewall has failed. Predeclared conflict rules should determine when discordant channels remain separate, trigger sensitivity analysis, narrow the estimand, or require abstention rather than allowing disagreement to disappear inside a composite score.

Table 14.3. Measurement and data-flow locks.

Data layer	Locked before enrollment	Reason
Candidate physiological momentary-valence estimator	Context of use, sensors, raw units, transforms, sign anchors, artifact rules, and cadence	Prevents the estimator from being tuned to terminal results
Interval valence-contribution path	Rate interpretation, integration window, posterior path draws, and uncertainty propagation	Prevents summing scores as if they already had additive ledger units
Reserve proxies	Independent development, biological rationale, units, confounds, proxy error, and abstention rules	Prevents reserve from being fitted to force closure
Endpoint channels	Unity and endpoint proxies, stopping rules, confirmation windows, analyst separation, and jitter plan	Prevents the endpoint from being defined by ledger behavior
Treatment context	Medication, sedation, analgesia, delirium, procedures, care changes, and family presence	Allows rivals and clinical confounds to explain patterns
Provenance	Versioned acquisition, preprocessing, quality control, missingness marks, and audit trail	Allows later readers to know exactly which data path produced the result

14.3.1 — Candidate Momentary-Valence Estimator Context of Use

The candidate momentary-valence estimator must be qualified for the target clinical context before terminal use. A physiological composite that behaves adequately in healthy volunteers, general outpatients, or laboratory stress tasks is not automatically valid in hospice, advanced illness, sedation, delirium, pain, dyspnea, fatigue, or low-movement states. Qualification must address the precise construct, population, state range, intended interpretation, and conditions under which the estimator abstains (FDA-NIH Biomarker Working Group, 2016; International Council for Harmonisation, 2026).

The context-of-use statement should identify the target population, state range, sensors, raw units, transformations, window lengths, artifact rules, sign anchors, calibration route, missingness rules, and prohibited inferences. It should say what the candidate momentary-valence estimator is intended to estimate, at what temporal resolution, and what it is not allowed to decide.

The candidate momentary-valence estimator remains a declared physiological estimator rather than a name for the entire evidence stack. Self-report, behavior, clinical notes, medication records, family context, and relational observations may validate, challenge, or explain it, but their inclusion does not collapse distinct channels into one index. A broad witness stack may be scientifically valuable precisely because disagreement remains visible.

Apply the performance profile in Section 9.1.4 to the relevant terminal clinical states. Reliability alone does not establish sign identification, state robustness, or terminal-state transport.

The candidate momentary-valence estimator needs explicit invalidity rules. Loss of sign-bearing information, artifact levels beyond qualification, sensor intolerance, model-version mismatch, failed calibration, or a clinical state outside the declared context of use should suspend the estimator for that interval. Invalid windows remain invalid; they are not replaced by the model's expected trajectory or silently imputed as neutral.

A well-defined context of use strengthens both inference and care. It specifies when the estimator is qualified, how participant testimony enters interpretation, and when a different measurement approach or requalification is needed.

14.3.2 — Reserve Proxies

Reserve proxies must be developed independently of the target trajectory, not tuned to make the ledger close. Candidate channels may include functional decline, frailty markers, autonomic flexibility, physiological variability, performance status, or disease-specific indices, but each requires a declared context of use, analytical validation, clinical interpretation, and failure rule. A proxy that mainly measures observation quality or prognosis cannot silently become reserve (FDA-NIH Biomarker Working Group, 2016; Goldsack et al., 2020).

Each proxy needs units, cadence, uncertainty, confounds, and context of use. Medication, disability, disease type, age, hydration, infection, pain, care quality, sleep, nutrition, family

support, and sensor gain can all affect apparent reserve. The protocol should treat those effects as modeled pathways, not as noise to average away.

Reserve should not be inferred from the ledger outcome. If a proxy is selected because it best aligns terminal compression with neutrality, the design is circular. Reserve construction must be frozen before confirmatory data and tested by negative controls and held-out prediction.

Reserve-proxy uncertainty should propagate into every interaction, slope, and route comparison that uses it. Classical error may attenuate associations, differential error may manufacture them, and shared inputs may create circular agreement with the affect estimator. When the proxy cannot distinguish the candidate route from disease severity or prognosis, the result is no estimate or a narrower observed-variable claim, not weak support.

Reserve proxies are used only for scientific modeling under consent and governance. The protocol excludes their use in triage, insurance, employment, care eligibility, family decisions, religious interpretation, or public ranking.

The strongest reserve design is independently justified, clinically interpretable, versioned, explicit about confounds, and capable of abstention. A reserve curve becomes useful when its interpretation survives measurement-error and shared-driver checks.

14.3.3 — Unity and Endpoint Channels

Unity and endpoint channels define the stopping architecture for the study. They should be separated from cumulative-value estimation channels wherever possible, and any unavoidable dependence must be modeled and reported. The endpoint cannot be an algebraic consequence of the candidate momentary-valence estimator or of the measured cumulative estimate; otherwise neutrality can be manufactured by the stopping rule.

The channel set may include clinical neurological observations, responsiveness, perturbational or electrophysiological markers where clinically appropriate, communication evidence, medication and sedation context, and charted care events. The protocol should declare which channels support candidate crossing, which support confirmation, and which only contextualize uncertainty.

Endpoint adjudication should be blinded to confirmatory ledger outcomes. Analysts constructing endpoint thresholds should not tune them against terminal interval valence contribution estimate behavior. If the endpoint threshold is chosen because it improves apparent neutrality, the endpoint firewall has failed even if the variables look separate on paper.

Endpoint adjudication should operate as a versioned state machine rather than a single threshold. Confirmation windows, reversible loss, return, device cessation, withdrawal, sudden death, low-signal states, and unresolved classifications each require an allowed transition and an evidentiary status. No one

observation can convert a protocol state into an irreversible truth-level endpoint.

Endpoint channels should also be clinically subordinate. Emergency intervention, comfort care, and communication with family are not delayed to preserve endpoint cleanliness. If care disrupts measurement, the protocol records a care interruption or no-estimate condition. It does not treat care as missing data to be repaired by imputation.

The endpoint system is the study's tautology firewall. A terminal study becomes meaningful only if the endpoint is independent enough that ledger behavior could have surprised it. If the endpoint follows the ledger, no terminal result is evidence.

14.3.4 — Treatment and Care Context

Treatment and care context must be recorded as time-varying data. Analgesia, palliative sedation, anxiolytics, antipsychotics, opioids, oxygen, ventilation, procedures, delirium treatment, repositioning, family visits, chaplain visits, and changes in goals of care can alter physiology, reports, observation availability, and endpoint classification at different lags. The protocol should predeclare which variables are exposures, confounders, mediators, observation modifiers, or competing events rather than treating the entire clinical record as an undifferentiated adjustment set (Chan et al., 2025; International Council for Harmonisation, 2026).

Medication, analgesia, sedation, and other treatment changes are humane clinical exposures as well as sources of scientific variation. They should be represented with timing, indication,

dose, route, and plausible lag rather than removed as inconvenient noise. Cleaner evidence obtained by withholding comfort is outside the design; the analysis must adapt to care, never the reverse.

Care quality and site practice should also be modeled. Different sites may handle dyspnea, pain, agitation, family communication, sedation, hospice referral, and device removal differently. A site effect may explain terminal patterns more plausibly than the candidate model. If so, that rival explanation should stand.

Treatment data should be captured with enough temporal resolution to align with observation windows. A medication dose recorded only by calendar day may be too coarse for physiological windows. Conversely, overburdening staff with minute-level coding may exceed the burden budget. The protocol should choose a cadence that is scientifically useful and clinically tolerable.

The analysis plan should include medication and care-context sensitivity models. It should ask whether apparent variance compression, drift, or endpoint prediction survives after accounting for sedation, analgesia, delirium, procedures, and observation quality. A pattern that vanishes under care-context modeling is not a failed life. It is sensitive to those modeling assumptions; a rival-explained verdict requires the declared identification and model checks.

Care context is where this burden-focused approach becomes concrete. Hidden burden can be carried by symptoms, by families,

by clinicians, and by research staff. Recording context makes that burden reviewable without making care subordinate to the theory.

14.3.5 — Observation Marks

Every planned observation should receive a mark. Completed, failed, refused, paused, removed, clinically interrupted, family-deferred, device-error, low-quality, sedated, transferred, and post-endpoint observations are different events. Treating them all as missing would erase the pathway by which evidence became available or vanished (Aalen et al., 2008; Andersen et al., 1993; International Council for Harmonisation, 2026).

Observation marks should be chosen before enrollment and kept simple enough for staff use. A mark system that demands too much judgment at the bedside becomes another burden. The protocol should favor a small controlled vocabulary with optional free-text notes for clinically important exceptions.

Marked observation is essential for rival testing. Observation shutdown can mimic variance compression. Device intolerance can correlate with severity. Refusal can indicate fatigue, distress, privacy preference, or family context. Clinical interruption can cluster near endpoints. Without marks, the model may mistake observation process for terminal dynamics.

Observation marks also protect participants. Refusal is not noncompliance. Device removal is not loss to be lamented by the study. A paused prompt is not missing evidence to be recovered by pressure. The marks should preserve participant agency as part of the data record.

Observation should be modeled as an outcome-bearing process. The analysis should estimate whether response, device quality, removal, staff contact, or mark type depends on the measured path, reserve proxy, clinical state, treatment, or endpoint proximity. If the observation model accounts for the apparent candidate signature, that explanation receives its own protocol-fixed verdict rather than being hidden inside a sensitivity appendix.

The public report should include an observation-flow display showing scheduled opportunities, completed measurements, refusals, pauses, device failures, clinically interrupted intervals, and unknown absences across the terminal window. The display should reveal both quantity and reason, allowing readers to see which portions of the claimed trajectory were directly observed and which depend on assumptions.

14.3.6 — Versioned Data Pipeline

The data pipeline must be versioned from acquisition to public report. Sensor firmware, calibration files, preprocessing code, artifact thresholds, quality rules, candidate momentary-valence estimator versions, reserve-proxy algorithms, endpoint-adjudication rules, analysis code, and reporting templates need stable identifiers before the confirmatory run. The final consolidated good-clinical-practice standard and reproducibility literature make this traceability part of the study, not clerical decoration (International Council for Harmonisation, 2026; National Institute of Standards and Technology, 2020; Nosek et al., 2018).

Development, validation, and confirmatory environments should be separated. Analysts may not tune preprocessing, thresholds, or feature definitions while viewing confirmatory endpoint outcomes; cross-fitting, held-out thresholds, locked containers, or independent analysis teams may be required. If an instrument or transformation changes after early inspection, the original output must remain recoverable and the migration must be tested under a declared plan rather than silently rescore history.

One authoritative clock map should connect prompts, wearable samples, clinical events, medication administrations, room changes, device restarts, and endpoint adjudication. Original timestamps, synchronization tolerances, rounding rules, time-zone handling, and every alignment transformation should be retained. A terminal-window pattern that moves when clocks are corrected is a lineage finding, not a stable biological signature.

Hardware and software changes require bridge evidence. Firmware updates, sensor substitutions, battery-saving modes, altered sampling frequencies, vendor preprocessing, and device replacement can create discontinuities that resemble physiological change. Every observation should therefore carry the active hardware, software, calibration, preprocessing, and quality-control version, and a channel should be withdrawn when old and new versions cannot be linked (U.S. Food and Drug Administration, 2023; International Council for Harmonisation, 2026).

Derived variables need feature-level provenance. A reserve proxy, movement index, autonomic composite, or quality flag should identify its raw channels, window, unit, normalization population,

missingness rule, device version, code commit, and validation rule. A machine-readable dictionary should bind every analysis field to that lineage so an independent team can distinguish a scientific feature from an implementation artifact.

The pipeline records access, consent, retention, and deletion. Raw identifiable signals, derived features, family context, clinical records, and model-training permissions have distinct consent requirements. Audit who viewed or altered each layer, and minimize collection at the outset.

Test reconstruction from a published result through the frozen dataset and feature table to source observations, consent, access conditions, and every transformation. Before enrollment, use synthetic records with clock conflicts, duplicates, missing marks, device and consent changes, and endpoint reversals to expose breaks in that chain.

Versioning preserves the history needed for correction. If an instrument, calibration, feature, or code path proves unsafe, biased, unstable, or nontransportable, identify every dependent estimate, figure, and public artifact and specify the required reanalysis or withdrawal.

14.4 — Estimands and Rival Models

An estimand prevents the data from choosing their own question. Before enrollment, each target should name population, treatment or exposure condition when relevant, time origin and window, outcome or latent object, intercurrent-event strategy, endpoint relation, summary measure, and uncertainty. Those fields align the scientific question with the analysis and stop a favorable pattern from being upgraded after inspection (International Council for Harmonisation, 2019; Hernán & Robins, 2020).

The primary estimands should be preterminal and comparative. They ask whether reserve-linked dynamics, innovation behavior, variance shape, and filtered endpoint prediction improve out-of-sample performance against serious rivals. Terminal equivalence may remain secondary, but only after origin, endpoint, observation, and whole-life limitations are carried honestly.

Rivals are executable generators, not a list of objections. Homeostasis, conditioned bridges, frailty, age, medication, sedation, observation shutdown, and hybrid models can reproduce different parts of the pattern. The candidate advances only when a protocol-fixed conjunction outperforms them under common data access, tuning resources, scoring rules, and abstention options.

$$\mathcal{E} = (\beta_r, \gamma_v, \Delta S, \eta_{obs}, \kappa_{burden})$$

Table 14.4. Estimands, rivals, and failure conditions.

Estimand family	Primary object	Key rival pressure	Failure condition
Relaxation and innovation	State-dependent drift and stochastic innovation under filtered windows	OU homeostasis, medication effects, endpoint-conditioned bridge	Parameters unstable, not recoverable, or no better than rivals
Variance shape	Reserve-space and time-domain variance relations under proxy-error correction	Frailty, observation attenuation, shared disease severity	Slope explained by noise floor, proxy drift, or observation process
Prospective endpoint prediction	Held-out prediction using information available before the endpoint	Generic time-to-death, age, prognosis, site practice	No gain beyond clinically simpler predictors
Observation process	Availability, quality, and missingness as data-generating processes	Observation shutdown, device intolerance, care interruption	Observation model explains apparent compression
Discriminating conjunction	Joint score across components that fail against different rivals	Flexible hybrid rivals and none-of-the-models data	Conjunction redundant, nonseparable, or unrecoverable in simulation

14.4.1 — Relaxation and Innovation Estimands

Relaxation estimands describe whether the measured path shows state-dependent movement toward the candidate neutral region

under conditions declared before analysis. Innovation estimands describe the size and structure of the unpredictable component after modeled drift, reserve, treatment, and observation processes are accounted for. Both are preterminal targets (International Council for Harmonisation, 2019; Hernán & Robins, 2020).

The primary relaxation and innovation estimands must use information available in the declared pre-endpoint filtration. Retrospective smoothing may support reconstruction or sensitivity analysis, but it cannot carry a claim about prospective dynamics. Filtering, forecasting, or cross-fitting should therefore isolate the state available before the held-out interval.

A useful estimand might ask whether drift toward neutrality strengthens as independently measured reserve declines, after accounting for site, diagnosis, medication, sedation, delirium, care changes, and observation quality. The exact model can vary, but the target must be declared before seeing terminal behavior.

Innovation matters because a candidate closure story should not only move the mean. It should also shape residual variability in ways rivals cannot easily reproduce. If the residual variance collapses because sensors stop capturing movement or because sedation flattens physiology, the innovation estimand belongs to an observation or medication rival, not to the candidate model.

Parameter recovery is mandatory. A complex drift model that cannot recover its own parameters in synthetic data should not be trusted on terminal data. Before enrollment, the team should show that the planned cadence, windowing, missingness, and proxy

error still allow the relaxation and innovation quantities to be estimated with decision-relevant precision.

The public result should separate drift support from innovation support. A favorable drift estimate without innovation structure is component support at most. Innovation compression without recoverable drift may be observation shutdown. The conjunction is stronger than either component because each can fail differently.

14.4.2 — Variance-Shape Estimands

Variance-shape estimands ask how measured cumulative estimate uncertainty and dispersion change as reserve declines and as endpoint approaches. They must separate reserve-space relations from time-domain scaling. A slope near two in reserve space means something different from a time-domain exponent, especially when reserve declines nonlinearly (Gneiting & Raftery, 2007; Vehtari et al., 2017).

Conditional variance in reserve space, variance indexed by a prospectively estimated horizon, and variance in windows aligned retrospectively to endpoints are distinct estimands with different risk sets and artifacts. The protocol should prospectively specify one primary object and treat the others as bridge or sensitivity analyses. Otherwise endpoint alignment can create apparent compression in a process with no native reserve-coupled structure.

Measurement noise must be included in the estimation model. An additive noise floor can bias apparent variance compression and flatten slopes. More data may sharpen a biased estimate. The

protocol should include noise-floor characterization and deconvolution before interpreting variance shape as support.

Reserve proxy error also matters. If the reserve proxy is noisy or shares disease severity with the measured cumulative estimate, conditional variance estimates can be attenuated, inflated, or shifted. The analysis should report sensitivity to proxy-error assumptions and abstain when those assumptions dominate the target margin.

Variance shape contributes one member of a joint fingerprint. OU homeostasis, endpoint-conditioned bridges, frailty, medication, observation shutdown, and sensor-gain changes can each reproduce pieces of compression. Its value comes from how it combines with drift, dependence, negative controls, and observation diagnostics, not from uniqueness in isolation.

A variance result should be reported with its rival explanation. A favorable reserve-space relation plus negative observation controls is stronger than a favorable time-aligned plot. A variance pattern that appears only after smoothing or endpoint-conditioned alignment requires explicit artifact and rival checks. A valid analysis may be confirmatory if prospectively specified for its declared estimand; it cannot establish a prediction made using only earlier information.

14.4.3 — Prospective Endpoint Prediction

Prospective endpoint prediction asks whether filtered preterminal features improve prediction of independently adjudicated endpoint states. The word prospective is doing real work. The features must be available before the endpoint window they

predict, and the endpoint rules must be declared without looking at ledger behavior (Lipsitch et al., 2010; Wilson & Collins, 2019).

Candidate features should be evaluated against a transparent clinical baseline containing diagnosis, age, site, performance status, recent decline, symptom burden, treatment, sedation, prognosis, and observation quality where available. Improvement is assessed in held-out data with calibration as well as discrimination. Failure to beat that baseline is informative, and it cannot be converted into support by emphasizing an in-sample coefficient.

Prediction should be evaluated with proper scores and calibration, not a favorable coefficient. The protocol-fixed report should provide held-out log or Brier score where appropriate, calibration-in-the-large, calibration slope, discrimination, horizon-specific error, and comparison with a transparent clinical baseline. A feature that improves rank ordering while degrading calibration has not earned a general endpoint-prediction claim (Gneiting & Raftery, 2007; Steyerberg, 2019).

The prediction target should be clinically and scientifically interpretable. It may be time to candidate endpoint, probability of transition into a confirmed endpoint state, or probability of no-estimate classification within a window. It should not be a dramatic label such as final balance, final meaning, or completed trajectory.

Calibration of predictions matters as much as discrimination. A model that ranks participants but is badly calibrated near the endpoint may be scientifically interesting but not confirmatory.

The protocol should report calibration, discrimination, decision-relevant error, and uncertainty separately.

Prospective prediction can fail cleanly: no added predictive information narrows the program; success requiring smoothing or endpoint tuning remains exploratory; superior clinical predictors give the clinical model victory.

14.4.4 — Observation-Process Estimands

Observation-process estimands test availability, quality, and modality as primary rivals. Weakening may bring sensor failure, reduced movement, refused prompts, device removal, or clinical interruptions that generate the apparent signature (International Council for Harmonisation, 2019; Hernán & Robins, 2020).

The probability and type of observation should be modeled from prior measured history, clinical state, treatment, site, family presence, device status, reserve proxy, and endpoint proximity. Complete-case analysis is defensible only under assumptions made explicit and stress-tested. When observation depends on the latent state under study, selection is part of the scientific model rather than a removable inconvenience.

Model how contact quality, motion artifact, ambient conditions, battery state, staff workload, device placement, and care procedures alter signals. A smooth terminal path may reflect a quieter device, not a quieter ledger.

The observation model must be capable of defeating the candidate. When observation availability or quality explains variance compression or drift, the result is a rival victory if the pathways can be separated and Model-ambiguous if adequate

pathways cannot be separated. Either outcome belongs in the main verdict.

Negative-control timing helps here. The protocol should test whether similar signatures appear in impossible windows, shuffled endpoints, nonrelevant channels, or variables unrelated to the hypothesized process. If the pipeline creates compression where no hypothesis predicts it, the confirmatory result fails.

Observation-process reporting protects trust by distinguishing device silence from experiential silence. At the endpoint, that distinction is scientific and humane.

14.4.5 — Strong Rival Set

The rival set should represent the strongest credible explanations of the same observations. Ordinary homeostatic mean reversion can create drift toward a set point. Endpoint-conditioned bridges can create terminal concentration. Frailty and age can reduce variability. Medication and sedation can flatten physiological signals. Observation shutdown can create false compression. Hybrid models can combine these routes (Gneiting & Raftery, 2007; Vehtari et al., 2017).

Each rival should be written as a generative model, not merely as a verbal objection. A rival that cannot produce simulated data cannot be tested fairly in model recovery. The candidate model should not receive a mathematical specification while rivals receive only prose.

The rival set must also admit that none of the named models generated the data. Real terminal trajectories may fall outside both candidate and comparator families. An explicit

misspecification and abstention branch prevents the analysis from converting model incompleteness into false certainty.

Rivals should be tuned under the same rules as the candidate. If the candidate receives cross-fitting, proxy-error modeling, and flexible dynamics while rivals are constrained to naïve forms, the comparison is unfair. A fair protocol gives rivals enough flexibility to represent their actual scientific strength.

When a rival wins, the report should explain what the victory teaches. Frailty may account for the apparent horizon effect, medication may explain a change in variance, and observation shutdown may reveal a defect in the collection system. These findings can improve clinical prediction or study design even while weakening the candidate route. Rival success is positive scientific content, not a rhetorical loss to be softened.

A strong rival set also protects the Law's positive case. If the candidate survives only weak rivals, the result will not persuade serious readers. If it survives the strongest rivals the field can build, the program gains real pressure-tested warrant.

14.4.6 — Discriminating Conjunction

The protocol's central result is a discriminating conjunction, not one favorable coefficient. Representation, calibration, measurement recovery, endpoint validity, observation coverage, predictive or structural performance, rival comparison, burden, and safety each have a declared role; when one prerequisite is noncompensatory, strength elsewhere cannot repair it.

Members, thresholds, tie rules, and stopping rules are fixed before the real-data pattern. Rivals receive comparable lags,

nonlinearities, calibration effort, and information, while recovery simulations map regions in which models are indistinguishable or absolutely inadequate so the procedure can abstain (Wilson & Collins, 2019; Durbin & Koopman, 2012; Talts et al., 2018).

The estimand register keeps held-out predictive value, terminal-band compatibility, feasibility, burden, missingness, and safety separate. Each target travels with its information set, horizon, update schedule, censoring rule, and covariates, preventing a retrospective reconstruction from masquerading as a prospective forecast (Hernán & Robins, 2020; Gneiting & Raftery, 2007).

Uncertainty is decomposed into sampling, calibration, proxy, endpoint, missingness, model, and transport components. A protected abstention branch applies when components are nonseparable, open-set checks fail, or the design lacks resolution.

The final report displays the conjunction as a decision path: gates passed, failed, or unusable; rivals still viable; and predeclared actions such as recalibration, route retirement, lighter design, different perturbation, or no further terminal recruitment. Decision relevance comes from consequences, not a compressed success label.

14.5 — Power, Recovery, and Negative Controls

Power in this protocol does not mean the probability of detecting one dramatic terminal association. A study can be powered to find a pattern and still be scientifically useless if that pattern is equally produced by observation shutdown, endpoint conditioning, medication timing, site practice, or ordinary homeostatic regulation. The first question is whether the design can tell one world from another while keeping care untouched and participation humane (Talts et al., 2018; Wilson & Collins, 2019).

The protocol therefore requires design-separability simulations before enrollment. The simulated worlds must include the Law candidate, the major rival families, hybrid worlds, and deliberately misspecified worlds. They must be passed through the same cadence, sensors, endpoint adjudication, reserve proxies, missingness marks, preprocessing rules, estimand definitions, and analysis pipeline planned for the real study. If the pipeline cannot separate those worlds under plausible clinical conditions, the study should not recruit.

Negative controls test whether the analysis produces the target signature where the candidate predicts none. Battery voltage, ambient temperature, prospectively justified shuffled endpoints, and impossible time windows can reveal how the measurement system creates apparent structure.

Table 14.5. Simulation and model-recovery design axes.

Simulation axis	Example levels	Decision use
Measurement noise floor	Low, moderate, high, state-dependent	Tests false compression and false negative risk
Endpoint uncertainty	Exact adjudication, interval censoring, delayed detection, jittered endpoint	Tests whether terminal alignment drives the result
Reserve proxy error	Independent, attenuated, shared-driver, drifting proxy	Tests reserve-interaction robustness
Missingness process	MCAR, MAR, MNAR, observation shutdown, comfort-driven removal	Tests validity under clinically realistic missingness
Rival worlds	OU, bridge, frailty, medication, observation shutdown, hybrid, none-of-the-models	Measures model confusion before recruitment

14.5.1 — Synthetic Data Generator

The synthetic data generator is the rehearsal room for the protocol. It creates candidate, rival, hybrid, and misspecified worlds under one shared observation system. Each world includes latent path structure, reserve trajectories, treatment events, endpoint states, observations from the candidate momentary-valence estimator, auxiliary context, missingness marks, device quality, burden stops, and site-level variation. The point is not to make the candidate look elegant; it is to determine whether the

planned study can distinguish elegance from reality (Talts et al., 2018; Wilson & Collins, 2019).

Candidate worlds instantiate the protocol-fixed reserve-linked conjunction, including conditional dispersion, reserve interaction, filtered endpoint prediction, and observation-process behavior. Rival worlds instantiate homeostasis, conditioned bridges, frailty, disease severity, age, prognosis, medication, sedation, observation shutdown, flexible time-to-event processes, hybrids, and generators outside the fitted library.

The generator should vary clinically plausible features rather than only mathematical parameters. Diagnosis, prognosis, site practice, care model, symptom volatility, medication cadence, family presence, communication capacity, device tolerance, staff burden, and transfer risk should be part of the scenario library. Testing those features helps prepare the protocol for the variability and care needs of an actual clinical setting.

Misspecified and none-of-the-models worlds are required. Nature may not follow the candidate or any named rival. If every simulated dataset is forced into one family, the analysis will learn to choose the least-wrong label rather than admit that its model space is inadequate. A serious first protocol must be able to say that its models did not contain the world it saw.

Scenario labels, parameters, seeds, preprocessing, and scoring rules should be fixed before real-data analysis and retained with the protocol package. Apply §6.7's prospective-specification terminology; later changes create a new version.

Synthetic data test the protocol's capacity to learn. If a generator shows that the design confuses the Law candidate with observation shutdown, researchers revise the design and rerun recovery before enrollment. This rehearsal helps direct participant contributions toward questions the study can answer.

14.5.2 — Parameter Recovery

Parameter recovery asks whether the analysis can estimate the quantities it reports. A model may look principled while failing to recover its own reserve interaction, drift parameter, innovation scale, observation-process effect, endpoint-jitter parameter, or medication coefficient. The first falsification protocol cannot ask the world to decide among theories until the pipeline has shown that it can recover known truths from data shaped like the planned study (Gelman et al., 2013; Vehtari et al., 2017).

Recovery should be tested across the expected clinical range, not only under ideal measurements. The simulation grid should include weak reserve proxies, high symptom volatility, irregular cadence, late enrollment, endpoint uncertainty, treatment changes, delirium, device removal, and site-specific practice. Clean recovery in a clean world is useful, but it is not a burden budget for terminal research.

Uncertainty calibration matters as much as point accuracy. A biased estimate with a narrow interval is more dangerous than a noisy estimate that admits its limits. Coverage, posterior calibration, interval width, rank calibration, and sensitivity to priors should be reported before the protocol is allowed to claim confirmatory capacity.

Nonidentifiability should be treated as a result. If medication effects and drift cannot be separated, the protocol cannot report a drift finding. If reserve-proxy error and disease severity cannot be separated, the reserve interaction is not identified. If endpoint jitter changes the sign or magnitude of the target estimate, the endpoint system is not strong enough for that claim.

The recovery report should name the estimands that are recoverable, those that are weakly recoverable, and those that are not recoverable under realistic conditions. The study may proceed only for the estimands that remain scientifically interpretable after this report. It must not keep an attractive target simply because it would be rhetorically useful.

This is a dignity rule as well as a statistical rule. A person near the end of life should not be enrolled in a study that cannot estimate the quantity it asks permission to study. Scientific humility is not a mood here. It is a pre-enrollment obligation.

14.5.3 — Model Recovery

Model recovery tests whether the pipeline can identify which generative family produced the observed pattern. It is possible to estimate parameters accurately within the wrong family and still draw the wrong conclusion. The protocol therefore needs a confusion matrix across candidate, OU, bridge, frailty, medication, observation-shutdown, shared-driver, and hybrid worlds before it interprets real participants (Lipsitch et al., 2010; Nosek et al., 2018).

For each simulated world, the analysis should score the candidate and every rival using the same held-out rules planned for the

confirmatory study. The protocol should record how often each world is classified as the candidate, how often the candidate is missed, and how often an unmodeled world is forced into a named family.

The most important failure is false candidate victory. If observation shutdown, endpoint-conditioned bridges, sedation, or shared clinical decline are frequently recovered as the Law candidate, the design is not ready. False candidate victory is not a conservative error. It is exactly the public-risk path by which a fragile study becomes proof language.

Model recovery also measures false rejection of the candidate. Coarse cadence, proxy noise, or endpoint jitter may cause candidate-generated data to be classified as frailty or medication effects. Those errors identify where the design needs improvement before a hypothesis comparison.

Hybrid worlds prevent easy triumph. A real terminal pattern may contain ordinary homeostasis, care-quality changes, medication effects, social context, and reserve-linked dynamics at once. The model-recovery plan should not require one winner when the honest conclusion is a mixed or nonseparable result.

A protocol that cannot recover the relevant models stops before recruitment. Early simulation results then guide a more informative design with an appropriate participant burden.

14.5.4 — Power Across Noise and Missingness

Power analysis must vary measurement noise, missingness, endpoint uncertainty, reserve-proxy error, sample size, cadence, site heterogeneity, and burden stops together. Treating one source

of uncertainty at a time gives a beautiful but misleading design. Terminal research is not a laboratory of isolated imperfections. Its difficulties arrive in clusters (Talts et al., 2018; Wilson & Collins, 2019).

Measurement noise floors are especially important. More participants do not remove a systematic noise floor or a biased estimator. They can make a biased conclusion look more precise. The simulation plan should therefore test whether additive noise, state-dependent noise, device-quality changes, and smoothing choices alter variance-shape conclusions.

Missingness mechanisms must be clinically realistic. Measurements may be missing because a participant refused, a device was uncomfortable, a nurse removed it for care, sedation changed behavior, a family member requested privacy, a transfer occurred, or death arrived faster than expected. Treating all such losses as random missingness would be a scientific and ethical error.

The relevant power is discriminating power. The protocol should report the probability of distinguishing the candidate from each rival, not merely the probability of finding a nonzero coefficient. A design that has high power to detect time-to-endpoint change but low power to distinguish the candidate from a Brownian bridge is not a falsification protocol.

A separability threshold is fixed before enrollment. Across plausible noise and missingness, the benchmark may require a stated upper bound on confusion between the candidate and its strongest rival, together with protection against falsely defeating

a rival that generated the data. The threshold belongs in the protocol record, not in prose written after the outcome.

Statistical power describes a study's ability to detect the effect specified in its design. Reporting that effect, the sample assumptions, and the decision rule makes the study's expected contribution clear.

14.5.5 — Negative-Control Outcomes

A negative-control outcome must be justified as outside the hypothesized causal pathway while remaining informative about the relevant bias. Battery state, contact quality, ambient temperature, and administrative timing are candidate diagnostics, not automatically valid negative controls: temperature may affect comfort, and device or staffing variables may affect both observation and experience. The protocol should identify the assumed causal paths and distinguish negative-control outcomes from technical quality checks (Lipsitch et al., 2010).

Negative-control outcomes require a prospective rationale. The protocol record should explain why the candidate does not predict the target signature in that outcome and why the outcome remains exposed to relevant artifacts such as device behavior, staffing, or endpoint alignment. A variable chosen after it looks convenient is not a valid negative control.

If the negative-control outcomes show the same apparent reserve-linked compression or endpoint-related drift as the measured cumulative estimate, the candidate interpretation weakens or fails for that analysis. The result is informative because it reveals a source of false structure.

Negative controls reveal operational rivals: battery effects may indicate changed device wear near the endpoint; ambient temperature, room transitions or care procedures; administrative timing, staff workflow. These explanations belong in the scientific record.

Set quantitative control thresholds. Incidental correlations need not defeat the analysis, but matching the primary signature's direction, timing, and magnitude should trigger a predefined observation-process or no-estimate branch.

A target-like pattern in battery voltage can identify an observation artifact before it is mistaken for a biological finding. This control helps the protocol distinguish a promising signal from a feature of the measurement system.

14.5.6 — Negative-Control Timing and Alignment

Timing controls test whether alignment creates the signature. Shuffled, displaced, person-swapped, too-early endpoints and anchors unrelated to the truth-level stream endpoint expose geometry imitating mechanism. Time-to-endpoint structure alone is not a Law-specific pattern (Lipsitch et al., 2010; Nosek et al., 2018).

Endpoint conditioning is a strong rival: aligning trajectories by a terminal event can make deterioration, observation loss, and selection resemble structured convergence. Negative-control timing tests whether the pattern survives deliberately incorrect endpoint labels.

Timing controls should be protocol-fixed before enrollment. The plan specifies endpoint jitters, shuffled or cross-person labels,

impossible windows, summary statistics, multiplicity handling, and the similarity threshold that triggers an observation-process, rival-favored, or no-estimate branch.

If displaced or shuffled endpoints reproduce the primary signature, the confirmatory branch fails. The accurate public statement is that the pipeline could not distinguish the protocol-fixed endpoint from false alignment, not that terminal closure was almost observed.

Look-ahead must be handled with particular care. Features built using future data may appear in sensitivity analyses only when clearly labeled as smoothed or retrospective. Primary confirmatory claims use filtered, forecast, or cross-fitted features that do not borrow information from the future they claim to predict.

The timing plan gives the study clear, testable standards for prospective inference. Meeting those standards makes a favorable result more persuasive and gives critics a reproducible way to assess it.

14.5.7 — Circular Perturbation-Design Gate

The circular perturbation-design gate rejects any design in which the reserve construction, endpoint rule, preprocessing, normalization, or perturbation already forces the target pattern. Reproducing a consequence of the analysis pipeline is not evidence that the same pattern exists in nature. Before enrollment, an independent reviewer should be able to derive what the pipeline would produce under neutral and rival generators (Talts et al., 2018; Wilson & Collins, 2019).

The review should examine centering, baseline subtraction, endpoint-normalized time, adaptive weights, derivative transforms, smoothing, inclusion rules, and endpoint adjudication. Each step must be tested for whether it can manufacture closure, variance compression, or apparent neutrality when the candidate process is absent. The relevant question is not whether the step is common, but whether it creates the feature later presented as discovery.

The same gate applies to perturbation and invariance tests. Reserve cannot be built from the signals used to define ledger decline and then cited as independent support for reserve-linked compression. Endpoint thresholds cannot be tuned to maximize terminal concentration, reliability weights cannot be learned from the terminal window, and lag or time normalization cannot be selected after seeing which choice makes endings look most alike.

A failed circularity review blocks confirmatory interpretation. The design may remain useful for method development, simulation, or diagnostic exploration, but its outputs must be labeled nonconfirmatory and kept outside any status update. Sample size, statistical significance, or careful rhetoric cannot repair a result whose defining pattern was built into the analysis.

The design target is model separation, not merely rejection of a null. The simulator should test whether the frozen pipeline recovers the correct generator, distinguishes the candidate from the strongest protocol-fixed rival, detects failed measurement and endpoint bridges, and recognizes open-set inadequacy. Effect size, cadence, measurement error, endpoint uncertainty, missingness, and heterogeneity must vary across the benchmark

rather than remaining fixed at one favorable setting (Talts et al., 2018; Gelman et al., 2013).

Recovery exercises should include deliberately broken worlds: mis-zeroed scales, invalid reserve proxies, informative dropout, endpoint misclassification, time leakage, device drift, and generators outside the fitted family. Negative controls should have a predeclared expected direction, tolerance, and consequence; some should remain null, while others should reproduce a known artifact. A diagnostic that cannot detect the manufactured failure is too weak to protect the primary interpretation (Vehtari et al., 2017; Nosek et al., 2018).

Simulation can expose analytic weakness before enrollment, but real observation remains selective and ethically interruptible. Missingness models must preserve why information disappeared and the rule that care, refusal, and safety outrank completion of the record.

14.6 — Missingness, Safety, and Adverse Events

Terminal study data will be incomplete if the protocol is honest. Measurements may disappear because a participant is tired, a device is uncomfortable, medication changes, delirium emerges, a transfer occurs, family privacy is needed, staff workload spikes, an emergency interrupts the schedule, or the person dies before the planned window. Missingness is therefore not a nuisance term added after the study. It is part of the phenomenon and part of the burden structure (Little & Rubin, 2019; World Medical Association, 2024).

Safety is noncompensatory. A promising statistical pattern cannot rescue a protocol that increases suffering, confuses care, pressures families, exposes private data, or makes staff labor invisible. The protocol must define adverse events for participants, families, staff, sites, and data systems before the first enrollment.

The chapter's burden lens appears here as validity discipline. If the study shifts burden onto people, families, clinicians, or data systems, those shifts can change the data-generating process. A protocol that ignores those shifts may not merely be unethical. It may be wrong.

Table 14.6. Missingness, safety, and claim consequences.

Event type	Protocol action	Claim-status consequence
Participant refusal or fatigue	Pause or stop the component; mark reason only if voluntarily given	Missingness is agency-sensitive, not noncompliance

Event type	Protocol action	Claim-status consequence
Device failure or intolerance	Remove device; mark quality and burden; no pressure replacement	May trigger observation-process analysis or no-estimate
Clinical decline, sedation, or procedure	Care proceeds; measurement yields to care; time-stamp context	Modeled as treatment or competing explanation
Privacy or security incident	Contain, notify, suspend access, delete where required, review publication consequences	May stop study or prevent release of affected data
Unanticipated distress	Support participant or family, reduce or stop procedures, report adverse event	Ethical adverse result overrides statistical promise

14.6.1 — Marked Missingness

Marked missingness means that absence of data receives a meaningful label when that label can be collected without creating new pressure. The protocol should distinguish refusal, fatigue, device failure, device intolerance, clinical decline, sedation, transfer, discharge, family privacy request, staff unavailability, emergency intervention, death, and unknown absence. These categories are scientifically different (Little & Rubin, 2019; Rubin, 1976).

Refusal and fatigue are not measurement failures to be repaired. They are expressions of participant agency. The protocol may record that a scheduled observation was declined, but it should

not demand an explanation. If the participant volunteers a reason, it can be marked in a predefined category without being treated as noncompliance.

Device failure and device intolerance should be separated. A battery problem, contact-quality problem, lost signal, sensor displacement, or software failure implies one kind of observation problem. Skin irritation, discomfort, sleep disruption, embarrassment, or family objection implies another. Combining them hides both burden and instrument behavior.

Clinical interruptions require detailed but respectful marking. Sedation, analgesia, delirium, dyspnea, nausea, procedure, repositioning, bathing, family visit, spiritual care, and urgent symptom management can all alter observation and experience. These marks should not become a surveillance script. They should capture enough context to prevent false inference.

Unknown reasons for missingness should remain marked unknown rather than assigned a favorable explanation. A prespecified primary observation model may estimate missing quantities under explicit assumptions, with uncertainty and adverse sensitivity analyses. It must not set missing experience to neutral or enforce terminal closure by construction; §14.6.6 supplies the resulting abstention and verdict categories.

Marked missingness makes refusal, care, and burden visible without turning them into blame. It is one of the ways the protocol asks where burden is carried, hidden, shifted, reduced, repaired, or made reviewable.

14.6.2 — Joint Longitudinal–Event Model

Repeated measurements, observation availability, treatment changes, device tolerance, and the terminal event share causes and therefore belong in a joint data-generating account. A decline in clinical state may change both the estimated affect path and the probability that the path is observed. Joint models, multistate formulations, and marked observation processes answer different questions, so the protocol should state which dependence structure its primary estimand requires (Rizopoulos, 2012; Andersen et al., 1993).

A joint longitudinal-event model can represent this dependence without defining the endpoint through the cumulative-value estimate. The longitudinal component models observations from the candidate momentary-valence estimator, reserve, auxiliary channels, and quality marks over time. The event component models endpoint states, withdrawal, device cessation, transfer, death, and competing events. Shared random effects or latent clinical processes may explain dependence between the two without making the endpoint a function of the measured path.

The essential firewall remains: ledger-derived states may help model informative observation or rival explanations, but they must not define the primary endpoint. The endpoint channel is constructed independently and then brought into the joint analysis under declared dependence assumptions.

Missingness analysis should include a protocol-fixed primary model, at least one materially more adverse missing-not-at-random scenario, and a no-estimate region in which the target is

not recoverable. The comparison should show how the verdict changes as unobserved-state dependence strengthens. The most convenient missingness assumption is not treated as truth merely because it yields a precise answer.

Care events belong in the model as time-varying processes. Analgesia, palliative sedation, antipsychotic medication, oxygen support, hydration changes, procedures, family presence, symptom crises, and site practices may be causes, confounders, mediators, or competing explanations depending on the estimand. The protocol should not force all of them into one role.

The joint model is not a machine for rescuing incomplete data. Its purpose is to state the assumptions under which inference is possible, and to identify when the assumptions are too fragile. In this chapter, abstention remains a result.

$$Y_{it} = m_i(t; \theta, b_i) + \varepsilon_{it}, \lambda_i(t | b_i) = \lambda_0(t) \exp\{\alpha^T Z_i(t) + \gamma_b b_i\}$$

Here, b_i is the shared random effect or latent clinical process, and γ_b is the event-association parameter.

14.6.3 — Comfort and Clinical Stop Rules

Apply Chapter 3's stop authority locally: participants, clinicians, bedside staff, and designated research personnel may halt observation, with comfort controlling. Prespecified stops cover distress, device intolerance, clinical instability, privacy requests, and workflow conflict.

Participants may stop any component without giving a reason. A family member or clinician may request interruption when the participant cannot comfortably decide, when privacy is needed,

or when care would be impaired. Staff should not be required to negotiate for research continuation during clinical strain.

Stop rules should include device discomfort, skin irritation, sleep disruption, respiratory distress, agitation, distress during prompts, family distress, clinician concern, staff workload, procedure conflict, privacy need, and any sign that the person experiences the study as intrusive. The default should be removal or pause, not persuasion.

Clinical care remains unmodified. The protocol must never delay medication, repositioning, family access, spiritual support, symptom relief, resuscitation where appropriate, withdrawal of burdensome treatment where appropriate, or any ordinary clinical judgment. A research schedule has no authority over the terminal room.

Every stop event should be recorded as a burden and feasibility outcome when recording can occur without new burden. A study with many comfort stops may be telling the truth that the protocol is not humane enough, even if the remaining data look analytically attractive.

This stop system turns answerability into scientific design. The dying person does not carry the burden of completing the record; the protocol carries the burden of stopping when comfort, consent, or interpretability fails.

14.6.4 — Privacy and Security Incidents

A privacy or security incident is not a mere administrative problem in this study. It can injure dignity, expose families, distort participation, alter trust, and determine whether the study can

ethically continue. The protocol should define incident classes before enrollment and connect each class to containment, notification, deletion, and publication consequences (National Institute of Standards and Technology, 2020; World Medical Association, 2024).

Relational data require special care. Family presence, speech, touch, conflict, spiritual practices, room context, and caregiver behavior may be scientifically relevant but personally intimate. The study should minimize such data, obtain appropriate permission where data are intentionally collected, and avoid covert transformation of family life into research material.

Data access should be separated by role. Clinical staff should not receive research summaries that could alter care unless a predefined safety finding requires communication. Analysts should not receive identifiable family narratives unless the analysis cannot be performed without them. Model developers should not receive data for secondary training unless separately permitted.

Incident response should include immediate containment, access suspension where needed, audit-log review, participant or surrogate notification when appropriate, family notification when affected, IRB or oversight reporting, deletion or quarantine where required, and a written decision about whether affected data can be analyzed or published.

Security incidents require scientific as well as administrative action. Versions that expose identifiers, ignore consent flags, leak relational data, or permit unauthorized secondary training should

be quarantined and retired, and outputs derived from them should be reexamined. A compromised pipeline cannot remain evidentially valid simply because its statistical code still runs.

Privacy discipline strengthens science. Participants who fear exposure, families who distrust the study, or staff who feel watched can change behavior and missingness. Protecting privacy is therefore not outside the model. It is part of maintaining a valid research environment.

14.6.5 — Unanticipated Distress

Unanticipated distress must be treated as an adverse event, not as an intense data point. A prompt, device, conversation, family reaction, or research presence may create distress even when the design looked minimal on paper. The protocol should assume that such events can occur and specify immediate support routes (World Medical Association, 2024).

Distress may arise in the participant, family, staff, or research personnel. A dying person may feel watched. A family member may feel judged or excluded. A clinician may experience added moral stress. A researcher may be affected by repeated terminal exposure. The burden budget should include all of these groups.

The first response is support and reduction of burden. The study should pause, remove devices, stop prompts, provide clinical or psychosocial support through ordinary care routes, and document only what is needed for safety and oversight. It should not ask for an explanatory interview during distress.

Unanticipated distress should be reviewed for pattern. One incident may be local. Several incidents of the same kind indicate

a design defect. The independent monitoring process should be able to reduce cadence, remove a modality, narrow the population, pause enrollment, or stop the study.

A participant's fear, agitation, grief, or pain calls for present care. Research records those states only within the agreed purpose and observation plan.

The chapter's rule is simple: distress can teach the protocol where it failed, but it cannot be converted into proof material. That distinction protects both the participant and the science.

14.6.6 — Abstention and Inconclusive Conditions

Apply the evidence-state taxonomy in Table 14.7 and §§24.2 and 27.4. For this protocol, failed estimator qualification, unstable sign, dominant device artifact, unresolvable channel conflict, invalid endpoint separation, excessive jitter, model-recovery failure, strong-rival nonseparability, or uncertainty crossing the decision boundary routes the primary inference to the corresponding prespecified branch. The local task is to identify the blocking condition, not redefine the status vocabulary.

Ethical conditions can also close authority: unacceptable burden, coercive recruitment risk, privacy incident, staff overload, distress-related withdrawal, or interference with care. The study may still report instrument, feasibility, safety, or narrower observed-variable findings, but it may not promote them to the primary claim.

Operational monitoring remains separated from outcome interpretation. An independent review can examine burden, device tolerance, recruitment pressure, privacy, staffing, and

observation loss without learning whether the candidate model is performing well, preventing scientific excitement from raising the stop threshold.

When a threshold is crossed, the protocol version closes with its data and adverse result intact. Restart requires a reviewed successor, new burden analysis, and an account of which inference remains comparable across versions; stoppage is part of the evidentiary history, not an inconvenience to erase.

Every burden signal, mitigation, pause, and restart is timestamped and linked to the protocol in force. A study able to return No adequate estimate is stronger than one compelled to produce a claim because it can surrender authority before it loses trust.

14.7 — Decision Tree and Public Reporting

A falsification protocol is incomplete until its result branches and consequences are fixed. Without a decision tree, a favorable component can inflate into whole-program support, a rival win can dissolve into ambiguity, and a measurement or ethical failure can disappear behind method language. The protocol records each exit before outcome inspection, and the report later shows which branch was reached, why, and what action follows (Chan et al., 2025; Hopewell et al., 2025; Nosek et al., 2018).

The protocol-fixed decision tree is used by analysts, investigators, oversight bodies, and public communicators. Every branch states the permissible claim, prohibited inference, required next action, and whether the result supports a component, returns to development, narrows a reference class, retires a route, or rejects a declared branch.

Public reporting completes the scientific object. Protocol-fixed methods are not enough when the public summary suppresses deviations, missingness, burden, negative controls, recovery performance, rival scores, or adverse events. The reporting plan should map each component verdict to exact language and preserve the same status in the abstract, registry record, figures, press materials, and corrections (Hopewell et al., 2025).

Table 14.7. Protocol-fixed result branches and permitted public language.

Result branch	Required public status	Next action
Candidate outperforms rivals after all gates pass	Component support within declared reference class	Independent replication and transport checks
Rivals match or win	Model-ambiguous for adequate inseparable models; Rival-favored when a rival meets the frozen victory criterion	Diagnose nonseparation; revise or retire the tested bridge only as warranted
Measurement or endpoint failure	Unusable targeted inference	Return to instrument or endpoint development
Mixed or nonseparable results	Model-ambiguous for inseparable adequate models; otherwise apply the gate, adequacy, and identification rules in Section 14.7.4	Redesign before expansion
Adverse ethical result	Protocol route failed or must narrow	Stop, report, protect participants, review route
No-estimate	Valid refusal to infer	Publish feasibility and failure reasons

14.7.1 — Candidate Outperforms Rivals

A candidate-outperforms-rivals verdict requires the entire prerequisite chain to pass: a qualified candidate momentary-valence estimator, an intact endpoint firewall, a sufficiently

independent reserve proxy, adequate model recovery, negative controls without the target signature, interpretable missingness, and ethical burden within the protocol-fixed budget. Predictive superiority is then judged under the same information and scoring rules used for the rivals (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

The public report names the population, endpoint class, instrument version, reserve proxy, rival set, and tested result. Those particulars give readers a clear account of what the study achieved.

The correct status is preliminary component support or route-favored within the declared class. A report may say that, under one qualified estimator and endpoint system, the protocol-fixed reserve-linked conjunction improved held-out performance over named rivals. It must also state the first unresolved gate and the replication required before any stronger status.

An open-problem register links remaining questions, such as scale calibration or transport, to the studies needed to address them.

A favorable result is a promising milestone and the basis for independent replication. Different sites, devices, analysts, endpoint adjudicators, reserve proxies, and rival models should test its robustness before stronger public status is assigned.

The replication packet identifies the exact component that survived, its observation window, the tested specification, and the comparison models. Another team can then reproduce the

analysis and evaluate its transport to a new setting (Hopewell et al., 2025; Nosek et al., 2018).

14.7.2 — Rivals Match or Win

A rival wins when it meets the protocol-fixed victory criterion under the common scoring and adequacy rules. If no model meets that criterion and adequate candidate and rival models remain inseparable, the result is Model-ambiguous. Endpoint changes, post hoc covariates, retrospective narrowing, or relabeling the rival as partial support would change the question after the answer and are therefore reported only as new exploratory analyses (Nosek et al., 2018; Chambers & Tzavella, 2022).

Different rivals carry different consequences. An OU or homeostatic rival may retire a dynamical interpretation while preserving measurement development. A bridge rival may show that endpoint alignment explains the pattern. A frailty or disease-severity rival may relocate the finding to clinical trajectory. A medication or sedation rival may make the result directly care-relevant.

A rival win can be scientifically valuable. It may improve palliative understanding, reveal device behavior, expose site practice, refine endpoint adjudication, or show that the first reference class was poorly chosen. The protocol should treat such findings as knowledge that informs the next study.

Public language should name the winning rival, the failed candidate component, and the resulting action. It may report that the bridge narrowed, the route retired, the clinical process explained the pattern, or the study must return to measurement or

endpoint development. It may not preserve a promise that the protocol-fixed comparison rejected.

A rival win may defeat one component without defeating every possible form of the Law. That distinction is legitimate only if the component and claim version were named before the study. The protocol should not invent a new version after the result and pretend it was always the target.

14.7.3 — Measurement or Endpoint Failure

Measurement or endpoint failure suspends the targeted inference and identifies the bridge that needs further development (Gneiting & Raftery, 2007; National Academies of Sciences, Engineering, and Medicine, 2019).

Measurement failure includes failure to qualify the candidate momentary-valence estimator, sign ambiguity, unstable calibration, excessive artifact, device drift, incompatible versions, or response-shift failure. These failures send the program back to measurement development rather than into a weaker interpretation of the same data. Posterior path uncertainty larger than the target region can instead leave a valid analysis Inconclusive; it is not by itself a measurement-validity failure.

When the endpoint bridge fails, the result names the failed property and exits the terminal-window branch. Loss of independence sends the design back to endpoint construction; false crossings or unresolved returns require a revised state machine; inadequate terminal coverage narrows the estimand to an earlier window; and future-leaking adjudication voids the

prospective analysis. The action follows the defect rather than being softened into generic uncertainty.

Measurement or endpoint failure is reported as failure of the targeted bridge unless the protocol prospectively defined that bridge as a necessary component whose failure defeats a broader claim. The public sentence should name the unusable object and the reason it failed. Calling damaged evidence negative evidence for PTVC would be as misleading as calling it support.

A measurement or endpoint failure may still produce useful secondary findings. It can show that a device is too burdensome, a clinical state is not yet a valid context of use, a stopping channel is too dependent on the ledger, or a site cannot support the cadence. Those findings should be preserved.

When a measurement or endpoint bridge fails, the protocol returns to the first failed gate. Investigators may qualify a new instrument, revise the endpoint classifier, narrow the context of use, or classify the affected evidence as Unusable. They may not cross the gap by rhetorical continuity or treat unusable data as weak support (National Academies of Sciences, Engineering, and Medicine, 2019; Wilson & Collins, 2019).

14.7.4 — Mixed or Nonseparable Results

Mixed or nonseparable results arise when the data do not allocate the observed pattern cleanly among the candidate, named rivals, and observation process. These patterns require the applicable gate and adequacy checks: inseparable adequate models yield Model-ambiguous; an inadequate model set yields Open-set inadequate; a failed required gate yields Unusable evidence; a

valid but undecided analysis yields Inconclusive evidence; and a target that cannot be identified or validly bounded yields No adequate estimate. The correct response is to diagnose nonseparation, not to select the most favorable coefficient (Munafò et al., 2017; National Academies of Sciences, Engineering, and Medicine, 2019).

Mixed results are judged against the entire protocol-fixed conjunction. Reserve coupling with failed negative controls, improved prediction with endpoint leakage, or a favorable mean with unrecovered dependence can produce component findings but cannot advance the route verdict. The report preserves the fracture instead of averaging it into a reassuring middle category.

A mixed result may still be informative. It may show that reserve coupling exists but is mediated by care quality, that endpoint prediction works only under one site practice, that medication explains part of the variance, or that observation shutdown and biological decline are entangled.

The decision tree should specify whether mixed results trigger redesign, additional measurement qualification, richer rival modeling, narrower reference class, or a no-estimate branch. It should not allow expansion to a larger trial simply because some results were attractive.

If the study permits repeated interim looks, adaptive stopping, or rolling site entry, the evidence process must be fixed with the same rigor as the endpoint. A conventional fixed-sample p value cannot be repeatedly inspected without changing its error guarantee. The protocol should therefore choose in advance

between fixed-sample analysis and a time-uniform method such as a confidence sequence or e-process, state the information times and stopping consequences, and report every look. Sequential validity protects early stopping for futility or harm and resists opportunistic stopping after a favorable fluctuation (Howard et al., 2021; Ramdas et al., 2022).

Nonseparability should be named in ordinary language. Readers should not need statistical training to understand that the study could not tell whether the pattern belonged to the candidate, a rival, or the observation process.

Mixed results should be diagnosed by source: model overlap, inadequate cadence, weak negative controls, informative missingness, endpoint ambiguity, or open-set inadequacy. Each source implies a different redesign or stopping rule. Collapsing them into a generic claim of complexity would hide the scientific reason the decision tree stopped (National Academies of Sciences, Engineering, and Medicine, 2019; Talts et al., 2018).

14.7.5 — Adverse Ethical Result

An adverse ethical result is a scientific result for this chapter. If the protocol creates excessive burden, distress, privacy risk, staff overload, family pressure, care confusion, or withdrawal due to discomfort, the route has failed or must narrow. A statistically promising pattern does not compensate for that failure (Nosek et al., 2018; Chambers & Tzavella, 2022).

The adverse branch should be protocol-fixed, with pause, modification, and termination thresholds; authorized trigger roles; support and incident procedures; data-disposition rules; and

required public reporting. Ethical feasibility cannot be reconstructed after the study by subtracting the participants who carried the greatest burden.

Adverse outcomes may be participant-level, family-level, staff-level, site-level, data-level, or public-communication-level. A privacy incident after data collection is not less important than a device discomfort event during collection. A public artifact that creates dangerous misunderstanding can also be an adverse result of the research program.

Once an ethical stopping rule fires, the event must propagate through the abstract, public registry where applicable, methods, participant-flow account, limitations, data disposition, and replication status. Investigators report exposure before the stop, support offered, whether collected data remain usable, and whether the design may be modified or must be retired. A buried appendix cannot carry an adverse result that changes the study's legitimacy.

An adverse ethical result should trigger route review. The program may move to less intrusive designs, safer populations, instrument-only development, retrospective feasibility studies, or no further terminal recruitment until the cause is repaired.

Participation remains voluntary through the final observable moment. A participant may sleep, decline, disconnect a device, refuse a question, withdraw, or become unable to continue without owing the study a replacement observation. The design treats those outcomes as part of feasibility and the observation process, never as a moral or scientific failure by the person

(Council for International Organizations of Medical Sciences, 2016; World Medical Association, 2024).

14.7.6 — Registered Public Report

Before enrollment, investigators prepare a protocol-fixed report shell for participant flow, burden, missingness, endpoint adjudication, deviations, negative controls, recovery, rival scores, adverse events, and claim-status consequences. For this prospective protocol, the plan qualifies as preregistered only when it is deposited before enrollment in a timestamped, read-only external registry record with a persistent identifier (Chan et al., 2025; Hopewell et al., 2025).

The report protects raw terminal and family material while identifying the measurement version, reserve proxy, endpoint system, estimand, rival set, reference class, missingness model, decision rule, analysis version, and deviations behind each component verdict. Null, adverse, unusable, inconclusive, and rival-win outcomes remain publicly auditable under privacy rules.

Versioned correction connects replication failure, data corruption, classifier retirement, privacy incidents, or coercive recruitment to revised status and visible notice on every high-reach artifact. Answerability comes from reconstructable provenance and branch-matched language, not a dramatic terminal image (von Elm et al., 2007; National Academies of Sciences, Engineering, and Medicine, 2019).

14.8 — Protocol Limits and Replication Gate

The first protocol is designed to produce a bounded, informative, humane result. A finding that survives the specified prerequisites and comparisons can justify independent replication; other outcomes can justify stopping, returning to development, narrowing the route, or identifying a more informative next question (Chambers & Tzavella, 2022; Munafò et al., 2017).

The protocol specifies site coverage, observation windows, estimands, measurement qualification, and permitted analyses before recruitment.

The protocol-fixed public report should ship with a replication packet that makes independence possible: frozen code, schemas, endpoint-adjudication materials, calibration recipes, rival specifications, hardware and firmware identifiers, incident logs, and a list of judgments reserved for the replication team. The report should distinguish computational reproduction of the original analysis from a genuinely independent test of the scientific claim.

Table 14.8. Protocol limits and replication gates.

Limit	Rule	Reason
Single-site result	Preliminary only	Site practice, care model, staffing, and population may drive patterns
Whole-life claim	Not allowed without independent initial-ledger bridge	Late windows observe increments, not entire lives

Limit	Rule	Reason
Individual verdict	Forbidden	Scientific models evaluate specified research outcomes
Replication	Independent sites, analysts, calibration, endpoint, and rival checks required	Protects against local, technical, and interpretive artifacts
Public artifacts	Embargoed until claim-status and safety review	Prevents early diagrams or summaries from becoming proof language

14.8.1 — Single-Site Results Are Preliminary

A single-site result is preliminary even if it is statistically strong. Hospice practice, staffing, culture, diagnosis mix, symptom protocols, family presence, documentation habits, device tolerance, and endpoint adjudication can all be site-specific. The study may learn something real about that site without learning a transportable law (Chambers & Tzavella, 2022; Munafò et al., 2017).

The first protocol may deliberately begin in one or a small number of highly prepared sites because ethical and operational quality matter more than breadth. That choice is defensible only if the public status remains local. A carefully governed site is not a miniature universe.

Site context should be described as part of the data-generating environment: care model, population mix, staffing, palliative expertise, medication practice, device workflow, family-room

norms, documentation systems, and endpoint adjudication. Those features can change both what occurs and what becomes observable.

A favorable single-site result should trigger replication design, not broader claim language. The next site should not be selected because it is likely to reproduce the result. It should test whether the result survives meaningful change in care context, population, device environment, and analytic personnel.

An unfavorable single-site result may also be preliminary. If the design fails because the site cannot support cadence, endpoint independence, or burden limits, that result may be operational rather than theoretical. The report should distinguish site infeasibility from component defeat.

14.8.2 — No Whole-Life Reconstruction

A late clinical window identifies an increment under its measurement model. Complete-history reconstruction uses an independently qualified initial-state bridge or sufficiently comprehensive prior observation specified before terminal outcomes are examined (National Academies of Sciences, Engineering, and Medicine, 2019; Nosek et al., 2018).

The initial state therefore enters the analysis explicitly, with its available information, bounds, and sensitivity to alternative assumptions.

The window-level targets are defined in §14.1.2. Terminal-regime concentration or equivalence may be analyzed secondarily under declared origin and bias assumptions, but a whole-life claim requires a qualified bridge to the unobserved history.

A report should never say that a participant's life balanced because the observed terminal window approached a band. At most, it may say that a measured window-level trajectory showed or failed to show a protocol-fixed signature under a specified estimator and endpoint system.

Complete-history inference requires long-term longitudinal observation, independent bounds on the initial ledger, or a formally justified bridge between observed windows and earlier history.

State the observed terminal window and its estimand in the abstract, figures, and public summary. Identify any independently qualified historical or measurement bridge used to extend the analysis beyond that window (National Academies of Sciences, Engineering, and Medicine, 2019).

14.8.3 — No Individual Verdict

The protocol returns study-level findings and agreed descriptions of observed windows. It excludes personal judgments about worth, meaning, or whether a life balanced. Consent materials, staff training, and result-return plans specify that scope in ordinary language (Council for International Organizations of Medical Sciences, 2016; World Medical Association, 2024).

This rule applies even when an individual trajectory looks dramatic. A graph can appear to approach neutrality, flatten, compress, or turn. Such displays may be useful for internal quality review or aggregate modeling, but they are not personal truth and should not be shown as meaning.

Participant and family communication should avoid claim language. The study may explain participation, privacy, withdrawal, burden, and general scientific aims. It should not tell families that a pattern suggests closure, balance, fairness, peace, failure, or destiny.

Individual-level estimates may exist within the statistical model, but access should be restricted and purpose-limited. They are research quantities used for model fitting, diagnostics, and uncertainty assessment. They are not records of worth, prognosis, holiness, trust, eligibility, or care entitlement.

This rule also protects clinicians. A bedside team should not receive research interpretations that could shape care unless a predefined safety issue requires communication. Care decisions follow clinical judgment, patient preference, and established practice, not a fairness estimator.

Population and component estimates remain statistical objects with uncertainty and reference-class limits. Even a well-calibrated individual random effect is not a verdict about a person's inner truth, worth, prognosis, or complete life. Interfaces and access controls should prevent model diagnostics from being repurposed as personal interpretations (Council for International Organizations of Medical Sciences, 2016; Nissenbaum, 2010).

14.8.4 — Independent Replication Required

Independent replication requires more than rerunning code on a new sample. It requires meaningful independence in site selection, recruitment route, clinical workflow, endpoint adjudication, measurement implementation, reserve proxy,

analyst team, rival model specification, and public reporting review (Chambers & Tzavella, 2022; Munafò et al., 2017).

The replication plan should include at least one site differing in care model or population, an analyst team independent of the original primary analysis, and an endpoint adjudication team applying the same protocol-fixed rules without access to ledger-derived features. The replicated estimand and the intentionally changed transport dimension must be identified separately.

Device and pipeline replication matter. A result that survives only under one sensor model, preprocessing version, or quality-control rule may be a technology artifact. A result that survives across devices may still require calibration and versioned provenance before it can be compared.

Rival replication is essential. Replication does not count if the candidate is tested carefully and the rivals are simplified. OU, bridge, frailty, medication, observation shutdown, shared-driver reserve, and hybrid models should travel with the replication package and be improved when criticism shows they were too weak.

Publication of replication should preserve negative and mixed outcomes. A first positive followed by unpublished failures would recreate the very selective evidence problem this chapter exists to prevent. The replication record should be cumulative and correction-ready.

Only after independent replication can public scientific status begin to strengthen beyond preliminary component support. Even then, status changes remain component-level until broader

reference classes, measurement versions, endpoints, and transport assumptions are tested.

14.8.5 — Transport and Calibration Recheck

Transport is not automatic. A protocol that works in one hospice system may not work in another region, language, illness group, disability context, cultural death practice, family structure, or technology environment. The transport gate asks whether the measured object, endpoint, reserve proxy, and burden structure retain their meaning outside the original context (National Academies of Sciences, Engineering, and Medicine, 2019; Nosek et al., 2018).

Calibration must be rechecked at each new site and population. The context of use for the candidate momentary-valence estimator, sign identification, instrument version, device behavior, response shift, clinical-state robustness, and endpoint-classifier performance may all change under different conditions. A common label does not create a common scale.

Transport analysis should specify which assumptions are being moved. Population, clinical state, endpoint class, instrument version, reserve proxy, medication regime, cadence, and observation process should each receive a transport statement. If one cannot be defended, the claim narrows.

Transport studies should include overlap wherever feasible: dual devices, parallel scoring versions, shared calibration samples, and independent endpoint review during a bridge period. The overlap data should be held apart from the final transport test so that the bridge is estimated before its success is judged. Silent migration

across sites or versions creates a new measurement system, not a replication.

When transport fails, the result is not useless. It may reveal that the phenomenon is site-dependent, that measurement is not stable, that care practice dominates, or that a reference class was too broad. Such findings are valuable if they are reported plainly.

Failed transport should cost the program scope, not cost participants additional exposure merely to defend a preferred conclusion. When language, device, care setting, or observation cadence changes the measurement bridge, the study recalibrates, narrows, or stops. The burden of demonstrating continuity remains with the investigators and sponsor (Dahabreh et al., 2019; World Medical Association, 2024).

14.8.6 — Public Artifact Embargo

Public artifacts remain embargoed until claim-status, privacy, recruitment, and hostile-crop review are complete. The rule covers graphs, diagrams, dashboards, animations, social excerpts, donor summaries, press language, educational guides, and model images. Every released object should identify the population, measured object, observation window, comparator set, uncertainty, and verdict ceiling within the artifact itself (Hopewell et al., 2025; Fischhoff & Davis, 2014; Spiegelhalter, 2017).

Artifacts should distinguish observed, filtered, forecast, smoothed, simulated, synthetic, retrospective, endpoint-aligned, and sensitivity-only quantities. Recruitment materials face a stricter rule: beauty, destiny, spiritual resonance, belonging, aid, care access, or fear of missing out may not be used to influence

participation. Burden, privacy, withdrawal, and the possibility of no usable inference must be stated with equal visibility.

Review standalone images, captions, and sentences for accurate context, privacy, and consistency with the study's result. Revise any item that could misstate the finding or expose participants and families before release.

A first study that survives its gates should provide a complete replication packet. It includes the protocol and registry identifier where available, endpoint manual, data dictionary, codebook, simulation library, model and rival specifications, burden limits, missingness marks, adverse-event definitions, decision table, analysis environment, and report templates needed for independent evaluation.

Replication materials preserve threshold sensitivity, alternate windows, competing missingness models, rival specifications, and analyses that nearly changed the decision. Private terminal narratives, identifiable family material, and raw records unnecessary for verification remain protected.

Table 14.9. Replication packet minimum contents.

Replication packet item	Minimum content	Why it matters
Protocol version	Registration date, amendments, freeze points, responsible committees	Prevents silent claim-version drift

Replication packet item	Minimum content	Why it matters
Endpoint manual	Candidate, detected, adjudicated, censored, return, and no-estimate rules	Protects the endpoint firewall
Momentary and interval estimator dictionary	Channel version, transforms, cadence, quality marks, posterior path rules	Prevents score summation from replacing measurement theory
Reserve proxy specification	Context of use, units, confounds, calibration, error model, abstention rule	Prevents reserve from becoming an all-purpose frailty label
Rival and simulation package	Generative worlds, parameter ranges, model-recovery thresholds, confusion matrix	Shows that the design could distinguish alternatives
Burden and safety ledger	Participant, family, staff, privacy, and clinical stop events	Keeps feasibility and ethics inside scientific status
Public language templates	Branch-specific summaries for support, rival win, no-estimate, and adverse result	Prevents post hoc rhetorical rescue

A second study should be adversarial in at least one consequential dimension, such as device family, site, endpoint adjudication team, population, cadence, or the rival that most threatened the first result. Reproducing every favorable local choice is a repeat performance rather than a transport test. The replication protocol

should state which changes test generalization, which require recalibration, and which create a new estimand.

The bounded protocol record consists of population and context of use, measurement and endpoint systems, estimands and intercurrent-event rules, rival and open-set generators, simulation and recovery thresholds, missingness and safety branches, stopping rules, public language, correction routes, and replication gates. The freeze checklist below is part of the scientific object. Apply §6.7's prospective-specification terminology to the finalized pre-enrollment package. The frozen package should also include hashes or equivalent identifiers for the exact code, model, and instrument versions used at enrollment.

Table 14.10. Protocol freeze checklist.

Protocol element	Required freeze before enrollment	Failure if absent
Population and reference class	Sites, diagnoses, care settings, consent pathways, exclusions	Results generalize by rhetoric rather than design
Measurement system	momentary-estimator version, auxiliary channels, calibration, artifact rules, cadence	Measured patterns cannot be interpreted
Endpoint system	Independent clocks, adjudication rules, return handling, censoring, no-estimate states	Terminal inference becomes circular or unstable

Protocol element	Required freeze before enrollment	Failure if absent
Estimands	Attributes, windows, intercurrent events, population level, summary measures	Analysts estimate different questions after seeing data
Rival set	Model families, scoring rules, hybrid and none-of-models branches	Candidate wins by comparison to weak alternatives
Recovery simulations	Parameter recovery, model recovery, noise floors, missingness, endpoint jitter	The study may be unable to learn before it recruits
Negative controls	Outcomes, timing controls, endpoint shuffles, artifact channels	Design artifacts may masquerade as signatures
Safety and burden plan	Stop rules, adverse events, privacy incidents, staff burden, family protections	Human cost becomes invisible to the scientific verdict
Reporting tree	Support, rival win, failure, mixed, no-estimate, adverse-result language	Public meaning is rescued after the fact

The gates remain noncompensatory, and the final report should state which future studies are barred until prerequisites improve. Simulation cannot repair coercive recruitment, endpoint precision cannot repair an unqualified instrument, rival comparison cannot erase a privacy incident, and comfort-triggered missingness cannot be relabeled as convenient missing-at-random data.

Measurement failure may redirect work to calibration, endpoint failure may limit the result to method development, and excessive burden may stop terminal recruitment until a lighter design is independently reviewed. The report should distinguish a gate that can be repaired before replication from one that invalidates interpretation of the current cohort entirely.

The first protocol closes with an ethic of small, exact learning. It may narrow, pause, redirect, or stop the program. Trust is earned by learning one bounded thing without taking more from participants, families, or clinical teams than the scientific question has the right to ask. A small valid result should outrank a broader conclusion assembled by combining components whose prerequisites were never jointly satisfied.

Chapter 15 — Sleep, Dreams, and Affective Reprocessing

Sleep provides a repeated natural laboratory in which consciousness, report, memory, physiology, and affect separate and recombine. Its scientific richness becomes useful when those layers are kept explicit. Nocturnal change can then generate discriminating hypotheses without being turned into hidden balancing, prophecy, or privileged access to the latent ledger.

Sleep and dream data provide auxiliary evidence about state, report, memory, and affective transition. Dream content may illuminate fear, desire, grief, pain, bodily disturbance, and memory recombination, but the report remains an observation rather than a nocturnal ledger. Dream experience, awakening, recall, coding, and later interpretation are therefore modeled as distinct stages of one pathway (Palmer & Alfano, 2017; Tempesta et al., 2018; Siclari et al., 2017).

The fairness question enters through burdens that silence can hide. Fear, bodily discomfort, grief, medication, respiratory struggle, trauma recurrence, and fatigue may occur without public report, while measurement earns access only through consent and purpose limitation. Bounded sleep studies can test specified auxiliary mechanisms only while preserving privacy and giving strong sleep-science rivals equal standing.

The most basic discipline is separation. Sleep experience, dream report, dream recall, physiological stage, next-day affect, and clinical sleep disorder are not the same object. A vivid dream report may reflect a strong nocturnal experience, a memorable fragment, an awakening effect, a cultural narrative habit, or an interviewer's timing. A quiet morning may reflect recovery, depletion, medication, dissociation, habituation, or simple lack of

recall. The chapter's first scientific task is to keep these objects apart.

The second discipline is equal-status rivalry. REM and NREM processes, emotional-memory consolidation, extinction, fear generalization, noradrenergic modulation, predictive updating, homeostatic sleep pressure, circadian phase, nightmares, sleep-disordered breathing, targeted memory reactivation, medication, and ordinary recovery can all produce apparent affective adjustment. A Law-specific auxiliary mechanism advances only when its frozen predictions outperform these alternatives under the same observation model.

Time supplies a third discipline. Within-night transitions, awakening reports, morning mood, next-day behavior, and longitudinal recurrence answer different questions. Reduced autonomic arousal after a REM-rich period, a morning report of relief, and a month-long reduction in nightmares after treatment therefore require distinct estimands and mechanisms.

For that reason, the chapter treats a dream report as the output of an observation process. Experience, awakening, selection, memory, language, coding, confidence, and later interpretation are separate stages. Scientific use requires the protocol to record the stage, delay, medication, daytime burden, prompt, privacy option, and uncertainty that shaped what became reportable.

Affective reprocessing is a candidate mechanism. Nightmares, trauma replay, grief dreams, and recurrent threat may reflect harm, emotional learning, failed integration, medication, arousal, or a clinical state requiring care. Their occurrence alone

establishes neither a balancing mechanism nor moral payment. Any genuinely felt contribution remains part of the stream under its declared representation; the signed remainder requirement and the explanation of a particular dream are separate questions.

Sleep remains unusually valuable because it permits repeated within-person designs, natural state transitions, stage-specific sampling, noninvasive physiology, next-day follow-up, and negative-control nights. These features make it possible to test whether a proposed auxiliary mechanism transports across nights and channels, or dissolves into ordinary memory, arousal, respiratory, circadian, and measurement explanations.

The inquiry follows the observation pathway rather than touring dream theories. It fixes what sleep evidence can update, separates experience from report, compares reprocessing accounts, centers nightmares and trauma, links physiology to specific measurement questions, and ends with study families, data fields, privacy, and verdict ceilings. Each step reduces the inferential distance between a hidden state and a public claim.

The payoff is a set of bounded outcomes. A study may support one reprocessing component, favor an ordinary rival, show that awakening changes the state, reveal that privacy or burden prevents adequate observation, or return No adequate estimate. Each outcome improves the next design.

Sleep research can contribute mechanisms, instruments, comparisons, and increasingly informative observations. Optional reporting and participant-controlled disclosure keep that

inquiry compatible with private experience and personal meaning.

The preferred designs can reduce confidence as well as increase it. Dream reports may add nothing after sleep continuity, medication, waking concern, and report probability are modeled; trauma recurrence may explain nightmare patterns; awakening may distort the target state; privacy review may exclude decisive content. These outcomes retire weak bridges before they become public claims.

15.1 — Sleep as Auxiliary Evidence

Sleep belongs in the science volume because it offers repeated observations of changing consciousness, physiology, memory, and affect. The night can reveal transitions that daytime reports miss, creating a valuable setting for state-sensitive measurement and carefully specified reprocessing hypotheses (Walker, 2009; Siclari et al., 2017).

Sleep offers repeated opportunities to test state-dependent experience, memory updating, affective residue, and physiological recovery. These questions connect specific measurements to candidate mechanisms and prospective predictions.

The central discipline is to keep scientific interest separate from evidentiary scope. A sleep pattern can reveal a useful mechanism, improve measurement, or defeat an auxiliary route without making exact terminal closure more probable. That distinction protects the public from treating dream science as proof and protects participants from being cast as characters in a theory they never agreed to embody.

A final discipline follows from that separation: the sleep chapter must never become the emotional substitute for the first falsification protocol. Sleep studies are safer and repeatable, which makes them valuable, but their safety does not enlarge their warrant. They can strengthen instruments, reveal rivals, and test mechanism fragments; they cannot perform the work of endpoint and longitudinal designs.

Table 15.1. Auxiliary sleep evidence and claim limits.

Evidence family	Can update	Cannot update
Sleep-stage physiology	State timing, arousal context, rival mechanisms	latent cumulative process level, terminal valence closure, human worth
Dream reports	Selected nocturnal content, recall and disclosure processes	Whole-night experience, hidden ledger access, moral meaning
Next-day affect	Local transition and residual burden under controls	Whole-life closure or endpoint equality
Repeated-night patterns	Within-person auxiliary mechanisms and rivals	Universal Law status or cross-person rank

15.1.1 — Auxiliary, Not Foundational

A sleep study connects a specified conscious state, observation channel, and prediction about experience, reporting, or measured affect. Those connections define its empirical question (Walker, 2009; Palmer & Alfano, 2017).

Dreams can be vivid, personally transformative, and central to grief or identity. Research can preserve those qualities while describing the sampling and measurement process that produced each record.

An auxiliary hypothesis can be exact. It may predict that specified affective residues change during particular sleep states, that prespecified dream features add next-day predictive information after report bias is modeled, or that sleep disruption changes a

transition expected under a reprocessing account. Each prediction receives its own test.

Sleep's strongest contribution is often diagnostic: it can localize where an experience-to-report bridge fails before any Law-specific interpretation is assigned. Section 15.2 develops that observation chain in full.

Participants control dream disclosure. Refusal, no recall, partial disclosure, and privacy-based exclusion remain legitimate observation states, recorded according to the agreed data plan.

Before collection, label each sleep question by its role: mechanism, measurement, model comparison, exploration, or privacy feasibility. The public report connects each finding to that question and its declared reference class.

15.1.2 — Conscious Experience During Sleep

Sleep is not a uniform absence of consciousness. People may later report visual imagery, emotion, bodily sensation, thought-like mentation, lucidity, fear, relief, confusion, or nothing at all. The absence of a report is not identical to the absence of experience, and a report of experience is not identical to continuous awareness across the whole interval (Tempesta et al., 2018; Cartwright et al., 1998).

Sleeping consciousness should be analyzed by state and transition rather than averaged into one nocturnal category. REM, NREM stages, microarousals, sleep onset, awakening, and fragmented sleep differ in report probability, cognitive organization, autonomic activity, and memory accessibility. A pooled score can

therefore mix changes in experience with changes in access and retrieval.

The Law's bearer problem becomes sharper during sleep. A stream may be unified, dim, fragmented, intermittently reportable, or inaccessible to later memory. That is why this chapter defers final unity classification to the consciousness and endpoint chapters, while still requiring sleep studies to record the uncertainty instead of treating all sleep as ledger-active or ledger-silent by assumption.

Sleep also stresses the distinction between access and experience. A person may have dream experience that cannot be retrieved on waking, or may retrieve a narrative that was reconstructed from fragments. Conversely, physiological arousal may occur without reportable dream content. None of these possibilities authorizes a single easy rule about whether the latent cumulative process is accumulating.

State labels travel with report status, timing, confidence, medication context, and missingness. Useful categories include report-positive, report-negative after awakening, no awakening, awakening-distorted, low-confidence, medication-confounded, and No adequate estimate. These labels preserve uncertainty in analyzable form instead of treating a silent night as neutral.

The framework gives experience scientific importance even when ordinary report is unavailable. Sleep research helps identify which methods can recover useful evidence about those intervals and where uncertainty must remain explicit.

The research design should therefore use graded state confidence rather than binary sleep-consciousness declarations. A report-positive REM awakening, a report-positive NREM awakening, a spontaneous morning memory, and a no-report interval under medication should not be coded as equivalent states of access. They each carry different uncertainty about consciousness, memory, and affective contribution.

A difficult but necessary implication follows: the measured absence of report can never be used as a simple zero in a ledger-like construction. If an interval is low access, low signal, or no-estimate, the data structure should say so. The scientific program gains more from honest unknowns than from a smooth nocturnal curve built by calling the invisible empty.

15.1.3 — Sleep Architecture and Affect

Sleep architecture gives the chapter its first ordinary scientific scaffolding. REM sleep, NREM stages, slow-wave activity, spindles, arousals, respiratory events, cardiac events, and circadian timing can shape memory, affect, reportability, and next-day function (American Academy of Sleep Medicine, 2023; Siclari et al., 2017).

A recent experiment makes the opportunity tangible. Greco and colleagues analyzed 18 healthy adults after replaying, during REM sleep, sounds associated with half of a set of negative images. At the 48-hour assessment, cued images elicited lower responses in selected emotion-related brain regions and less heart-rate deceleration than uncued images. Subjective arousal decreased for initially more upsetting images but increased for

less upsetting images. This small study supports selective, baseline-dependent modulation of emotional responses. Following all three channels helps identify which part of an emotional response changes (Greco et al., 2025).

Sleep continuity provides a complementary research opportunity. Wassing and colleagues (2019) studied 29 participants with evening and morning brain measurements surrounding overnight sleep recording. More uninterrupted REM sleep was associated with greater overnight amygdala adaptation, while more restless REM was associated with less adaptation. Sleep continuity can therefore enter a prespecified model of affective change alongside memory and waking context. Existing-data reanalysis and voluntary observation of natural nights can test whether cumulative affective history adds prediction beyond recent distress and sleep quality.

NREM sleep is equally important. Slow-wave sleep, spindle activity, hippocampal-cortical replay, and homeostatic pressure may influence memory stabilization, abstraction, and next-day regulation. NREM-linked change directs the analysis toward memory consolidation and stage-specific mechanisms.

Circadian phase and homeostatic pressure also matter. A person's evening burden, sleep debt, temperature rhythm, cortisol pattern, light exposure, and awakening time can affect mood before dream content enters the analysis. Without these controls, a study may mistake time-of-day physiology for nocturnal affective work.

The evidence baseline is layered. Stage architecture can orient hypotheses; physiology can time candidate processes; reports can

sample selected experience; next-day measures can test residual change.

Sleep architecture offers a rich set of measurable mechanisms. The chapter asks which findings refine the proposed route, which are explained by established sleep science, and what prospective comparison would distinguish them.

Stage information helps interpret changes in physiological variability. Sedation, exhaustion, respiratory obstruction, sensor limitations, and deep sleep can each produce a quieter signal through different processes. Channel-specific models distinguish those explanations.

For field experts, the crucial standard is context of use. A sleep-stage feature can be used to schedule awakenings, stratify reports, model arousal, or define a rival pathway. It cannot be treated as a universal psychological variable. The chapter's later protocols preserve this distinction by requiring stage labels, report status, and next-day outcomes to remain separable.

15.1.4 — Reprocessing as Candidate Function

Affective reprocessing names the possibility that sleep changes how affective material is organized, carried, recalled, or embodied. Researchers can investigate its timing, mechanisms, and relationship to waking experience through explicit models and observations (Walker, 2009; Palmer & Alfano, 2017).

A workable reprocessing hypothesis needs a direction, a time scale, a measurement object, and a rival set. It might predict reduced next-day reactivity to a daytime stressor after intact sleep, altered dream affect after targeted memory reactivation, or a

reserve interaction in which poor sleep quality weakens preterminal affective stabilization. Without such specificity, reprocessing is only a beautiful word.

The Law-specific version would need to do more than show that sleep affects emotion. It would need to show a pattern that is prospectively specified, distinct from ordinary memory consolidation and arousal regulation, robust to report bias, and tied to the particular burden-and-trajectory structure under investigation. That is a much harder target and therefore a more useful one.

Failure must be allowed. Sleep might worsen next-day affect, leave affect unchanged, amplify nightmares, stabilize traumatic memory, or produce improvements fully explained by ordinary sleep quality. Each result narrows the mechanism rather than inviting a rescue story. A hypothesis that turns every dream into evidence has left science.

Sleep-related distress calls for care on the person's own terms. Reprocessing describes a candidate mechanism; clinical and personal decisions respond to the sleeper's needs, experience, and preferences.

The candidate function supports disciplined hope: sleep offers repeated opportunities to study affective transition and improve its measurement. A distinct route signature would justify further testing; an ordinary sleep-science explanation would still identify mechanisms that help the program become more precise.

A reprocessing model specifies the conditions under which sleep should improve next-day affect, leave it unchanged, or increase

distress. Sleep disruption, nightmares, and ordinary memory consolidation provide concrete comparisons for testing those predictions.

The most useful form of the hypothesis is not a statement about dreams fixing emotion, but a set of conditional predictions. Given a measured pre-sleep burden, a qualified sleep-state profile, a report model, and a next-day residual, the study asks which rival family best predicts the transition. That framing makes reprocessing testable without making it mystical.

15.1.5 — Waking Comparators

No sleep hypothesis can stand without waking comparators. Affective change occurs during waking rest, social contact, distraction, rumination, medication, therapy, exercise, pain relief, food, light exposure, and ordinary time. A sleep-linked pattern matters scientifically only if it differs from plausible waking baselines or interacts with sleep-specific mechanisms in a protocol-fixed way (Tempesta et al., 2018; Cartwright et al., 1998).

The simplest comparator is within-person daytime burden. A study should know what the person carried before sleep: stressor exposure, pain, conflict, grief cue, medication, fatigue, social support, physical symptoms, and anticipatory worry. Without this pre-sleep baseline, a morning report cannot be interpreted as recovery, persistence, worsening, or measurement noise.

The second comparator is an altered-sleep or poor-sleep night. Fragmented sleep, delayed sleep, REM suppression, respiratory disruption, nightmare recurrence, and awakening protocols can

all change the next-day affective trajectory. These conditions should be modeled carefully rather than treated as mere exclusions, because they may reveal which processes are actually doing the work.

The third comparator is a no-dream-report night. If next-day affect changes without recalled dream content, the mechanism may lie in sleep physiology, memory consolidation, or unreported experience. If recalled content predicts change only after high-intensity awakenings, the report mechanism itself may be creating the association.

The fourth comparator is waking reappraisal: people reinterpret events, receive comfort, change plans, and forget details while awake. Without measuring this, sleep studies may credit the night with what the day accomplished.

Comparators prevent unmeasured waking life from making sleep seem mysterious. Fairness science must track burden across day and night; neglecting either distorts the other.

The comparator problem is especially important for ordinary days. This method of locating hidden cost asks where burden is carried, and much burden is carried in chores, caregiving, conflict, anticipation, or quiet support. A sleep design that samples only the night risks treating the day as an unmeasured disturbance when the day is the burden field from which the night begins.

15.1.6 — Rival Sleep Science

Rival sleep science must be named before data arrive. Emotional-memory consolidation, extinction, reconsolidation, threat

simulation, predictive updating, arousal regulation, circadian mood effects, medication effects, and sleep-disorder mechanisms belong in the comparison set. Zhang and colleagues provide one active-dreaming result within that larger field; it is not a general theory of sleep or a warrant for closure (Palmer & Alfano, 2017; Tempesta et al., 2018; Zhang et al., 2024).

Regulation rivals predict that ordinary sleep may reduce next-day reactivity through restoration, memory abstraction, autonomic settling, or reduced physiological stress. A candidate account that also predicts improvement must therefore specify a distinct dependence on pre-sleep signed burden, state sequence, or independently measured capacity. Improvement by itself is not discriminating.

Other rivals predict worsening rather than repair. Nightmares may rehearse fear, fragmented REM may amplify distress, pain and dyspnea may repeatedly interrupt sleep, and sleep-disordered breathing may leave the person more depleted. The study family must permit those directions and report them without forcing every night into a recovery narrative.

Report selection can create strong apparent effects even when underlying sleep mentation is ordinary. Intense, bizarre, emotional, recently cued, or repeatedly rehearsed dreams are more likely to be remembered and described. Sampling only remembered dreams therefore conditions on a collider-like reporting process whose determinants should be modeled explicitly.

Language and cultural interpretation shape how the same remembered event is narrated. A grief dream may be described as visitation, stress, memory, bodily disturbance, or spiritual experience, and those labels need not represent comparable measurement units. Coding should separate descriptive content from participant meaning and should not erase nonbelief or culturally specific interpretation.

The chapter invites sleep scientists to help specify and test the auxiliary mechanism. Their strongest models give the proposed route a clear benchmark and make any additional predictive value easier to recognize.

The rival set should be operationalized, not merely named. A memory-consolidation rival should define memory outcomes, a threat-simulation rival should define threat content and recurrence, an arousal-regulation rival should define physiological and next-day markers, and an observation-selection rival should define report probability. Rival seriousness means each alternative has enough structure to win.

A night can include tonic affect, phasic images, state changes, and altered memory. Modeling how sleep redistributes, suppresses, amplifies, or transforms particular signals helps identify which dynamics a candidate mechanism needs to explain.

15.2 — Dream Experience, Report, and Recall

Dream evidence passes through several filters before it reaches a dataset. Experience may occur without later recall; recalled fragments may remain incomplete; an interview may be delayed, interrupted, or declined; and coding may erase ambiguity. High-density EEG work on parasomnia episodes is valuable precisely because the presence of experience and the recovery of content separated within the same observed state (Siclari et al., 2017; Cataldi et al., 2024).

The observation chain is now explicit: sleep state, possible experience, awakening, encoding, recall, report, coding, and later interpretation. Every link can fail or change the signal. Dream research remains valuable precisely because the design refuses to substitute one late link for the entire chain.

The report chain is also a consent chain. Every movement from experience to report, from report to code, from code to model, and from model to public summary changes what the participant has allowed the study to hold. This section treats those transformations as scientific facts rather than merely administrative permissions.

Because that chain is fragile, the most truthful dream dataset will often look less complete than a public audience expects. It will contain refusal, fragments, uncertain reports, no-recall intervals, cultural notes, and restricted content. Those markings are not defects. They are the visible form of scientific honesty around a private state.

15.2.1 — Dream State Versus Dream Report

The dream state is the candidate experience; the later report is the observation. A person may experience without recalling, recall only fragments, reshape content after awakening, or decline to disclose material that feels private, shameful, sacred, or confusing. Report probability and recall confidence therefore belong in the observation model, and silence cannot be equated with dreamlessness (Siclari et al., 2017; Cataldi et al., 2024).

A dream report therefore has to be treated like a measurement with a sampling mechanism. Its presence depends on sleep stage, awakening timing, intensity, salience, language, confidence, context, and willingness. The narrative may preserve affective truth while losing temporal order, or preserve a striking image while losing the emotion that surrounded it.

The report supplies a filtered record of sleep experience or memory. Its interpretation includes the awakening procedure, recall interval, and reporting conditions.

The observation model should include report availability, content length, affect rating, confidence, disclosure limits, and refusal. A refusal is not invalid data. It may be an ethically successful boundary that tells the study which measurements are too intimate for the participant or the setting.

The model also needs uncertainty about the unreported portion of the night. A vivid nightmare report does not imply that the entire sleep period was negative. A pleasant fragment does not imply repair. A blank report does not imply absence of experience. These are partial observations with structured ignorance.

Separating state from report creates testable questions about the filter itself. Report probability can be modeled as a function of stage, awakening method, medication, pre-sleep burden, arousal, and next-day mood. The study can then ask whether an apparent affective pattern belongs to sleeping experience or to which experiences became reportable.

The dream-state/report distinction should be built into the variable names themselves. A study that labels a field dream valence when it actually stores reported dream-valence after awakening has already hidden a major assumption. The more exact name is report-coded dream affect, with separate fields for stage, delay, confidence, and disclosure restriction.

This naming discipline helps clinicians and participants too. A person may disagree with a coder's label, may not want an image interpreted, or may state that the report captured only a fragment. If the dataset preserves those distinctions, disagreement becomes information instead of an error to be corrected by the researcher.

15.2.2 — Awakening and Sampling

Awakening is not a neutral camera. It interrupts sleep, changes physiology, alters memory access, and can affect the next report. A dream study that wakes participants for temporal precision buys information at the price of sleep disruption, reactivity, and burden. The protocol should randomize or otherwise model awakening schedule where feasible, report failed and refused awakenings, and distinguish the state being studied from the state created by measurement (Palmer & Alfano, 2017; Tempesta et al., 2018).

Sampling time matters. Reports after REM awakenings, NREM awakenings, spontaneous awakenings, morning recall, and middle-of-night probes may differ in content, emotionality, length, and confidence. A study that mixes them without labels may convert methodological heterogeneity into false psychological findings.

Sampling intensity also matters. Frequent awakenings can increase recall while reducing sleep quality, and the resulting next-day affect may reflect the protocol rather than the dream process. The design must therefore include awakening burden, sleep fragmentation, and next-day fatigue as variables, not merely tolerability notes.

A privacy-preserving alternative is staged sampling. The study may use physiology and actigraphy on most nights, brief morning affect reports on many nights, optional dream keywords on selected nights, and full narrative only in a smaller consented sub-study. The richest data need not be the default data.

Sampling should be matched to the scientific question. If the question concerns within-night stage-linked mentation, awakenings may be justified. If the question concerns next-day residue, morning report and EMA may be enough. If the question concerns nightmares, clinical diary methods may be safer than laboratory interruption.

The burden lens is precise here. The more the study wakes, prompts, records, or asks, the more the protocol becomes part of the phenomenon. A fair design counts that burden as a causal input into the data-generating process.

Sampling also creates a burden gradient. Healthy volunteers in a sleep laboratory, older adults at home, trauma survivors, hospitalized patients, and palliative participants may tolerate awakenings very differently. A single protocol cannot be fair across those contexts merely because the instrumentation is noninvasive. The burden budget must be population-specific.

Sampling-dose sensitivity can compare suitable existing records or naturally varying observation schedules. Any newly assigned awakening schedule must first satisfy the Chapter 3 limits; a desire to compare zero, one, and several awakenings does not itself authorize sleep disruption. Report whether the permitted observation method changes sleep continuity, recall, morning affect, or willingness to continue.

15.2.3 — Recall Delay and Reconstruction

Recall delay changes the evidential object. A report given thirty seconds after awakening is not the same as a report given at breakfast, and neither is the same as a story told weeks later to a clinician or family member. Delay can reduce detail, select salient affect, invite narrative coherence, and add waking interpretation (Palmer & Alfano, 2017; Tempesta et al., 2018).

Dream memory is also reconstructed. A person may fill gaps, reorder scenes, translate images into culturally available symbols, omit embarrassing content, or intensify meaning after the dream becomes relevant. Reconstruction is not dishonesty; it is ordinary memory operating under unusual conditions.

A serious observation model records delay as a variable. It should include awakening time, report time, prompt type, confidence,

affect rating, and whether the participant distinguishes remembered content from inferred meaning. A report that says, I think I was afraid, should not be coded as the same kind of evidence as an immediate fear rating.

A compact model can make the filter visible. Let the observed report indicator depend on sleep stage, affect intensity, contextual willingness, and memory stability rather than on experience alone. The point of the equation is not to pretend certainty; it is to force the study to name the channels through which reports appear.

Recall delay should also be modeled as a nonlinear process. The first few minutes after awakening may preserve sensory and affective fragments that decay quickly, while later reports may become more coherent and more interpretive. A longer report is not automatically a better report; it may be more narratively organized and less temporally faithful.

The observation model should therefore separate immediate affect rating from later meaning attribution. A person can wake with dread and later understand the dream as helpful, or wake comforted and later find the content troubling. A single post hoc valence label loses the very trajectory the chapter is trying to measure.

$$\begin{aligned} &Pr(R_k = 1|S_k, A_k, C_k, M_k) \\ &= \text{logit}^{-1}(\alpha_0 + \alpha_S S_k + \alpha_A A_k + \alpha_C C_k + \alpha_M M_k) \end{aligned}$$

The same logic applies to missing reports. A missing dream report may reflect no experience, no recall, unwillingness, interruption, medication, cognitive impairment, language barrier, or device

failure. Treating all of those pathways as a single zero would manufacture a false night.

Recall delay enters the observation model as a measurable influence on selected nocturnal reports. Recording it helps separate changes in memory from changes attributed to the sleep interval.

15.2.4 — Language and Cultural Interpretation

Dreams arrive in language, and language carries culture. A dream of a dead parent, a flooded room, a pursuing animal, a missing child, or a bright doorway may be described through grief, religion, family obligation, trauma, folklore, illness, or ordinary metaphor. Coding dictionaries should therefore be translated and adapted as instruments, with evidence for construct continuity and room for unclassified meaning rather than universal symbolism (International Test Commission, 2018).

The first rule is to separate content coding from meaning coding. Content may identify persons, places, actions, bodily sensations, threats, social contact, or affective tone. Meaning coding asks what the dreamer takes the dream to signify. Those layers should not be collapsed, especially in cross-cultural or multilingual work.

Translation introduces another burden. Some languages encode emotion, agency, kinship, obligation, spiritual presence, or bodily feeling differently. A translated dream report may preserve plot while losing the social or affective grammar that made it meaningful to the participant. Back-translation alone is not enough when the construct itself is culturally shaped.

Cultural interpretation also affects disclosure. Some participants may freely report dreams because dreams are treated as ordinary psychological material. Others may avoid reporting because dreams are private, sacred, shameful, dangerous to speak, or relationally sensitive. Report probability is therefore not culturally neutral.

The science response is not to abandon dream research. It is to version codebooks, record language, preserve participant meaning separately from analyst categories, use local review where appropriate, and treat cross-cultural comparisons as bridge claims requiring evidence. A universal dream-valence score cannot be assumed.

This is where the project's fairness analysis becomes methodological. Hidden burden includes the burden of being translated into someone else's categories. A fair dream study does not claim access to the person by making their vocabulary convenient for the model.

15.2.5 — Lucidity and Metacognition

Lucid and metacognitive dream states show that awareness, access, and control vary within sleep. Participants able to signal or deliberately influence dream content provide a valuable selected sample; separate studies characterize ordinary dreaming, fragmented recall, parasomnia, and states with limited access (Palmer & Alfano, 2017; Siclari et al., 2017).

Time-locked communication during dreams has already been demonstrated. Across four research teams and 36 participants, Konkoly and colleagues obtained 29 correct answers in 158

communication attempts during signal-verified lucid dreams. Responses used agreed eye or facial signals; most attempts produced no clear answer. Three independent experts unanimously classified 26 of the 29 successful trials as REM sleep. This establishes a practical route for selected questions before awakening. Repeated signaling and broader recruitment are practical next steps toward more detailed observations during sleep (Konkoly et al., 2021).

Metacognition also complicates valence. A dream can be frightening while the dreamer knows it is a dream; a dream can be pleasant while the dreamer feels trapped; a person can choose to alter content and still wake distressed. Experience, appraisal, control, and later meaning must remain separate fields.

For auxiliary Law research, lucid dreaming may help test report timing, signal validity, and within-dream affect ratings under constrained conditions. It does not authorize invasive attempts to engineer dream content or to create special burdens for people who can report from within sleep.

Lucidity is especially important for public communication. A dramatic ability to signal from sleep can be misread as direct access to the hidden ledger. The correct language is narrower: it is evidence about one family of sleep states, one form of access, and one measurement opportunity under strong selection.

Lucid dreaming is a useful edge case for examining metacognition, agency, and time-locked communication during sleep, but it is not representative of ordinary dreaming. Findings from trained lucid dreamers should remain in their own reference

class unless transport to nonlucid sleep is independently demonstrated.

Lucidity provides a useful calibration case. It permits comparison of immediate in-dream signals with later reports, tests timing assumptions, and helps identify how metacognitive access changes recall.

15.2.6 — Interpreting Dream Evidence

Dream records can capture affect, memory, fantasy, threat, bodily sensation, moral imagery, and grief. Each study specifies which features it measures and how they connect to its research question, while preserving the dreamer's control over disclosure (Palmer & Alfano, 2017; Tempesta et al., 2018).

This boundary protects method and dignity together. Dream reports are selected observations shaped by awakening, encoding, recall, language, and reconstruction. The same rule keeps visitation, reconciliation, terminal, and grief dreams from being appropriated as evidence for PTVC, an afterlife claim, or a compensatory meaning the dreamer did not assign.

A bounded study may estimate associations among pre-sleep state, sleep stage, protocol-fixed report features, next-day affect, and ordinary rivals. Coding remains limited to the declared constructs, such as affect, threat, agency, social content, bodily sensation, recurrence, and recall confidence. Analysts must not treat symbolic resemblance, debts in a dream narrative, or post hoc reward stories as evidence of balancing. A separately specified test of signed experiential contributions requires its own valid measurements and comparisons. Separating report content

from signed experiential estimation allows rich qualitative data to inform rivals without granting symbolic interpretation quantitative ledger status.

Public artifacts require equal restraint. Word clouds, symbolic collages, dramatic quotations, and terminal anecdotes can make private narratives appear to be direct evidence of a hidden ledger. Sensitive content should be minimized or restricted, and every displayed variable should be identified as a report-derived measure rather than the experience itself. Where examples are necessary, synthetic or composite illustrations can sometimes communicate coding logic without exposing a participant's distinctive narrative.

A focused research question makes dream reports useful for comparing timing, content, recall, and affect across specified conditions. Its value increases when repeated awakenings or independent scorers can test whether the reported pattern is stable rather than a one-time reconstruction.

15.3 — Affective Reprocessing Hypotheses

Affective reprocessing becomes useful when translated into measurable stages: pre-sleep state, sleep architecture, dream recall, dream affect, physiological change, and next-day memory or reactivity. Reported associations between dream recall or mood and overnight emotional-memory outcomes make an active account testable without establishing that dreams generally repair affect (Cartwright et al., 1998; Zhang et al., 2024).

Sleep research provides a concrete example of emotional responses changing across time. Van der Helm and colleagues (2011) compared responses to previously viewed emotional pictures after a night of sleep or a day awake. The sleep group showed reduced amygdala reactivity and subjective emotional intensity, together with changed amygdala–prefrontal functional connectivity. The overnight reductions were associated with features of REM-sleep physiology. This creates a tractable setting for studying how earlier experience, intervening sleep, and later emotional response form a connected trajectory.

The local task is to explain changes across sleep. A model specifies what changes, what generates the change, and how its prediction compares with established sleep functions.

Affective reprocessing becomes a clear research question when the study specifies what changes, in which sleep state, relative to which pre-sleep condition, through which channel, against which rival, and over what time scale.

Prespecified outcome branches distinguish a valid test from an inquiry blocked by measurement or participant-protection limits.

Failed gates yield Unusable evidence. Valid tests can establish the predicted pattern, identify a different outcome, or favor an alternative mechanism. Each branch informs the next study.

15.3.1 — Pre-Sleep State and Post-Sleep Change

The primary transition in sleep research begins before sleep. Affective burden must be measured in the evening with enough detail to distinguish distress, arousal, pain, grief, anger, bodily discomfort, rumination, social support, and fatigue. Without a pre-sleep state, a morning state has no direction (Cartwright et al., 1998; Zhang et al., 2024).

The post-sleep state must also be more than a mood rating. It should include affective valence, arousal, bodily symptoms, sleepiness, pain, motivation, social readiness, intrusive memory, and confidence in recall. The Law's burden lens is not satisfied by asking whether the participant feels better; it asks what kind of burden changed and where it may have moved.

For a nightly within-person estimand, repeated observations help separate change within a participant from stable differences among participants. Parallel-group or randomized between-person designs can answer other sleep questions; their estimands and assignment assumptions should be stated separately. Neither design automatically licenses a complete-stream conclusion.

A simple time-series model can help keep the estimand visible. The next-day affective residual is modeled as a function of REM features, NREM features, nightmare burden, pre-sleep burden, and person-specific baseline. The equation does not validate the

mechanism; it prevents the study from pretending that morning affect speaks alone.

The pre-sleep baseline should also include expectation. If a participant expects the study to find nocturnal repair, or fears that the study will interpret nightmares, that expectation can change reports and next-day affect. The study should avoid deceptive expectancy manipulation and should measure ordinary expectation as a context variable.

The post-sleep measure should be timed more than once where burden allows. Immediate awakening state, first-morning state, midday residue, and evening recovery can diverge. A pattern that appears at 7 a.m. and disappears by noon should not be given the same status as a stable next-day residual.

$$\Delta A_{i,n+1} = \beta_{REM}REM_{i,n} + \beta_{N3}N3_{i,n} + \beta_{NM}NM_{i,n} + \beta_B B_{i,n} + u_i + \varepsilon_{i,n}$$

The study must also define failure. If adding prospectively specified dream-report features does not improve held-out prediction beyond pre-sleep burden and sleep architecture, those reports add little to that predictive task. If sleep-disordered breathing explains the morning change, the mechanism narrows. If a target pattern appears only after smoothing reports with future information, a claim of prospective prediction fails.

This transition gives auxiliary sleep evidence its strongest role. It is local, repeatable, humane, and open to rival comparison. The question is whether the night changes the next day in a way that survives serious sleep science, not whether one night reveals a whole-life closure.

15.3.2 — Dream Valence and Waking Residue

Dream valence and waking residue are separate targets. A negative dream may leave relief, a positive dream longing, a neutral dream unease, and a forgotten dream later change. Measuring both stages independently prevents the report from dictating the interpretation of the next day (Walker, 2009; Tempesta et al., 2018).

The first question is association. Does dream affect, when reported under controlled sampling, predict next-day affect after accounting for pre-sleep burden, stage, awakening timing, sleep quality, medication, and recall confidence? If the answer is no, dream content may still matter clinically, but it does not support the auxiliary reprocessing mechanism.

The second question is direction. A negative dream followed by reduced reactivity may fit extinction, exposure-like habituation, reconsolidation, or meaning-making. A negative dream followed by increased distress may fit nightmare pathology, trauma replay, arousal carryover, or sleep fragmentation. The same content sign can support different mechanisms depending on the temporal pattern.

The third question is selection. Highly emotional dreams are more likely to be remembered, reported, and discussed. If remembered negative dreams predict next-day burden, the association may arise because intense nocturnal states are selected into the dataset. The model must include recall probability before interpreting the valence path.

A candidate sleep model can predict an interaction among dream valence, sleep quality, a reserve proxy, and next-day residual affect. Specifying that pattern before analysis makes it comparable with alternative explanations.

A recent study makes the dream–waking relationship more specific. Lin and colleagues (2026) followed 87 adults with seven-day dream diaries and then recorded EEG during an emotional-picture task. An exploratory analysis linked greater dream fear to stronger late-positive-potential responses to negative pictures among participants reporting good sleep quality. Dream affect showed no significant association with subjective response ratings or waking emotion regulation. The result directs attention to a precise joint question: how do dream content and sleep quality predict each response channel across repeated nights?

This is also where mixed affect becomes critical. A dream can be frightening and meaningful, sad and comforting, disgusting and funny, or peaceful and empty. If the study forces one signed rating, the scalarization decision may determine the result. A more serious design allows positive and negative channels, arousal, agency, and meaning to be reported separately.

Next-day residue also needs multiple dimensions. Distress may fall while fatigue rises; fear may fall while shame rises; peace may coexist with low motivation; connection may deepen while grief remains. The relevant question is which burden moved and by what mechanism, not whether one morning score moved in a preferred direction.

15.3.3 — Habituation and Extinction

Habituation and extinction describe ways emotional responses can diminish through repeated or context-changed exposure. A study can compare those learning mechanisms with the additional contribution of sleep by measuring both processes (Palmer & Alfano, 2017; Siclari et al., 2017).

Variation across findings helps identify the conditions under which sleep changes emotional responses. In 29 adults, Halonen and colleagues compared REM suppression with slow-wave-sleep suppression. Skin-conductance responses to a social-stress task increased more overnight when REM was preserved, while no between-condition differences were detected in subjective affect or memory. The result supplies a useful contrast to accounts of universal emotional dampening. Future work can test moderators such as task type, initial arousal, sleep stage, and the outcome channel, using existing data or independently justified, low-burden observation (Halonen et al., 2024).

A usable design would measure the daytime fear or burden, the sleep-stage context, any dream or mentation report, physiological arousal during sleep, and the next-day response to a nonharmful cue. It would test whether the association is strongest under hypothesized reprocessing conditions and weaker under control nights.

Habituation also provides a falsifier for romantic dream theory. If repeated nightmares remain distressing or increase avoidance, the dream is not functioning as repair in any simple sense. If dream exposure reduces distress only in people with strong waking

therapy support, the mechanism may belong to therapy and memory rather than the Law.

The chapter forbids inducing trauma, fear, or nightmare burden for crucial testing. The appropriate designs use naturally occurring concerns, mild ethically approved learning tasks, clinical data where care is primary, or retrospective coding with strong limitations. Suffering is never created to see whether sleep balances it.

The extinction rival also requires attention to context renewal. A fear response may diminish in one context and return in another, which means a morning improvement after sleep may not represent durable change. Follow-up prompts should test whether the affective change persists across cues, settings, and time.

A Law-specific sleep mechanism would be more credible if it predicted patterns beyond standard extinction. For example, it might predict interactions among burden class, reserve, sleep continuity, and next-day residual that are not expected under ordinary cue-exposure learning. Those interactions should be specified before data are inspected.

15.3.4 — Reappraisal and Memory Updating

Reappraisal is another rival because the mind can change the meaning of an event without changing the event itself. A dream may reorganize roles, soften a memory, intensify a conflict, or place a person in a new perspective. Those possibilities predict changes in remembered meaning and next-day response, not a hidden payment or terminal balance (Cartwright et al., 1998; Tempesta et al., 2018).

Memory updating can occur through waking reflection, social conversation, therapy, sleep-dependent consolidation, targeted cueing, or spontaneous dream imagery. A study must separate the sleep contribution from waking meaning-making after the report. If a participant wakes and then interprets the dream with a partner, clinician, or interviewer, the post-report context becomes part of the outcome path.

Reappraisal also affects coding. The same dream can be coded as negative in immediate affect and positive in later meaning. A grief dream may hurt and comfort at once. A trauma dream may repeat threat while revealing a new sense of agency. Single-valence coding loses these distinctions.

A useful schema separates immediate dream affect, confidence in recall, later appraisal, perceived meaning, bodily residue, intrusive memory, and next-day functioning. Analyses can then test which fields are predicted by sleep-stage or physiological features after accounting for waking interpretation. This is a more discriminating target than asking whether a dream somehow balanced prior experience.

Here the fairness analysis asks where burden is carried after reinterpretation. A memory may feel lighter because the person has integrated it, or because the person has learned to silence it, or because medication changed arousal, or because reporting pressure shaped the story. Reappraisal is not automatically relief.

Affective reprocessing can be investigated more precisely when measurement distinguishes memory, appraisal, physiology, and social context.

Positive learning can influence which emotional memories remain accessible. In a study of 37 participants, Xia and colleagues first established word associations with negative images, then linked selected words to positive images. Replaying those words during subsequent NREM sleep weakened recall of the associated negative images and increased positive-memory intrusions relative to uncued items. The result supports selective memory updating and a concrete route for studying how positive experience changes later access to emotional material (Xia et al., 2024).

Reappraisal can arise through therapy, religion, family conversation, or private reflection. A study can examine changes associated with those processes while participants retain control over the meanings and experiences they choose to share.

$$\theta_{TMR} = E[\Delta A|cue, stage, context] - E[\Delta A|sham, stage, context]$$

15.3.5 — Reserve and Recovery

Sleep quality may interact with reserve because fatigue, illness, medication, grief, and clinical fragility change recovery capacity. A sleep study can examine how those conditions shape observed recovery dynamics (Walker, 2009; Tempesta et al., 2018).

A reserve-aware sleep study tracks the conditions that shape both experience and observability: sleep duration, fragmentation, REM proportion, slow-wave activity, respiratory disturbance, pain, medication, mobility, caregiving interruption, and daytime exhaustion. These variables help explain the capacity to sleep, dream, recall, and recover.

The candidate prediction must be modest. If a person has sufficient sleep continuity and lower physiological disruption, the association between pre-sleep burden and next-day residual may weaken. If sleep is fragmented, obstructed, painful, or nightmare-dominated, the expected transition may fail or reverse. That failure is scientifically informative.

Reserve also creates confounding. Severe illness may reduce sleep quality, increase medication, change report capacity, increase family presence, and alter next-day affect. A study that calls the result reserve-linked without modeling these pathways has confused a shared clinical driver with a mechanism.

The safest strategy is within-person and time-forward. Compare nights within the same person, include clinical covariates, preserve missingness, and test whether the reserve interaction predicts held-out nights. Do not use reserve to rank people, forecast worth, or guide care access.

Sleep can contribute to the reserve program only by making capacity-sensitive dynamics more testable. It cannot convert biological decline into evidence of fairness, and it cannot make the sleeping person responsible for whether recovery occurs.

Reserve interactions are modeled as moderators. Pain, respiratory disturbance, caregiving interruption, and advanced illness can change both sleep and recovery capacity, supplying specific conditions for comparison.

15.3.6 — Failure of Reprocessing Predictions

Failure is part of the reprocessing hypothesis. If protocol-fixed dream features do not predict next-day residuals, the dream-

content route weakens; if sleep architecture predicts change but content does not, the explanation moves toward physiology or memory consolidation; if neither adds information beyond waking burden and ordinary rivals, the auxiliary pathway may retire for that reference class (Palmer & Alfano, 2017; Siclari et al., 2017).

Worsening is an admissible result. Nightmares, insomnia, fragmented REM sleep, sleep apnea, pain, medication effects, and trauma recurrence may increase burden. A model that redescribes every worsening as deeper repair has lost the possibility of failure and revives the rejected idea that suffering serves balance.

Null and unusable results require different diagnoses. A null may follow from weak recall, poor timing, noisy coding, inadequate power, or absence of the hypothesized effect; unusable evidence may follow from sleep disruption, unacceptable burden, privacy limits, or missing reports that cannot be modeled credibly. The verdict should identify the failed component rather than declaring the whole Law protected or vindicated. The next study should be chosen by that diagnosis, because more participants cannot repair a timing failure and better coding cannot repair unacceptable burden.

Retiring a sleep mechanism narrows dream-content claims without deciding physiology, measurement, endpoint, reserve, or longitudinal branches. Tables and summaries must preserve that separation. A retired mechanism may still leave reusable timing or measurement findings, but those should be cited for their own object rather than as residual support for the route.

The protocol should prestate mechanism-favored, subgroup-narrowed, rival-favored, dream-content-retired, adverse-burden, privacy-limited, and no-estimate outcomes. Otherwise positive results are absorbed and negative results renamed. Precommitting the null and burden branches is especially important in sleep studies because missing reports and disrupted sleep can otherwise be redescribed after the fact.

Privacy-preserving review of null, adverse, and no-estimate sleep results shows what the program must narrow or stop. Affective reprocessing is scientific only when evidence can change or retire it. A mechanism that survives only after excluding nights with inconvenient reports should be treated as selection-sensitive rather than strengthened.

Table 15.2. Rival predictions for sleep and dream reprocessing hypotheses.

Result pattern	Law-specific auxiliary reading	Strong rival reading	Verdict limit
Dream affect predicts next-day residual after controls	Possible sleep-linked affective transition	Report selection or memory salience	Mechanism support only
Sleep architecture predicts change; dream content does not	Physiology may matter more than report	Ordinary sleep homeostasis	Dream mechanism narrows
Nightmares predict worsening	Reprocessing mechanism fails in this class	Nightmare pathology or trauma loop	No repair inference

Result pattern	Law-specific auxiliary reading	Strong rival reading	Verdict limit
No separable pattern	Auxiliary mechanism unsupported	Measurement limits or rival equivalence	Abstain; mechanism retirement requires valid adverse evidence

15.4 — Nightmares, Trauma, and Memory Rivals

Nightmares and trauma-related sleep are not edge cases. They are the settings in which a simple repair narrative becomes most dangerous. Repetition, fear, bodily arousal, impaired extinction, and fractured memory may mark suffering that needs care, not evidence that the mind is balancing itself (Giesermann et al., 2019; Zhang et al., 2019).

Failure of a reprocessing prediction should identify which link failed: no state-specific change, no relation to pre-sleep burden, no improvement beyond memory rivals, poor report reliability, or unacceptable participant burden. The chapter then narrows the auxiliary claim rather than preserving it through symbolic interpretation. Harmful exposure, nightmare induction, or trauma amplification remains outside crucial testing.

The chapter's ethical seriousness is tested most severely here. The same evidence that might fascinate a researcher may cost the participant sleep, safety, dignity, or trust. For that reason, clinical support, optionality, and no-exposure rules are not soft constraints added after the science; they define which science can be attempted at all.

The section also keeps language clean. It does not call nightmares lessons, balancing, correction, or needed experience. It calls them high-burden phenomena with clinical rivals, measurement hazards, and care obligations. That language choice is part of the ethical firewall because words can make harm sound useful before a protocol ever begins.

Table 15.3. Nightmare and trauma rival paths.

Observed pattern	Primary rival to test	Required safeguard
Recurrent threat dreams with next-day distress	Nightmare pathology, trauma replay, hyperarousal	Care referral and no exposure induction
Negative dream followed by lower reactivity	Extinction, reconsolidation, therapy support	Measure waking treatment and reappraisal
No dream report with persistent distress	Recall failure, avoidance, medication, insomnia	Missingness category and privacy option
Dream improvement after intervention	Clinical treatment pathway	Do not attribute to spontaneous balancing

15.4.1 — Nightmares and Recurrent Threat

Nightmares are clinically important experiences that call for careful attention and effective support. They may repeat threat, loss, helplessness, bodily danger, or social humiliation, and chronic forms may involve hyperarousal and impaired fear extinction. Research should help explain and reduce that burden (Gieselmann et al., 2019; Zhang et al., 2019).

Recurrent threat may accompany trauma, anxiety, grief, medication, sleep disruption, pain, withdrawal, fever, neurodegenerative conditions, or ordinary stress. Comparing those contexts can help identify the processes maintaining the symptoms and the conditions that improve them.

Nightmares can provoke awakenings, avoidance of sleep, daytime fatigue, hyperarousal, and anticipatory fear. Tracking the

following day captures how nocturnal experiences and waking symptoms interact.

Nightmare studies should distinguish frequency, affective intensity, thematic recurrence, autonomic arousal, awakening, recall confidence, avoidance, sleep fragmentation, and next-day impairment. These fields may move together, but they support different mechanisms and clinical consequences. Collapsing them into one negative-dream score hides the rival structure the study is meant to test.

The auxiliary hypothesis specifies when recurrent threat should change, when it should persist, and which clinical conditions explain the difference. Nightmare pathology supplies a substantive comparison for these predictions.

The burden lens is especially strict here. A person with nightmares is not thereby shown to be paying a moral debt or receiving nocturnal justice. The scientific obligation is to reduce harm, respect privacy, and avoid making symbolic meaning more important than care.

The coding scheme should therefore include recurrence, anticipatory anxiety, avoidance of sleep, awakening distress, and next-day impairment. These variables can distinguish a vivid but isolated negative dream from a disorder-like loop. The Law-specific mechanism has no right to call both examples reprocessing.

15.4.2 — Trauma Replay and Fragmentation

Trauma replay is not ordinary dream drama. It can carry sensory fragments, bodily threat, helplessness, shame, and physiological

arousal in ways that destabilize sleep and waking life. The dream may not tell a coherent story because the memory itself may be fragmented, state-bound, or linked to threat systems more than narrative memory (Palmer & Alfano, 2017; Tempesta et al., 2018).

Persistent trauma dreams give reprocessing models a specific explanatory task: account for repeated imagery, arousal, avoidance, and the conditions under which those patterns improve.

The chapter distinguishes trauma replay from trauma processing by examining re-experiencing, intrusive imagery, nightmare recurrence, physiological activation, and indicators of safe memory integration. Intervention studies can help identify which changes accompany recovery.

Study designs in trauma contexts require the highest restraint. No participant should be exposed to trauma cues, asked to intensify nightmares, or pressured to disclose dream content for a theoretical test. Existing clinical care, optional diaries, and de-identified coding are the ethical limits unless expert review justifies a narrower design.

Trauma also changes report. Some participants cannot describe dreams without distress; others avoid sleep, suppress recall, or disclose only fragments. Missingness may be a protective response. Treating missing trauma-dream data as absence of dream burden would be a serious error.

Trauma-related sleep gives the program a clear empirical responsibility: describe persistent burden accurately, identify

conditions that improve it, and test reprocessing predictions against that evidence. An auxiliary mechanism must accommodate both recovery and continuing symptoms.

Fragmentation also challenges dream-content coding. Trauma dreams may contain sensory flashes, bodily states, or scene fragments that resist ordinary narrative categories. A codebook designed for plot, characters, and valence may misclassify the most clinically important material. Trauma-informed coding should include no-code, fragment, and bodily-threat categories.

The research team should plan for post-report support. A participant who describes trauma-related dream content may need grounding, clinician referral, or a pause in participation. Those procedures are not outside the study; they are part of conducting a fair study in a high-burden domain.

15.4.3 — Memory Consolidation Rival

Memory consolidation is one of the strongest rivals to Law-specific sleep reprocessing. Sleep can stabilize, transform, prioritize, or reorganize memories. Emotional memories may become more accessible, less reactive, more generalized, or more persistent depending on context (Walker, 2009; Tempesta et al., 2018).

A consolidation account predicts relationships among prior learning, sleep stage, cue exposure, memory accuracy, emotional reactivity, and later recall. Those predictions are concrete and often testable. A Law-specific account must either make different predictions or explain why the same pattern means something more than ordinary memory science.

Dream content may reflect memory fragments, day residue, recent concerns, remote associations, or recombination. The presence of emotionally relevant content does not imply that the dream is repairing affect. It may simply show that memory networks are active and reorganizing during sleep.

Therapeutic learning offers another concrete application. After one EMDR treatment session, 33 patients with PTSD received either memory cues timed to slow oscillations during sleep or sham stimulation. The cueing group showed greater reduction in avoidance during a later script-driven imagery assessment. Baseline avoidance was higher in the cueing group, which complicates interpretation of the size of that improvement. Cue-evoked slow oscillations and spindles also correlated with symptom reduction within that group. These early results motivate further study of sleep as an adjunct to treatment, with avoidance and overall PTSD symptoms assessed separately (van der Heijden et al., 2024).

The design implication is direct. Sleep studies should include memory-task rivals, cueing histories, day residue measures, and next-day memory outcomes. If dream affect tracks memory strength rather than burden relief, the memory rival has earned priority.

A strong comparison sharpens the auxiliary hypothesis. If memory consolidation explains the observations, that result identifies the relevant mechanism and guides the next question.

The consolidation rival can also predict emotional persistence. Some memories become less reactive after sleep, while others

become better organized and more available. If a dream study assumes all sleep-driven memory change is relief, it will misread precisely the cases most relevant to trauma, grief, and fear.

A useful analytic plan should include both memory accuracy and affective tone. A memory may become more accurate and less distressing, less accurate and less distressing, more generalized and more distressing, or unchanged. Those combinations distinguish mechanisms more effectively than a single next-day mood score.

15.4.4 — Medication and Sleep Disorder Effects

Medication, withdrawal, pain, respiratory disturbance, and other sleep disorders can jointly alter stage architecture, arousal, recall, and next-day affect. The protocol therefore records drug, dose, timing, indication, respiratory events, and sleep-disorder status as time-varying exposures and observation modifiers rather than unexplained noise (American Academy of Sleep Medicine, 2023; Zhang et al., 2019).

Sleep-disordered breathing, restless legs, periodic limb movements, pain, nocturia, fever, neurodegeneration, and circadian rhythm disruption can also shape dream reports and next-day affect. A dream study that fails to measure these mechanisms may falsely attribute burden movement to sleep reprocessing.

Medication and disorder effects are especially important in clinical or terminal settings. The same drug may relieve pain, reduce anxiety, suppress REM, impair recall, and change morning affect. A humane intervention can make dream evidence less

interpretable. Care comes first, and the resulting loss of interpretability is acceptable.

Medication, pain treatment, sleep-disorder symptoms, respiratory disturbance, and dose timing should be recorded at the resolution relevant to the night under analysis. The protocol also needs predeclared abstention rules for major medication changes, severe sensor disruption, or untreated sleep pathology that makes the candidate contrast uninterpretable. A confounded night can remain clinically meaningful without entering the confirmatory estimate.

These effects can also be informative in safer populations. If REM suppression weakens dream-report associations but not next-day recovery, dream content may be less central. If apnea severity predicts negative next-day residue, respiratory disruption may explain the pattern better than reprocessing.

Medication and sleep disorders make the research question more realistic. Sleep occurs within ordinary bodies, habits, illnesses, and treatment plans. Representing those conditions makes the findings more useful for clinical and everyday settings.

Dose timing should be recorded at a resolution relevant to sleep. A medication taken at bedtime, a rescue dose during the night, and a morning dose after awakening may each alter stage architecture, recall, pain, or affect differently. A daily medication indicator is often too coarse for this chapter's questions.

The same applies to sleep disorder treatment. Continuous positive airway pressure use, mask discomfort, oral appliances, sleep-position advice, and treatment adherence can change sleep and

next-day burden. Treatment success should be celebrated clinically, but analytically it becomes a pathway that must be modeled before any reprocessing claim is made.

15.4.5 — Clinical Support Before Study

Clinical support precedes study in every high-burden sleep context. A person with nightmares, insomnia, trauma replay, severe anxiety, sleep-disordered breathing, or medication-related sleep distress needs care pathways before research curiosity. The study must not turn untreated distress into an opportunity for observation (Palmer & Alfano, 2017; Tempesta et al., 2018).

This does not mean research cannot occur. It means research must be designed around care already being offered, around optional participation, and around procedures that stop when distress, fatigue, or privacy burden rises. Sleep research can coexist with treatment only when treatment remains sovereign.

The consent process must state that declining dream disclosure, refusing awakenings, stopping devices, omitting sensitive content, or leaving the study will not affect care. This is especially important for people receiving therapy, hospice services, or institutional support. Dependence can silently become pressure.

A randomized study provides a hopeful treatment example. Thirty-six adults with nightmare disorder received imagery rehearsal therapy. Both groups then heard a sound during REM sleep at home for two weeks, but only one group had first associated that sound with its positive rehearsal scenario. Mean weekly nightmares at two weeks were 0.19 in the association group and 1.02 in the comparison group. This small trial supports

further study of a specific treatment enhancement. The contrast identifies a concrete way that positive rehearsal and sleep cueing can work together (Schwartz et al., 2022).

Support procedures should precede content collection. Referral routes, distress response, participant-controlled privacy limits, and clinician review of awakening or interview procedures should be operational before enrollment. When a report evokes destabilizing material, the participant receives support or withdrawal options; the protocol does not pursue detail because the narrative is scientifically rare.

Care before study is not a slogan. It is an analytic condition. If a design ignores care, it changes the data-generating process and fails the ethical architecture that this science volume has already established.

A care-first sleep study should also have a withdrawal-without-explanation option. Participants should not have to justify refusing dream questions or stopping a sleep device. Requiring explanation can itself become pressure, especially when the content is private, frightening, or relationally sensitive.

Clinical support also includes staff training. Researchers collecting dream reports need guidance on trauma-informed responses, noninterpretation, confidentiality, and escalation. A poorly trained interviewer can turn a harmless question into a burden, and that burden can distort both the participant's experience and the dataset.

15.4.6 — No Exposure for Crucial Testing

No study may induce trauma, nightmares, serious fear, humiliation, grief intensification, sleep deprivation, treatment interruption, or comparable distress to create a decisive test. The prohibition also covers repeated awakening when clinical need favors rest, emotionally provocative prompts, public challenges, and designs that make care or belonging feel contingent on participation (World Medical Association, 2024; Council for International Organizations of Medical Sciences, 2016).

The no-exposure rule belongs in prospective specification, consent, staff training, monitoring, stop criteria, and public materials. A protocol that cannot state how distressing procedures are prevented, recognized, and stopped is not ready for enrollment. Discriminating power that depends on prohibited exposure is a design failure, not an ethical tradeoff.

Natural variation, clinically indicated treatment, within-person observation, low-burden awakening schedules, independently collected archives, and simulation can test many reprocessing predictions without manufacturing harm. Some causal contrasts will remain unresolved, and that is an acceptable limit of a humane program.

Nightmare analysis still requires temporal precision. Pre-sleep state, nightmare timing, awakening, immediate report, delayed recall, next-day symptoms, treatment changes, medication, and subsequent sleep should remain separate so trauma replay, consolidation, arousal, recall reconstruction, and ordinary symptom fluctuation can compete (Tempesta et al., 2018;

Gieselmann et al., 2019). The clock map should be frozen before content coding so later recall cannot silently redefine when the relevant experience occurred.

Psychotherapy, medication, pain control, safety, and treatment of sleep disorders can alter dream frequency, recall, arousal, and waking distress. The analysis represents those therapeutic pathways alongside consolidation, rehearsal, fragmentation, current concern, and reconstruction at report. Treatment effects should be modeled as clinically meaningful changes, not nuisance corrections, because they may alter both the underlying state and the observation pathway.

Report the tested sleep prediction and its observed outcome. The study preserves its specified exposure limits and uses the result to evaluate the proposed route. A concise outcome statement should also identify the strongest rival that remained compatible with the data, preserving the comparison that gives the prediction meaning.

15.5 — Sleep Stage, Physiology, and Measurement

Sleep measurement is powerful because it can mark state, timing, physiology, and disturbance. It is limited because those markers are not consciousness, not valence, and not the latent cumulative process. This section builds the measurement architecture while keeping those limits in view (American Academy of Sleep Medicine, 2023; Siclari et al., 2017).

The goal is a state-specific evidence system: polysomnography and staging for architecture, autonomic and respiratory signals for bodily regulation, awakening protocols for selected reports, ecological momentary assessment for next-day residue, and sleep-specific validation before the candidate momentary-valence estimator is used at night.

Reliable sleep measurement comes from connecting each channel to a defined construct, artifact rules, lag and timing model, calibration context, uncertainty estimate, and abstention rule. These specifications make physiological records useful for testing rather than simply observing change.

Clear presentations make scoring uncertainty, stage transitions, lag, artifact, respiratory burden, awakening effects, and report confidence easy to follow. Tables and visualizations should show the dependencies relevant to the question being tested.

Table 15.4. Sleep-stage measurement roles.

Layer	Primary use	Main limit
EEG staging	Classify wake, NREM, REM, arousals, transitions	Not consciousness or valence by itself

Layer	Primary use	Main limit
Autonomic signals	Arousal, regulation, bodily stress context	Confounded by movement, respiration, medication
Respiratory signals	Sleep-disordered breathing and oxygenation	Can dominate next-day affect without dream mechanism
Awakening reports	Selected access to recent mentation	Sampling burden and recall reconstruction
Morning EMA	Next-day residue and function	Affected by waking context and delayed memory

15.5.1 — EEG and Sleep Staging

EEG-based sleep staging gives the chapter a common clinical and research language. Wake, NREM stages, REM, arousals, respiratory events, and transitions can be scored under established rules, but scoring remains an interpretation of signals rather than direct access to experience. The manual version, montage, scorer process, and any automated classifier should be preserved because each can alter the state sequence (American Academy of Sleep Medicine, 2023; Siclari et al., 2017).

The AASM scoring framework is useful because it standardizes sleep stages, arousals, respiratory events, movements, and related technical specifications. The Law program should use such standards as measurement discipline, not as evidence that a stage contains a particular affective process.

Stage scoring uncertainty should be preserved. Automated and human scoring can differ, and difficult epochs occur around transitions, artifacts, unusual physiology, medication, age, and

sleep disorders. A sleep study should record scorer confidence, algorithm version, epoch length, montage, and adjudication rules. Stage labels also have different inferential uses. REM may be relevant for dream reports and emotional memory, NREM for slow-wave activity and consolidation, arousals for disruption, and transitions for recall. None of these uses makes the stage a valence meter.

A fair sleep design uses staging to align evidence. It asks whether a report came after REM, NREM, transition, spontaneous awakening, or forced awakening. It asks whether physiology changed before the report. It does not infer the report from the stage or the experience from the stage alone.

The science gains credibility by resisting the comfort of a single label. Sleep stage is essential, but it must stay in its lane. It locates the night; it does not explain the whole night.

Automated staging can support large studies, but it should not hide scoring uncertainty. Model version, training population, montage, disorder status, and confidence should travel with each epoch. If automated and human staging disagree in key windows, the analysis should treat disagreement as uncertainty or sensitivity, not as an inconvenience.

The science also needs state-transition information. A report collected after a stable REM epoch is not equivalent to one collected after a mixed transition or arousal cluster. Transitions can be especially relevant to recall and affective residue. Collapsing them into the nearest stage may erase the timing the study needs.

15.5.2 — Autonomic and Respiratory Signals

Autonomic and respiratory signals can reveal arousal, stress physiology, sleep disruption, and bodily burden that dream reports miss. Heart rate variability, respiration, oxygen saturation, skin conductance, movement, and temperature can help interpret the night, especially when reports are absent or unreliable (American Academy of Sleep Medicine, 2023; Tempesta et al., 2018).

These signals are also vulnerable to artifact. Sensor contact, movement, sweating, room temperature, sleep position, device tolerance, battery state, and algorithmic smoothing can create apparent change. A study that treats wearable physiology as transparent affect will repeat the measurement errors this volume is designed to prevent.

Respiratory disturbance deserves special attention. Sleep-disordered breathing can fragment sleep, alter oxygenation, increase sympathetic activation, and worsen next-day mood or fatigue. If respiratory events explain the affective residual, they are not nuisance variables; they are the mechanism.

Autonomic signals also lag and smooth. A frightening dream, an arousal, a movement, and a respiratory event may appear close in time without a clear causal order. The analysis should specify lag windows and sensitivity ranges rather than forcing a single narrative.

Channel separation can reveal useful mechanisms. In a counterbalanced study of 17 participants, Viselli and colleagues found that experimentally fragmented REM sleep impaired

cardiac habituation to emotional stimuli, with no detected change in subjective ratings, electrodermal responses, or recognition memory. Fragmentation was accompanied by shorter REM duration. The value for this program is a clear measurement lesson: physiology can identify a sleep-sensitive process even when reported affect does not change. Naturally occurring sleep variation and clinically indicated improvements in sleep can investigate that distinction (Viselli et al., 2026).

The burden lens again matters. More sensors may improve data and increase discomfort. A participant who removes a sensor has provided ethically meaningful information about burden. Device tolerance belongs in the dataset.

The respiratory pathway also offers a strong rival test. If apparent negative dream residue is strongest on nights with oxygen desaturation or respiratory-event burden, the result may belong to sleep-disordered breathing rather than dream reprocessing. That rival is clinically actionable and scientifically important.

15.5.3 — Awakening Protocols

Awakening protocols offer temporal precision but impose cost. An awakening close to a scored epoch can improve report availability, yet repeated awakenings alter sleep continuity, fatigue, mood, and later recall. The study should register the maximum number and timing of awakenings, participant-controlled refusal, recovery intervals, and the estimand that remains when an awakening is skipped (Palmer & Alfano, 2017; Tempesta et al., 2018).

Different awakening strategies answer different questions. REM-targeted awakenings may enrich dream reports. Random awakenings help estimate report probability across stages. Spontaneous-awakening reports reduce intervention burden but increase selection. Morning reports preserve sleep but add recall delay.

Begin with natural nights, spontaneous awakenings, low-burden morning reports, and tolerated physiology. Any additional awakening procedure must satisfy Chapter 3's prohibition on research-induced suffering and sleep disruption for Law-specific evidence; healthy status and consent alone do not create an exception. Where the desired contrast requires prohibited disruption, use suitable existing data or narrow the question.

Awakening effects must be measured. After each awakening, the study should record sleepiness, distress, willingness to continue, report confidence, and whether the awakening itself changed the content or mood. These measures are not administrative; they are part of the observation model.

The fairness test is whether the question justifies the interruption. If the study can learn enough without waking the participant, curiosity should not win. The sleeping person is not obligated to become more observable.

Awakening burden should be included as an endpoint of the protocol itself. If participants report annoyance, distress, fatigue, reduced willingness, or worse next-day functioning, the protocol has produced a cost. Population-specific review determines whether the awakening protocol is permissible within Chapter 3's

limits; healthy status alone does not authorize otherwise prohibited sleep disruption or distress.

Training and analytic nights should be separated because equipment, prompts, laboratory novelty, and repeated awakenings change sleep. Adaptation nights can establish tolerability and stable procedures, while confirmatory nights follow the frozen schedule. Treating early nights as exchangeable with later nights risks interpreting acclimation as physiology.

15.5.4 — Experience Sampling After Awakening

Experience sampling after awakening should be structured enough to compare nights and gentle enough not to invade the dream. A useful report can ask for presence of experience, affective tone, bodily sensation, social content, threat, agency, recall confidence, and willingness to provide detail without demanding a full narrative. Immediate interviews may improve temporal linkage, but refusal and no-recall remain substantive marks rather than failed compliance (Siclari et al., 2017; Cataldi et al., 2024).

The order of questions matters. Asking for a full story first may reshape affect ratings; asking for affect first may prime content selection. The protocol should standardize the sequence and test whether the sequence changes reports. Method order is a measurement variable.

Reports include confidence and nonresponse options. A participant may indicate experience without recall, recall without confidence about affect, affect without narrative, or a wish not to

disclose. Those categories preserve more information than a forced choice among positive, negative, and neutral.

Post-awakening sampling should also track immediate reactivity. The act of recalling a dream can change mood, arousal, embarrassment, grief, or fear. If the report itself creates burden, the study must record the burden and allow the participant to stop.

The best sampling instruments use bounded fields and optional narrative. A coded minimal report supports comparison; an optional narrative supports qualitative and coding work; a privacy setting can restrict who sees raw content. Scientific reproducibility does not require maximal exposure.

Experience sampling therefore becomes a dignity-preserving bridge. It acknowledges that sleep experience may matter, that memory is partial, that privacy is real, and that a measured field is not a confession.

The prompt should also avoid interpretation. Questions like what did the dream mean can invite cultural, spiritual, or therapeutic reflection, which may be valuable but not comparable. A scientific prompt should first ask what was experienced, what was felt, what is remembered, and how confident the participant is.

The study can then allow an optional meaning field under separate status. That field should be analyzed as participant interpretation, not as coder-inferred truth. This separation allows meaning to be honored without letting it become an unvalidated measure of affective balance.

15.5.5 — Candidate Momentary-Valence Estimator Qualification During Sleep

The candidate momentary-valence estimator cannot be imported into sleep as if waking calibration automatically applies. Sleep changes muscle tone, autonomic balance, respiration, movement, reportability, temperature, and consciousness state. A physiological composite trained during waking distress may fail or reverse under REM, NREM, sedation, illness, or sleep disorder (American Academy of Sleep Medicine, 2023; Tempesta et al., 2018).

Qualification of the candidate momentary-valence estimator for sleep must begin with a declared context of use. The estimator may be used to describe physiological arousal during sleep, support a state model, or predict next-day affect. Each use requires different validation, and none licenses direct measurement of the latent cumulative process.

Sign identification is especially difficult. A heart-rate increase may reflect fear, respiratory obstruction, movement, fever, medication, pain, or excitement. A flat signal may reflect deep sleep, sensor failure, autonomic dysfunction, or drug effect. The sign of valence cannot be read from physiology without auxiliary validation.

A sleep-specific qualification program for the candidate momentary-valence estimator should require stage-specific calibration, artifact rules, lag sensitivity, device-shift checks, missing-modality analysis, and comparison with reports and next-day outcomes. The estimator should abstain when the channels

cannot support sign or when the state lies outside the validated domain.

This qualification work belongs here only as sleep-specific application. The general measurement stack is owned by earlier chapters. The present chapter asks what changes when the same estimator meets sleep architecture, dream reports, respiratory disturbance, and awakening burden.

The necessary safeguard is technical: do not let a composite score become more authoritative because the participant is asleep and cannot correct it. Measurement qualifies claims; it does not speak over the sleeper.

The candidate momentary-valence estimator should first be qualified for sleep in lower-risk contexts. Healthy-adult studies, controlled sleep laboratories, and naturalistic wearable cohorts can test whether channels behave consistently before any clinical or terminal use. A terminal or trauma cohort should not be the first setting in which an estimator learns what sleep does to its signals.

The estimator should also have a no-output state. If artifact, medication, respiratory disturbance, or state uncertainty defeats sign identification, the system should abstain rather than output a smoothed value. An abstention is more honest than a number whose authority comes from the sleeper's inability to object.

15.5.6 — No Unity or Valence From One Marker

No single report, sleep stage, electroencephalographic feature, autonomic pattern, respiratory event, movement signal, or behavioral sign can decide consciousness, unity, or valence during sleep. Marker meaning depends on theory, context, timing,

disorder, medication, and the observation pathway (American Academy of Sleep Medicine, 2023; Siclari et al., 2017).

Single-marker authority fails in both directions. A quiet or absent signal may coexist with experience the channel cannot reveal, while an active signal may reflect arousal, movement, breathing disturbance, memory, or artifact. False-negative and false-positive burdens therefore require separate evaluation rather than one blended accuracy score. Separate error profiles can reveal whether a marker is useful for screening, confirmation, or neither, without granting it universal classification authority.

The appropriate architecture uses multiple imperfect witnesses with explicit abstention. Reports, stage, physiology, behavior, clinical context, and scorer judgment should enter through declared rules, while vector, set-valued, or unresolved outputs remain available when the channels do not license one classification. Discordance is a result to analyze, not contamination to erase. The fusion rule should state whether disagreement widens uncertainty or changes the estimand, since those responses imply different scientific objects.

Temporal alignment is part of validity. Stage labels, physiological events, awakenings, reports, and recall delays should share a versioned clock map with prospectively fixed tolerances. Predictive value that appears only after flexible lag selection or retrospective realignment does not establish a prospective marker. Lag uncertainty should be propagated into the marker estimate rather than resolved by choosing the alignment that maximizes association.

Qualification should survive channel removal, lag perturbation, scorer disagreement, stage uncertainty, nights without report, and clinically relevant subgroups. A protocol-fixed discordance matrix should state what each pattern permits, what remains unresolved, and when No adequate estimate is required. Discordance that clusters by state, medication, or device can reveal where a marker requires narrower qualification instead of a global rejection.

Every marker needs provenance: channel identity, device and firmware, preprocessing, artifact rules, scorer version, temporal window, report pathway, and missingness status. Tables, captions, dashboards, and public summaries must carry the same ceiling so that one striking trace cannot travel as direct evidence of hidden valence, unified experience, or absence of experience. Provenance also makes cross-site harmonization possible by revealing whether apparent biological differences are actually differences in devices, scoring, or preprocessing.

15.6 — Study Families and Data Schema

Sleep research becomes useful for the program only when its designs are specific enough to fail. This section turns the preceding distinctions into study families, data fields, coding rules, and privacy layers that make replication possible without making disclosure compulsory (Shiffman et al., 2008; Nosek et al., 2018).

The study families are arranged from lower burden to higher precision. The common rule is that no design may treat more intimate data as automatically better data. Reproducibility and dignity have to be built together.

Study families are also publishing commitments. If the data schema, missingness categories, privacy tiers, coding manuals, and rival models are not defined before analysis, the study will be tempted to publish whatever story the night makes vivid. The schema is a guardrail against post hoc dream mythology.

The data schema also gives the research team a deletion rule. If a variable cannot be tied to a prospectively specified question, rival test, privacy requirement, or safety monitor, it should not be collected merely because it might become interesting later. Dream research becomes less invasive when curiosity has to state its purpose in advance.

Table 15.5. Minimal sleep-study data schema.

Domain	Fields to version	Why it matters
Sleep architecture	Stage, epoch, scorer, algorithm, confidence	Prevents stage claims from floating free

Domain	Fields to version	Why it matters
Dream report	Prompt, delay, confidence, privacy level, coding version	Separates report from experience
Physiology	Device, units, artifact rule, lag window, missingness	Keeps sensors from becoming opaque authority
Context	Medication, pain, trauma, disorder, family event, environment	Names rival mechanisms and burden paths
Outcome	Next-day affect, sleepiness, function, intrusive memory	Defines the transition actually tested

15.6.1 — Repeated-Night Within-Person Design

The core sleep design should be repeated-night and within-person. Each participant contributes multiple nights with pre-sleep affect, sleep architecture, optional dream report, physiology, next-day affect, and context. This design controls stable individual differences and lets the study test whether night-to-night changes predict next-day residuals (Shiffman et al., 2008; Stone et al., 2007).

Repeated nights also reveal ordinary variability. One nightmare night, one unusually restful night, or one missing report should not define the person or the mechanism. The pattern matters across nights, especially when sleep quality, burden, medication, and report probability change.

One concrete extension is a preregistered test of history dependence. Compare nights that begin with similar momentary

affect, sleep opportunity, medication, and available support but differ in an independently specified summary of earlier affective history. Test whether that history summary improves next-day predictions after current state, waking events, sleep architecture, memory salience, and report probability are modeled. The proposed auxiliary route must specify its direction, lag, capacity interaction, and failure criterion before analysis. Ordinary learning models must receive the same history. A surviving contrast would identify additional predictive structure. Natural variation or independently justified care provides the setting, with the history summary defined over the observed window.

Repeated-night designs should include negative-control nights with a prospectively justified null prediction for the proposed auxiliary signal, alongside observation-process stress tests for no report, severe sensor failure, and major external disruption. Low pre-sleep burden qualifies as a negative control only when the proposed mechanism predicts no signal under that condition. A model that produces the same favorable pattern on every night lacks specificity even if its average fit is high.

Within-person modeling can still overreach. If a participant's sleep changes because of medication, illness, therapy, grief rituals, family visits, or pain flare, the model must treat those as time-varying pathways. The person is not a fixed laboratory system.

A simple mixed model may estimate next-day affect from stage features, nightmare burden, pre-sleep burden, and person-specific intercepts, but the model must be protocol-fixed, tested out of

sample, and compared against sleep-science rivals. Good fit is not enough.

Repeated-night design is humane because it can begin in ordinary life and avoid terminal vulnerability. It is scientifically valuable because it turns sleep into a sequence of testable transitions rather than a collection of dramatic anecdotes.

The repeated-night design should predefine the minimum number of usable nights per participant and the maximum burden allowed. A person with too few interpretable nights should not be forced into analysis through imputation that hides why the nights were missing. Missingness is part of the design result.

Carryover should be modeled across nights. A nightmare can change the next evening's affect, an awakening schedule can alter later sleep, and reporting a dream can provoke rumination or relief. Calendar separation does not create independence; washout assumptions and lag structure should be protocol-fixed and tested.

Table 15.6. Prospective repeated-night protocol sketch.

Phase	Low-burden default	Higher-resolution optional layer
Evening	EMA on burden, pain, affect, medication, social context	Brief cognitive or memory cue task when ethically justified
Night	Actigraphy or comfortable wearable physiology	PSG, stage-targeted awakenings, or TMR sub-study
Morning	Sleep quality, recall status, affect residue, willingness to disclose	Structured dream coding with consented narrative

Phase	Low-burden default	Higher-resolution optional layer
Next day	Short EMA residuals and functioning	Clinical or behavioral follow-up when relevant

15.6.2 — Naturalistic and Laboratory Designs

Naturalistic and laboratory designs answer different questions. Naturalistic sleep preserves the participant’s own bed, schedule, relationships, stressors, and privacy boundaries. Laboratory sleep increases measurement precision but changes the setting, increases burden, and may alter sleep through first-night effects and observation pressure (Nosek et al., 2018; Chambers & Tzavella, 2022).

A fair research program uses both only when each is needed. Naturalistic studies are better for ecological validity, day residue, family context, long-term recurrence, and low-burden repeated sampling. Laboratory studies are better for stage-targeted awakenings, precise physiology, cueing, and controlled stimulus exposure within ethical limits.

The first-night effect must be modeled, not ignored. Sleeping in a laboratory can change architecture, arousal, reportability, and next-day mood. A study that treats the first laboratory night as ordinary sleep may confuse adaptation to the lab with the mechanism under study.

Wearable designs have their own limits. Actigraphy, consumer EEG, heart-rate wearables, and phone prompts may support low-burden longitudinal data, but device version, placement,

algorithm, battery, user behavior, and missingness must be recorded. Convenience cannot become validity.

Hybrid designs may be strongest. A study can use a laboratory calibration phase to validate stage and report procedures, then deploy a naturalistic repeated-night phase with lower-burden measurements, then return a subset for targeted questions. The bridge between phases must be tested rather than assumed.

The design choice is itself a fairness question. Precision bought by intrusion is not automatically better science. The right design is the least intrusive design that can still distinguish the relevant rival mechanisms.

Naturalistic work should not be treated as soft science. It is often the only way to observe the ordinary middle of sleep, where grief, parenting, illness, work, noise, and private routines coexist. Its difficulty is precisely why it matters for this analytic question.

Laboratory work should not be treated as pure truth. It provides precision under altered conditions. The bridge from laboratory finding to ordinary sleep must be defended with replication, bridge samples, and context-of-use language. A beautiful laboratory signal can still be a poor measure of life.

15.6.3 — Dream Database Resources

A substantial shared resource is already available. The initial DREAM database assembled 20 datasets from 505 participants, linking sleep M/EEG with standardized reports across 2,643 awakenings. It makes cross-study tests of stage classification, report availability, and neural predictors of reported experience feasible across laboratories. A useful first analysis would freeze

its report model on some datasets and evaluate transfer to independent datasets, preserving sleep-stage and sampling differences. Its linked neural recordings and awakening reports give measurement development a shared empirical resource (Wong et al., 2025).

Database interpretation begins with its sampling frame: who agreed to dream research, slept in a laboratory, tolerated awakenings, recalled dreams, and disclosed content. These documented conditions define the population and observations available for analysis.

Dream databases also vary in prompts, languages, scoring systems, electrode montages, awakening timing, and report classification. A meta-analytic comparison must respect those differences rather than treating all reports as interchangeable. Harmonization is an analytic achievement, not a default.

Existing datasets may be especially limited for privacy-sensitive questions. Raw dream narratives may contain bystanders, intimate material, trauma, or religious meaning. Access should be tiered, de-identified where possible, and restricted when content cannot be responsibly shared.

For the Law program, databases can test measurement feasibility, report models, coding reliability, stage-specific recall, and competing sleep mechanisms. Prespecified analyses and clearly identified exploration make the resulting contributions reproducible.

A dream database is a valuable resource for method development. It can help qualify measurements, compare observation models,

and design more informative prospective sleep studies within its documented sampling limits.

Open multicenter resources also reveal differences among methods. A codebook that performs differently across datasets can identify cultural, prompt, stage, or laboratory-protocol dependence and guide more effective measurement.

Identify these as analyses of existing data and disclose what investigators had already seen before fixing the analysis plan. Existing-data use does not by itself make a hypothesis test exploratory: its status depends on prior access, prospective specification, selection, and the suitability of the data for the declared estimand. A database should not determine the question merely because it is available.

15.6.4 — Multimodal Data Dictionary

A sleep study needs a data dictionary before it needs interpretation. The dictionary should version sleep stage, epoch length, scoring method, device, sensor placement, signal quality, artifact decisions, awakening protocol, report prompt, report delay, affect rating, privacy level, and missingness reason (Shiffman et al., 2008; Stone et al., 2007).

The dictionary should keep layers separate. Stage data, physiology, report content, report confidence, pre-sleep burden, next-day affect, medication, clinical events, environment, and privacy restrictions should each have distinct fields. A combined score may be derived later, but the raw distinctions must remain recoverable.

Missingness categories are central. No awakening, no recall, refusal, distress stop, device failure, low signal, medication confound, language barrier, and clinician intervention mean different things. A single missing code erases the very burden the study needs to understand.

Versioning matters because sleep devices and scoring algorithms change. A report generated under one device firmware, one automatic staging system, or one codebook cannot be silently rescored under another without a bridge. Historical sensitivity analysis should preserve both versions.

The dictionary should also include derived variables with provenance. REM density, slow-wave activity, fragmentation index, nightmare burden, recall confidence, next-day residual, and coded dream affect must point back to the raw fields and rules that generated them.

Good data architecture is not clerical. It is the difference between a sleep study that can be criticized and one that can only be believed or dismissed. The Law program requires the criticizable kind.

The data dictionary should include a privacy field for each report element. A participant might allow affect rating, allow theme coding, restrict raw text, prohibit quotation, or request deletion of relational details. These permissions should travel with the data so later analysts cannot accidentally exceed consent.

The dictionary should also include provenance for derived dream variables. Who coded the report, under which manual, with what training, with what reliability, and with what uncertainty? A

dream-valence field without provenance is not a scientific variable; it is a loose interpretation stored in a cell.

15.6.5 — Protocol-Fixed Coding and Analysis

Under §6.7's prospective-specification terminology, coding variables, coder training, reliability thresholds, uncertainty categories, noncodable states, primary contrasts, and the definitions of dream valence, threat, social content, agency, bodily sensation, grief, recurrence, lucidity, and meaning are fixed before outcome inspection (Nosek et al., 2018; Chambers & Tzavella, 2022).

The analysis plan should state which outcomes are confirmatory and which are exploratory. Within-night change, next-day residual, nightmare recurrence, dream-report probability, and stage-specific physiology cannot all become primary after the data are known. Flexibility after inspection is how a dream chapter becomes unfalsifiable.

The prospective plan links each rival to a frozen feature set, observation model, and adjudication rule. Memory consolidation uses retained-memory outcomes; threat simulation uses protocol-fixed threat codes and recurrence; arousal regulation uses stage-linked physiology; and report selection models dream-report probability. The coding manual, training set, reliability floor, and held-out adjudication sample are fixed before model comparison.

Coding should also include abstention. Some reports will be too fragmentary, too private, culturally ambiguous, or emotionally unsafe to code. A valid codebook includes no-code and restricted-code categories rather than forcing content into convenient cells.

Confirmatory coding uses features available at the protocol-fixed analysis time. Later family narratives, clinical interpretations, or revised autobiographical meaning may support separate retrospective analyses, but they cannot redefine the original dream variable. Time-forward coding preserves prediction, reconstruction, and later meaning as distinct objects.

Prospective coding control protects the analysis from the human tendency to discover meaning after the result is known. Its purpose is not administrative purity; it is to keep an intimate, ambiguous report from becoming whatever variable best favors the model.

Coder disagreement should be planned. Dreams are often ambiguous, metaphorical, fragmented, or culturally specific. A useful codebook reports disagreement, confidence, and unresolved cases rather than pressuring coders to agree in order to make the model easier.

Analysis should include model recovery before human data are interpreted. Simulated nights should test whether the proposed design can distinguish sleep reprocessing from memory consolidation, arousal regulation, report selection, and sleep-disorder pathways. If the design cannot distinguish them, recruitment should not proceed.

15.6.6 — Open and Restricted Data Layers

Sleep research needs reproducibility, but intimate dream content is not ordinary open data. A layered architecture separates public codebooks, synthetic examples, aggregate stage features, missingness summaries, model specifications, coding manuals,

and de-identified derived variables from restricted narratives and identifiable context. Openness should improve criticism without making privacy the price of replication (National Institute of Standards and Technology, 2020).

Raw reports may reveal partners, children, deceased relatives, clinicians, trauma, sexuality, religion, or private conflict. Transparency alone does not justify release, and a closed repository is not ethical by default. Restricted access needs a stated purpose, trained users, audit logs, redaction or withdrawal routes, and sanctions for use beyond the approved question.

Open methods often contribute more than open narratives. Analysis code, frozen model specifications, negative controls, sensitivity plans, data dictionaries, and labeled synthetic or paraphrased examples can make the work answerable while protecting the person. Synthetic material demonstrates structure; it is not evidence.

Each layer operates under a versioned contract naming fields, units, clocks, values, missingness meanings, provenance, derivation code, access class, retention, and retirement. Changed dream categories, stage definitions, or coding rules create a new analytic version and require a bridge rather than silently rewriting earlier nights. Schema migration tests should verify that old and new versions produce equivalent derived objects on shared records before pooled analysis is allowed.

Federated analysis, secure enclaves, or site-level sufficient statistics can answer some multisite questions without moving raw narratives into one repository. They reduce what travels but

do not erase privacy risk or establish comparability. The plan records what leaves each site, what remains local, how updates are audited, and how withdrawal propagates (National Institute of Standards and Technology, 2020; Nissenbaum, 2010). A privacy-preserving architecture should also record the inferential limits created by local-only variables so missing cross-site information is not mistaken for absence.

Consent to sleep-reprocessing research is not consent to train general language models, infer personality, build public artifacts, or support unrelated prediction. Purpose limits attach to raw and derived layers, and materially new uses require separate permission and review. Reproducible science can invite criticism without turning sleepers or their relationships into exhibits. Derived embeddings and summaries should inherit the same purpose limits as the source narratives, because transformation does not erase consent boundaries.

15.7 — Privacy, Public Risk, and Verdict Limits

Dream research is public-risk sensitive because it is easy to quote, easy to mystify, and easy to misuse. A single terminal dream or grief dream can become more persuasive to the public than a careful protocol. That is why verdict limits belong in the chapter, not in an appendix (Nissenbaum, 2010; National Institute of Standards and Technology, 2020).

This final section connects sleep findings with their public communication. Dream research can advance accounts of sleep mechanisms, report formation, within-person dynamics, and privacy design. Participants retain control over disclosure and the personal meaning they assign to their experiences.

Dream evidence may become culturally powerful faster than it becomes scientifically strong. The closing section therefore specifies what may be said, what may be shown, what remains private, and which verdict labels can travel beyond the specialist context.

A bounded verdict is also a promise to participants. It tells them that their sleeping life will not be used to make claims about their worth, their faith, their grief, their family, their death, or the hidden balance of their lives. The result may enter science, but the person remains larger than the result.

15.7.1 — Dream Content as Sensitive Data

Dream content is sensitive because it can expose desire, fear, shame, trauma, religion, sexuality, violence, family conflict, illness, and grief without the dreamer having chosen those images

while awake. The content may not reflect endorsement, intention, memory, or character, yet it can still harm if exposed (National Institute of Standards and Technology, 2020; Nissenbaum, 2010).

Data minimization should begin before collection. Many studies can ask for affect ratings, themes, intensity, or coded categories without raw narratives. Full narrative should require separate permission, clear purpose, and the ability to skip or redact details.

Access should be tiered. Study staff who need coded variables may not need raw content. Coders may not need identifiers. Public reviewers may need methods and synthetic examples rather than dreams. The default should be less access, not because dreams are shameful, but because they are intimate.

Participants should have control over sensitive passages where scientifically possible. They may designate content as private, allow coding but not quotation, permit paraphrase but not raw text, or withdraw narrative from future use. Those options should be explained before collection.

Security failures in dream data are not ordinary breaches. A leaked dream can harm relationships, identity, and dignity through exposure of distinctive narrative and relational content. Protocols should include incident response, participant notification, deletion rules, and publication consequences.

The no-score rule is strongest here. A dream is not a moral record. It is not a loyalty test, holiness marker, psychological rank, or eligibility signal. It is sensitive data from a person whose dignity is prior to the study.

Privacy protection should be designed before the most interesting report arrives. A protocol that invents access rules after a dramatic dream will be pulled by fascination, urgency, and public value. The correct procedure is to decide in advance what can be coded, quoted, shared, restricted, or deleted.

Dream content also deserves temporal limits. A participant may consent to analysis during a study but not to indefinite storage of raw narrative. Retention schedules, withdrawal options, and derived-result rules should be specific enough that future researchers cannot treat dream archives as permanent reservoirs of intimate material.

15.7.2 — Bystander and Relationship Privacy

Dreams often contain other people. A partner, child, parent, clinician, friend, enemy, deceased relative, public figure, or stranger may appear in a report. Those people did not consent to become research content, and the dreamer may not want the relationship exposed (World Medical Association, 2024; Council for International Organizations of Medical Sciences, 2016).

Bystander privacy should be handled as a design problem. Reports can use role labels, initials, generalized categories, or redaction before coding. A raw name is rarely necessary for sleep-science inference. When relational identity matters, the purpose must be narrow and access restricted.

Relationship privacy also protects the dreamer. A dream involving conflict, desire, violence, or grief can be misunderstood if treated as waking intention. The protocol should warn against interpretation, prohibit moral inference, and keep raw content

away from employers, institutions, family members, public archives, or scoring systems.

In terminal or grief settings, families may share dream reports for comfort, ritual, or meaning. Research preserves those personal interpretations while describing its own observations and methods.

Bystander content also complicates open data. A de-identified dream can still identify a relationship if the narrative is distinctive. De-identification should therefore include contextual rarity, not just names and dates.

Fairness science must not shift the burden of reproducibility onto people who never joined the study. Bystanders are part of the hidden cost of dream research, and their invisibility cannot be used as permission.

The research team should also avoid creating family burden by returning raw dream content to relatives. A participant may choose to share a dream, but the study should not become the channel through which private or ambiguous material reaches others. Relationship repair or rupture is not a research deliverable.

15.7.3 — Terminal Dreams and Personal Meaning

Dream reports during serious illness may carry profound personal and family meaning. Research can examine their recall, affect, physiology, content, and change over time using a stated question and a qualified coding scheme. Participants retain control over how their material is used (Palmer & Alfano, 2017).

Studies of terminal dreams document whether reports are immediate or retrospective, direct or family-mediated, and how culture, medication, and report availability enter the record. A defined sampling frame makes population comparisons possible.

Terminal illness also changes sleep, cognition, medication, delirium risk, pain, oxygenation, and family presence. These conditions can affect dream content, recall, disclosure, and interpretation. The report may still be meaningful, but the causal path is too complex for proof language.

A study may examine terminal dreams as a clinical or phenomenological domain under care-first rules. It may ask about prevalence, themes, distress, comfort, relation to sleep disruption, medication, delirium, and family communication. It may not use a dream as evidence that a life has reached balance.

Use dream quotations only with permission and context appropriate to the agreed purpose. Review privacy and family implications before publication.

A dream can matter deeply to a person, family, or spiritual tradition. Research can investigate its occurrence, content, and effects while respecting the meaning it holds for the dreamer.

Captions and summaries distinguish the study's observations from the dreamer's own interpretation. Any narrative is shared on the participant's agreed terms.

A missing terminal-dream report is recorded as an observation outcome, with the reason retained where known.

15.7.4 — No Grief Interpretation by Science

Grief dreams can comfort, disturb, reopen longing, or feel like contact. Science should not tell bereaved people what such dreams mean. It should not explain away comfort, certify visitation, rank mourning, or turn grief into evidence for a theory. The chapter's responsibility is methodological restraint (National Institute of Standards and Technology, 2020; Nissenbaum, 2010).

A grief dream may be studied as experience, memory, attachment, emotion, or sleep disruption. It may be coded for themes only with consent and careful privacy. The participant's meaning should be recorded separately from analyst interpretation, and neither should be forced into a universal scale.

People grieve in different ways. Some find comfort in dreams; others experience distressing dreams or recall none. Support responds to each person's experience and preferences.

Grief can change recall and reporting. People may attend to dreams involving the deceased more than other dreams, share them more often, and remember them longer. Those selection processes enter the observation model.

Clinical and pastoral services may help people interpret dreams according to their needs and traditions. The science volume contributes descriptions of the research, its methods, and its findings.

The burden analysis asks where burden is carried. In grief dreams, burden may be carried in love, absence, memory, body, family expectation, and culture. A scientific chapter becomes fair by not pretending to settle what grief has not asked it to settle.

The safest public language treats grief dreams as experiences people may interpret within their own lives and traditions. Science can study report frequency, distress, comfort, sleep disruption, and memory processes; it cannot tell a mourner which meaning is correct.

This distinction should be preserved when results are favorable. If grief dreams correlate with next-day comfort in a study, the conclusion is not that grief dreams are messages or repairs. The conclusion is that a measured association appeared under specified sampling, coding, and cultural conditions.

15.7.5 — Hostile-Crop Review

Hostile-crop review asks how a sentence, table, figure, headline, or quotation reads after its surrounding safeguards disappear. Dream research especially needs this test because vivid material can turn an auxiliary finding into claims about hidden balance, useful trauma, mystical access, or personal moral status (World Medical Association, 2024; Council for International Organizations of Medical Sciences, 2016).

Figures and tables should keep uncertainty, missingness, stage, report selection, and rival explanations visible. Titles, colors, captions, axes, and row labels carry claims; a label such as dream repair signatures can mislead even when the cells are careful.

Raw dream quotations require necessity, consent, redaction, and protection from spiritual or moral inference. Public summaries should instead name the tested auxiliary relation, such as reported dream affect predicting a next-day outcome after stage and recall controls.

An independent reviewer should crop the artifact and ask what a skeptic, journalist, family member, or online critic could reasonably infer without the chapter. Review includes proof drift, privacy drift, score drift, and mystical drift across prose, graphics, and tables (Fischhoff & Davis, 2014; Spiegelhalter, 2017).

The artifact is revised until its auxiliary status and uncertainty survive detachment. Public reach is earned when a bounded result remains bounded outside the page that first explained it.

15.7.6 — Bounded Auxiliary Verdict

The chapter evaluates its protocol-fixed sleep and dream estimands: report, reprocessing, memory, physiology, and privacy-feasible measurement. The result states which hypotheses gained support, which weakened, and which remain unresolved (Nosek et al., 2018).

A favorable result names the reference class, measurement version, pre-sleep variables, report model, window, rivals, and better-predicted pattern. Narrowing or adverse outcomes can localize effects, contradict simple repair accounts, expose recall or medication confounding, or stop a burdensome and privacy-risky design.

Refusal, no recall, partial disclosure, unclassified narrative, and non-disclosure are valid observation states. Sleep can inform state, memory, and reprocessing while remaining a private domain not owed to research.

Every summary carries the component verdict and its limits. The night remains meaningful and private while the program learns exactly where auxiliary mechanisms survive, narrow, or fail.

Chapter 16 — Terminal-Window Tests

A terminal boundary claim becomes empirical when it predicts relations before the final point, not when a curve merely looks persuasive after alignment. Conditioning, censoring, selection, mean reversion, clinical decline, and observation floors can all concentrate trajectories near an endpoint. The chapter tests joint restrictions on preterminal drift, dispersion, dependence, horizon, reserve, intervention response, and detectability using information available before the endpoint.

A discriminating signature is a typed relation among declared objects: route state or proxy, filtration, endpoint branch, risk set, observation kernel, time coordinate, estimand, and rival family. Removing any field invites a different generator to imitate the same picture. The scientific object is the frozen conjunction, not the visual smoothness of a terminal curve (Doob, 1957; Gneiting & Raftery, 2007).

The leading reserve-coupled realization earns attention through cross-equation restrictions on drift, conditional dispersion, two-time dependence, and perturbation response. Brownian bridges, Doob transforms, homeostatic controllers, frailty selection, treatment, and informative observation can reproduce individual pieces. The route is therefore tested as a transportable conjunction, with each component able to fail independently.

The chapter moves from state identification to exponent restrictions, covariance kernels, terminal windows, observation floors, and rival adjudication. Each step can fail separately. A route can be mathematically coherent but empirically unidentifiable; a proxy can be reliable but unrelated to the

candidate state; a terminal pattern can be real but better explained by selection or care context.

The strongest evidence would transport without retuning. One frozen representation, endpoint rule, reserve proxy, observation model, and scoring system would predict held-out relations across cohorts, resolutions, channels, care contexts, and safe perturbations. A result that needs a new window, origin, floor, or endpoint for each dataset remains a local fit rather than a transported signature.

The human setting matters throughout. Terminal cohorts include sedation, delirium, analgesia, communication loss, family presence, device dropout, and changing goals of care. Those are not nuisance variables to erase after collection. They are parts of the observation and intervention process, and research remains subordinate to comfort, consent, and ordinary clinical duty.

The reserve-coupled conjunction connects several tests: representation, endpoint adjudication, observation, measured-to-latent inference, and route comparison. Success across these tests would favor that route within the studied reference class. The result then guides replication and comparison with other boundary architectures; an unsuccessful route can be revised or retired while those alternatives remain available.

Mean, variance, tails, covariance, path class, and support describe different features of a trajectory. Heterogeneity, symmetric error, or cancellation can produce a mean near zero, making the additional distributional features especially informative for comparing models.

Concrete design begins with repeated reports, wearable channels, medication timing, care events, missingness marks, and independently defined endpoint probes. These records become prospectively specified estimands scored under a common information budget. The central question is which candidate, rival, hybrid, or open-set generator could have produced the complete observed process, including the pattern of observation failure.

Each principled failure result has a scientific destination. A stable noise floor can make an exponent unidentifiable; a bridge can dominate a reserve route; reserve can collapse into severity; terminal windows can be too sparse; a covariance surface can fail held-out recovery. The correct response is to narrow, redesign, or issue No adequate estimate, not to protect an evocative plot.

By the end of the chapter, the reader should be able to tell a route state from its proxy, a prospectively estimated horizon from retrospective time-to-event, a theoretical scaling restriction from a fitted slope, a covariance kernel from a smoothed trend, and route-favored evidence from evidence for the boundary law itself.

The program is most scientific here because its preferred route receives no privileged data, window, tuning budget, or rescue language. It must face ordinary stochastic, clinical, and observation-process models on common rules and preserve the exact result when one of them wins.

16.1 — Candidate Route and State Identification

A route-specific signature begins by fixing the state that is supposed to carry it. The state may include a signed residual, a reserve variable, a filtered horizon, a route indicator, and contextual covariates. None is automatically observed. The study must state which components are truth-level objects, which are candidate mechanism states, and which are measured proxies (Durbin & Koopman, 2012).

State identification is not achieved by naming a familiar quantity. Fatigue, frailty, pain, time remaining, and treatment intensity can all correlate with a proposed reserve while representing different causal processes. A defensible route state therefore comes with a measurement map, exclusion restrictions where possible, and sensitivity analyses showing how the signature changes when the state is misspecified.

The filtration matters. A prospective route state may use information available up to time t , including current measurements and declared history. It cannot use the eventual endpoint class, later retention, or future observations unless the analysis is explicitly retrospective. This no-look-ahead rule prevents a terminal pattern from being built out of information that the proposed mechanism could not have possessed.

Two participants may have the same realized time to an eventual endpoint but very different contemporaneous information, symptom burden, treatment options, and support. A retrospective clock places them at the same distance; a filtered route state need

not. The difference is not cosmetic because the route predicts from the state available before the endpoint is realized.

A state model may remain useful for forecasting observation shutdown, care transitions, or affective volatility even if no terminal invariant exists. PTVC relevance requires a separate bridge to the declared phenomenal residual and endpoint branch. When several latent states generate the same measured process, the correct outcome is an identified set, a new perturbation, or No adequate estimate.

16.1.1 — Route State, Filtration, and Observability

The first scientific object in this chapter is not the endpoint. It is a filtered estimate of remaining opportunity, formed before the endpoint is known and revised as new evidence arrives. Perceived future time is already known to reorganize motivation; the route-specific question is whether a prospectively estimated horizon interacts with unresolved state and independently measured reserve in a pattern that ordinary finite-horizon accounts do not explain (Carstensen, 2006; Särkkä, 2013).

Filtered horizon belongs to the same claim-status discipline as the measured cumulative estimate. It is not a destiny meter. It is a latent state inferred from information available at time t : symptoms, prognosis, functional capacity, social obligations, task structure, perceived time, clinical context, and observed behavior. The analyst may later know more, but the confirmatory model must not.

A useful horizon construct has three obligations. It must name its information set, it must separate belief from realized time, and it

must state how error changes the claim. If a horizon estimate works only because the model secretly sees the realized endpoint, the result is endpoint leakage, not prediction.

A route state should therefore be represented as a typed collection rather than a suggestive scalar. At minimum, the collection distinguishes the cumulative residual under study, the capacity variables that could alter future trajectories, the opportunity or horizon variables available under the current information set, and the contextual variables that govern observation. This typed construction prevents a change in fatigue, prognosis, missingness, or treatment access from being mistaken for movement in the latent target. It also makes clear which quantities belong to the route, which belong to measurement, and which belong only to the analyst's reconstruction.

Observability is a separate question from existence. A latent route state may be scientifically meaningful yet unrecoverable from the available channels, while a highly predictive observable may fail to identify the state that the theory requires. State-space practice therefore demands an explicit transition model, an explicit observation model, and recovery checks under realistic noise, irregular sampling, and dropout (Durbin & Koopman, 2012; Särkkä, 2013). The chapter treats this distinction as a gate: a route cannot be favored because a flexible filter fits the observed series unless simulation and held-out recovery show that the fitted state is distinguishable from serious alternatives.

Prospective transport tests whether a candidate state improves prediction across declared windows, cohorts, interventions, and observation regimes. The state is constructed from information

available before the outcome. Changes in care setting, device availability, or filtering method are examined for changes in its meaning. The resulting analysis can identify a stable route state or a more specific forecasting role.

16.1.2 — H_t From Available Information

The notation H_t names the filtered remaining-horizon candidate at time t . It is not the true remaining lifetime. It is the model's expectation, distribution, or decision-relevant summary of remaining opportunity given the information set available at that moment (Särkkä, 2013; Hernán & Robins, 2020).

The information set, written as $\mathcal{I}_t$, must be declared before analysis. It may contain current clinical status, functional change, self-reported future-time perspective, observable task context, recent choices, and approved auxiliary data. It may not contain future death date, future endpoint adjudication, future sensor loss, or later family narrative except in explicitly retrospective sensitivity work.

One compact definition is to let H_t equal the expected positive remaining time to a latent endpoint under a specified horizon model. The definition is useful only if the model also reports its uncertainty. A point horizon without an uncertainty distribution invites the false impression that the future is already known.

For behavioral tasks, H_t can be discretized into opportunity bins rather than calendar time. A participant may have a short task horizon because only two trials remain, a short social horizon because an interaction is ending, or a short clinical horizon because mobility or communication options are closing. The

shared scientific object is remaining usable opportunity, not metaphysical finality.

The strongest use of H_t is within-person. The model asks whether the same person changes allocation as filtered horizon changes, after reserve, disease severity, medication, fatigue, and context are modeled. Between-person comparisons are possible only after calibration and transport conditions are defended.

A filtered horizon makes the proposed route more concrete by supplying a prospectively defined state for comparison. Qualification asks whether that state improves held-out prediction and distinguishes the candidate from adequately informed rivals.

Every horizon estimate should carry an evidence card: information available at the time, excluded future data, the filtration timestamp, prediction target, uncertainty interval, and permitted downstream use. This card turns horizon from a retrospective story into a testable state variable. It also makes look-ahead leakage visible when prognosis, endpoint adjudication, or later outcomes have entered the predictor.

The design implication is that horizon can be manipulated safely in nonterminal tasks only when the participant knows the information structure. Hidden horizon manipulation may test surprise or anxiety, but it does not test the filtered state this chapter defines. A fair experiment can vary whether the horizon is known, probabilistic, or learned, but each condition must be labeled so the analysis knows whether it is testing available information, uncertainty, or revision.

16.1.3 — Uncertain and Revisable Horizon

Horizon uncertainty is not a nuisance to be hidden. It is part of the construct. Prognosis changes, opportunities return, treatments work, plans collapse, symptoms improve, and social support appears. A serious horizon model must allow revision without pretending that revision is failure (Seow et al., 2011; Vogel et al., 2013).

A horizon distribution is often more honest than a horizon point. The distribution can place probability mass over short, medium, and long opportunity windows, and those probabilities can update as new information arrives. This is especially important in clinical settings, where point prognosis can be both emotionally powerful and statistically fragile.

Revisability also prevents prophecy language. If H_t changes after a new scan, new medication response, or regained function, the old estimate was not a false oracle. It was a time-stamped inference under an earlier information set. The record should preserve both the old state and the update.

In a task environment, revision can be experimentally controlled. A participant may learn that a block has fewer remaining trials than expected, or that a previously unavailable action has reopened. The model then asks whether choices adjust in ways consistent with finite-horizon control rather than with a fixed personality trait.

Uncertainty affects the value of exploration. If the horizon might be long, learning can retain future value. If it is almost certainly short, exploration may compress. But if uncertainty itself is high,

information-seeking can increase. A model that always predicts urgency under uncertainty is too crude.

The withdrawal rule is straightforward: if horizon estimates cannot be revised coherently, if updates depend on future information, or if uncertainty overwhelms the behavioral effect, the chapter may keep horizon as an illustration but must withdraw it as a confirmatory state variable.

A useful analysis should therefore report not only the current horizon estimate but also the revision history. A stable estimate, a sudden compression, and a widening horizon can have different behavioral consequences even if they share the same current mean. The revision itself may carry information about burden, because a person living under repeated route closures may respond less to a nominally open future than a person whose horizon was shortened by one clear event.

Revisions should also be bounded by credibility. If every new observation radically changes H_t , the model may be unstable; if no observation changes it, the filter may be insensitive. A useful filter learns at a rate that can be justified by the evidence stream. Sensitivity to that learning rate should appear in the design, because overreactive and underreactive horizons produce different behavioral predictions.

16.1.4 — Objective and Subjective Horizons

Objective and subjective horizons answer different questions. Objective horizon concerns the opportunity window available under external conditions. Subjective horizon concerns what the

person or system believes, fears, hopes, or attends to. The two can diverge sharply (Durbin & Koopman, 2012).

Time perspective already has a testable behavioral role. In studies in the United States and Hong Kong, older adults' preference for familiar social partners diminished when they imagined an expanded future; under an imagined time constraint, both younger and older adults preferred familiar partners. Preferences also changed around Hong Kong's 1997 handover (Fung et al., 1999). These findings connect anticipated opportunity with social goals and provide an experimental way to separate perceived time from chronological age.

The distinction also improves the comparator. In an integrated analysis of 2,504 adults, greater age was associated with a more favorable emotional profile, while a more limited future-time perspective was associated with a less favorable profile even after accounting for health-related factors (Grühn et al., 2016). Perceived horizon, emotional benefit, and age therefore require separate measurements. A declared PTVC route can build on these studies by predicting a specific interaction between independently measured signed history and remaining opportunity, beyond social preference, current mood, health, and ordinary goal regulation.

Objective and subjective horizons can differ for understandable reasons. Someone with a longer clinical prognosis may perceive fewer future possibilities after depression, trauma, displacement, or repeated loss; someone with advanced illness may experience an open future through meaningful relationships, projects, or spiritual practice. Measuring both helps the model represent those

differences without treating either lived perspective as a personal error.

The Law-specific question cannot simply privilege either side. If choices track subjective horizon, the mechanism may be belief, meaning, and attention. If choices track objective opportunity after controlling for belief, the mechanism may involve physical constraint, reserve, or task availability. If both matter, the model must include both.

In laboratory tasks, objective horizon can be manipulated by remaining trials, time limits, or available moves. Subjective horizon can be measured through belief reports, confidence, perceived urgency, and willingness to invest in delayed payoff. The two should not be collapsed into one variable because collapse hides the mechanism.

Clinical and social settings add cultural death scripts and prognosis awareness. Some communities emphasize preparation, repair, reconciliation, or acceptance under threat; others avoid direct prognostic talk. These scripts may produce horizon-like behavior without any reserve-coupled Law-specific pressure.

The acceptance condition is therefore tiered. A result may support subjective-horizon effects, objective-menu effects, or reserve-horizon interaction. Separating those components and modeling rival scripts makes the resulting contribution interpretable.

The most informative cases are often disagreements between the two. If objective routes remain but subjective horizon is short, the study must ask whether the routes are actually trusted, usable, safe, and known. If subjective horizon remains long while

objective options are narrowing, the study must ask whether support, faith, denial, cultural meaning, or incomplete information is sustaining the person. The divergence is not an error term; it is a research object.

For copy and protocol design, the two horizons should be reported side by side. A table can show objective route count, subjective route confidence, information source, and route trust without implying one is the true horizon. The divergence may guide interviews or task interpretation, but it should not become a correction of the participant's lived account unless independent evidence warrants that correction.

16.1.5 — No Endpoint Leakage

Endpoint leakage occurs when future endpoint knowledge enters a model that is supposed to predict behavior before the endpoint is known. It is a close cousin of tautology. The analysis appears prospective, but it is quietly using the last event as an input (Särkkä, 2013; Hernán & Robins, 2020).

A confirmatory horizon model must be filtered. It may use $\mathcal{I}_t$, the information available at time t , and it may use a protocol-fixed forecasting model trained on other people or held-out periods. It may not use the person's realized time-to-death as a predictor in the same analysis that claims to test horizon-sensitive behavior.

The same rule applies to retrospective labels. Analysts may later classify a window as near-terminal, but that label cannot define the horizon variable used for a prospective claim. Retrospective analyses can be valuable for description, sensitivity, and hypothesis generation, but they must be labeled as such.

Cross-fitting is a practical guard. One model estimates endpoint or prognosis on held-out data, and another model tests behavior using only the filtered estimate. Thresholds and tuning choices should be locked before outcome inspection. If the same analyst adjusts both until the signature appears, the result is not confirmatory.

Endpoint leakage can be subtle. Sensor dropout, hospice admission, sudden medication changes, or family alerts may encode proximity to death. These variables may belong in rival or missingness models, but they require caution if used to define the horizon. What looks like shrinking opportunity may be observation shutdown.

The rule is severe because the claim is severe. If the Law needs the realized endpoint to make horizon predictions, then it has not predicted horizon behavior. It has redescribed the ending.

This rule also governs graphics. A plot aligned backward from the known endpoint may be useful descriptively, but it must not be labeled as the prospective horizon that shaped behavior. The figure label should say endpoint-aligned, smoothed, retrospective, or filtered. This is not visual fussiness. In a public book, the caption may carry the claim more strongly than the paragraph.

Endpoint leakage can also enter through model selection. If investigators try many horizon filters and keep the one that best predicts the known endpoint-aligned pattern, the leakage is analytic rather than algebraic. The safe route is to preselect filters, hold out tuning data, or report the search honestly as exploratory.

A filtered horizon is only confirmatory when its construction was disciplined before the target pattern was known.

16.1.6 — Horizon Measurement Models

Horizon is measured indirectly. It can be inferred from reports of future time, changes in goal selection, task behavior, clinical prognosis estimates, mobility, communication capacity, and observable opportunity sets. None of these channels is horizon itself (Seow et al., 2011; Vogel et al., 2013).

A strong measurement model declares what each channel is allowed to say. A self-report item may measure perceived future time but can be shaped by mood, culture, and interviewer demand. A clinical prognosis may estimate survival distribution but not the person's lived sense of remaining possibility. A task choice may reveal policy under experimental conditions but not life meaning.

A horizon model may combine several imperfect channels, but disagreement among them should remain observable. Reported future opportunity, clinical prognosis, task-imposed time, and environmental options can diverge for principled reasons. The analysis should test whether that divergence predicts behavior or model failure instead of forcing all channels into a single latent score.

Horizon measurement also needs time scale. A person may have a short horizon for mobility, a medium horizon for communication, and a long horizon for relationship meaning. A single H_t can be used only when the domain is declared.

Otherwise the model should use a vector of domain-specific horizons.

In task settings, horizon can be measured by remaining moves, remaining time, probability of task continuation, or belief about continuation. The Virtual Terminal Maze described later uses these variants because they can be manipulated safely. A task horizon is not a death horizon; it is a model environment for testing control signatures.

A horizon measure is qualified only when it predicts protocol-fixed behavior out of sample, remains stable enough for its context of use, and fails gracefully when rivals explain the same data better. Without those conditions, horizon remains a useful word, not an estimand.

A horizon model should also declare its cadence. Daily clinical updates, hourly task states, weekly social-route checks, and momentary app prompts define different horizons. Mixing them can create false precision because a route may close between observations. The model should state whether it estimates horizon continuously, at visits, at decisions, or at protocol-fixed time bins. A horizon that is measured too slowly may explain behavior that happened before the measurement noticed the change.

The horizon variable represents available future options under a declared information set. Measures of despair, acceptance, readiness, meaning, optimism, and perceived opportunity can be collected separately when the research question calls for them.

16.1.7 — No Prognostic Authority

A filtered horizon estimate is a route-specific research object, not a prognosis for a person. It must not determine treatment, rescue effort, hospice eligibility, discharge, insurance, family communication, resource priority, or a participant's understanding of how long they have. In clinical settings, research estimates remain subordinate to licensed judgment, current care standards, and participant preferences. A scientifically useful horizon estimate can describe structure relevant to a model without possessing the validation required for individual prognosis. Keeping those functions separate allows the route hypothesis to be tested without creating an unintended clinical prediction system.

The boundary is scientific as well as ethical. If a horizon estimate changes care, communication, observation intensity, or endpoint timing, it changes the process under study and creates feedback, selection, and leakage. Such feedback can make the estimate appear predictive partly because people or systems began responding to it. Protocols should therefore record any exposure to route-state outputs that could alter the subsequent trajectory or observation process.

Purpose limits require access roles, prohibited-use rules, staff training, participant-facing language, audit logs, incident response, and withdrawal. Public copy may describe a filtered horizon estimate, opportunity model, or task horizon, but never a hidden future. Access controls should also distinguish who needs the estimate for scientific analysis from personnel whose care decisions should remain insulated from it. That separation

reduces the chance that a research variable acquires operational authority simply because it is available.

State identification begins with observability and recovery. The study must show which route states are distinguishable from reports, actions, physiology, and context, and when equivalent states require a coarser output, identified set, or abstention. Recovery should be tested across plausible combinations of states, including cases deliberately chosen to be difficult to distinguish. A state label earns scientific meaning only to the extent that the available observations can reliably separate it from competing latent explanations.

Transition timing must recover in held-out participants, sites, and windows; remain stable under plausible observation shifts; and fail under protocol-fixed rivals. Ablation tests whether horizon, reserve, unresolved state, and their interactions add information beyond severity, frailty, treatment, prognosis, and observation intensity. The strongest evidence comes when the same timing relation survives changes in site and observation conditions without requiring retrospective retuning. Failure to transport should narrow the route claim rather than be absorbed into a more flexible timing model.

The route-state verdict reports observability, recovery, invariance, ablation, rival comparison, and purpose control. Passing licenses further route research in the declared class, not individual forecasting, clinical authority, or PTVc support.

16.2 — Reserve and Horizon Proxies

Reserve and horizon are related but nonidentical. Horizon concerns continuation support or time structure available under current information. Reserve concerns the capacity through which a candidate route could alter future contribution. A long horizon can coexist with little capacity; a short horizon can coexist with intense but narrow capacity (Ramsay & Woods, 2014).

Candidate reserve proxies may include functional status, treatment access, cognitive capacity, autonomic flexibility, available actions, social support, or a route-specific controllability index. No single proxy is the reserve by definition. The measurement model must show shared variation, channel-specific variation, and confounding by the outcome.

Independence is a central design pressure. If reserve is estimated from the same affective reports used to construct the residual, a shrinking ratio may be algebraic rather than biological or psychological. Separate instruments, temporally separated estimation, negative-control channels, and cross-fitting reduce that circularity without curing an invalid construct.

Horizon estimates require uncertainty. A filtered distribution over remaining route time is usually more defensible than a point forecast. Prediction intervals should be calibrated in held-out data, while analyses indexed by realized time-to-endpoint must be labeled retrospective. Neither form may become a personal forecast or care recommendation.

The most useful reserve proxy is not necessarily the one most correlated with terminal decline. It is the one that creates a

discriminating relation after illness severity, medication, care context, and observation availability are modeled. Failure to separate reserve from generic severity blocks promotion of the reserve-coupled route while leaving the measurement work independently useful.

16.2.1 — Reserve as a Multi-Domain Capacity State

Reserve completes the horizon problem. A menu may remain open on paper while the body, attention, cognition, energy, pain tolerance, or social support needed to use it has changed. The model therefore separates remaining time from remaining capacity (Ramsay & Woods, 2014).

The reserve variable $U(t)$ in the formal candidate is not a clinical score handed down by nature. It is a latent capacity construct, and every observable proxy carries interpretation risk. Those risks must remain visible before reserve is used to explain any pattern.

Reserve should be measured with channels as independent from the affect estimator as the design can achieve. A capacity score built from distress, anhedonia, or the same physiological features used to estimate valence can manufacture the interaction it is meant to discover. Shared inputs should be disclosed, ablated, and tested through held-out channels before reserve-specific claims are made.

Reserve is often better modeled as a vector than as a single score. Physiological endurance, cognitive flexibility, communicative capacity, social support, treatment access, and environmental affordance can move in different directions, and each may matter for a different route. Collapsing them into one number can hide

the very mechanism the study hopes to identify. A defensible scalar summary must therefore be justified by a declared measurement model, supported by dimensionality analysis, and accompanied by domain-level sensitivity checks rather than treated as a natural quantity discovered by inspection.

The causal placement of reserve must also be explicit. Reserve may mediate the effect of disease severity on action, moderate the relation between a filtered horizon and choice, predict observation burden, or simply mark clinical decline. Those are not interchangeable roles. The protocol should draw the candidate graph before estimation, specify which time-varying variables are confounders and which are consequences, and test whether the reserve term adds information beyond prognosis, medication, frailty, and care context. Without that separation, an apparently elegant reserve interaction can be ordinary illness progression in new notation.

Finally, reserve has no permission to become a person-level rank. Its scientific use is local to a prospectively specified question, a declared population, and a stated observation regime. Transport requires recalibration when devices, supports, disability patterns, cultures, or care settings change, and failure to transport narrows the reference class rather than lowering anyone's status. The strongest reserve model is therefore not the model with the most persuasive dashboard. It is the model whose components remain interpretable, independently estimated, ethically bounded, and replaceable when better evidence arrives.

16.2.2 — Biological Reserve Candidates

Reserve candidates include physiological stamina, inflammatory load, sleep continuity, mobility, nutrition, oxygenation, autonomic flexibility, cognitive endurance, medication burden, and functional performance. None is the reserve. Each is a possible indicator within a context of use (Seow et al., 2011; Gerstorf et al., 2010).

A useful reserve proxy must state its raw units. Steps per day, grip strength, heart-rate variability, creatinine, oxygen saturation, gait speed, cognitive response variability, and clinician-rated performance status do not live on the same scale. Combining them requires transformation and a theory of what the composite means.

The Law-specific use of reserve is narrower than general health. Reserve matters because it may modulate viable action, volatility, and the admissible set of possible repair or avoidance policies. A biomarker that predicts mortality but not choice, capacity, or signal dynamics may be a prognosis marker rather than a reserve marker.

Clinical state matters. Medication, pain, sleep disruption, delirium, infection, disability, and care quality can all lower apparent reserve. Some of these are reversible. Some are context-dependent. Some affect measurement more than capacity.

Reserve is a latent candidate construct represented through competing indicator models. Each analysis states its normalization and the transformations that preserve the tested restriction.

A reserve candidate can be evaluated through out-of-sample task behavior, observation feasibility, and dynamic variance patterns, with disease severity and prognosis included in the comparison.

A candidate biological route can begin with an independently mapped system. Kleckner and colleagues (2017) identified a large-scale allostatic–interoceptive network in separate discovery and replication samples. J. Zhang and colleagues (2025) extended the map with high-resolution 7 Tesla imaging in 90 participants, mapping resting-state functional relationships between cortical regions and brainstem and other subcortical structures. This supplies specific candidates for studying how bodily condition and affective regulation interact. The useful PTVC-oriented contrast asks whether a frozen cumulative-history variable improves prediction beyond current physiology, recent experience and ordinary allostatic models.

The candidate reserve channels should be tested under perturbation where ethical. In safe settings, that may mean ordinary task fatigue, sleep variation, low-stakes effort, or recovery after a mild cognitive load. In clinical settings, it may mean naturally occurring changes in symptom burden or treatment timing. Reserve is more convincing when it predicts recovery and tolerance, not merely baseline status.

A reserve model should include positive support as well as decline. Oxygen support, assistive devices, caregiver skill, accessible transport, pain relief, and predictable routines can increase effective capacity. If the model only records biological depletion, it may falsely treat social neglect as natural exhaustion.

The fairness lens requires the model to ask when capacity was lost and when it could have been protected.

16.2.3 — Reserve Is Not One Biomarker

The simplest reserve error is to choose one convenient biomarker and let it stand for remaining capacity. That shortcut can make a study look clean while making the construct false. A single biomarker may reflect disease, treatment, sensor contact, socioeconomic access, or disability accommodation rather than the capacity needed by the model (Vogel et al., 2013; Särkkä, 2013).

Frailty scores are useful but not sovereign. They summarize vulnerability and function for particular clinical purposes. They do not automatically measure the formal reserve variable $U(t)$, and they can embed age, disability, mobility, or care-access assumptions that would be unacceptable as hidden Law-specific structure.

A reserve system should therefore report a specification table: channel, unit, transformation, cadence, expected direction, confounds, missingness, context of use, and retirement rule. Without that table, reserve language will drift into authority it has not earned.

The strongest designs use multiple reserve families and test ablation. If the reserve interaction survives only when one fragile indicator is included, the result is weak. If it survives across independent capacity channels with different artifacts, the candidate becomes more interesting.

A reserve proxy should also face a prognostic-ablation test. First fit the declared survival, disease-stage, recent-decline, treatment, and observation-quality baseline; then add the independently estimated reserve channels and evaluate held-out calibration and discrimination. Reserve earns a separate role only when its contribution survives that comparison and remains interpretable after shared inputs are removed.

The public rule is simple: no reserve measure ranks people. Reserve is a study variable for a narrow inference, not a measure of value, eligibility, courage, readiness, or dignity.

Table 16.1. Candidate reserve-proxy validation and misuse boundaries.

Reserve candidate	Raw scale	Primary confound	Use rule
Functional capacity	Mobility, grip, gait, fatigue tolerance	Disability access, pain, equipment, care support	Use only with accommodation and disease controls
Autonomic flexibility	HRV, respiratory coupling, recovery time	Medication, sleep, anxiety, sensor contact	Use as channel, not whole reserve
Metabolic/inflammatory load	Lab values, nutrition, fever, cachexia markers	Disease process, treatment, infection	Model as shared cause and capacity signal
Cognitive endurance	Latency drift, attention, task persistence	Delirium, sleep, medication, education	Use only in accessible tasks

Reserve candidate	Raw scale	Primary confound	Use rule
Social/environmental support	Available help, transport, communication aids	Inequality, family pressure, resources	Treat as menu modifier, not biology

Composite reserve needs interpretability safeguards. A weighted score may predict well while hiding that medication timing or device tolerance carries the effect; a hierarchical model may improve fit while obscuring the construct. Early studies should therefore favor transparent low-dimensional proxies, with richer latent models admitted only when they improve held-out prediction without erasing meaning.

This rule is especially important for commercial devices. Wearable outputs may be precise, frequent, and visually persuasive while remaining weak proxies for the reserve construct. A device score should be treated as a channel with firmware, placement, noise, calibration, and missingness, not as a direct measurement of capacity. That distinction must be clear before any reserve graph appears.

16.2.4 — Reserve and Disease Severity

Disease severity is the largest reserve confound. As illness progresses, reserve may decline, prognosis may shorten, medication may increase, observation may become harder, and choices may narrow. A naive model can misread this shared driver as a Law-specific reserve effect (Ramsay & Woods, 2014).

At least three pathways must remain separate: severity to reserve, severity to horizon belief, and severity to behavior or

measurement. When they move together, an apparent reserve interaction may be a disease-stage interaction, and the analysis should report that common cause directly.

Time-varying clinical covariates are not optional. Medication dose, pain level, dyspnea, delirium status, functional decline, sleep disruption, and care setting can change from day to day. A cross-sectional reserve score may be too coarse for horizon prediction.

A useful design can exploit within-person deviations. If reserve improves temporarily because symptoms are managed and horizon belief remains stable, do choices and latencies change? If prognosis worsens but functional reserve is maintained, does the model still predict menu compression? These contrasts help separate mechanisms.

Reserve must also remain distinct from socioeconomic constraint. Poverty, inaccessible environments, absent transport, and unsupported caregiving can shrink live menus without indicating biological reserve. Treating those conditions as an inner capacity deficit would naturalize a remediable injustice.

If reserve cannot be separated from disease severity, prognosis, resource access, treatment intensity, sensor tolerance, or prior knowledge of the endpoint, the reserve-specific interpretation fails. The remaining association may still describe those observed variables, but it cannot be promoted into evidence for an independent completion capacity.

The hardest cases occur when disease severity is not a confound to remove but part of the pathway through which reserve changes.

A model that over-controls may erase the very capacity decline it wanted to study; a model that under-controls may call disease progression reserve. The protocol should declare the causal question first, then decide which variables are confounders, mediators, stratifiers, or rivals.

The same disease severity can coexist with different effective reserve under different supports. Transport, medication access, quiet sleep, family protection, and disability accommodation can change a person's available capacity. Including these conditions makes the reserve model more complete and identifies practical opportunities for support.

16.2.5 — Reserve Over Time

Effective capacity may decline, recover, fluctuate, or change abruptly. Such trajectories require an explicitly declared reserve model. The nonincreasing reserve branch in Section 4.2.2 is a narrower candidate; its drift and boundary consequences do not automatically transfer to a recovering or stochastic reserve process. A baseline proxy alone cannot establish which branch describes the observed window.

Longitudinal reserve modeling requires cadence. A daily measure may capture fatigue and medication effects. A weekly measure may capture functional decline. A minute-level measure may capture task stamina. The choice of cadence should match the prediction.

Measurement error is especially important because reserve often appears inside interactions. Error in $U(t)$ can attenuate the estimated interaction with horizon, create false threshold effects,

or shift apparent variance slopes. Reliability is not a clerical detail.

State-space models can help by treating observed reserve proxies as noisy emissions from a latent capacity process. Such models should include process noise, observation noise, missingness, and version changes. They should also report uncertainty in reserve, not only a smoothed line.

Smoothed reserve trajectories using future data may be useful for retrospective interpretation, but confirmatory predictions should use filtered or forecast reserve estimates. Otherwise the model again learns from the future while pretending to be prospective.

Noise or instability that defeats the predicted horizon interaction is informative. Reserve may remain clinically meaningful while failing as a Law-specific dynamic variable.

Longitudinal reserve should be modeled with lags. Capacity at noon may affect action in the afternoon; action in the afternoon may alter capacity in the evening. A model that treats U_t and behavior as simultaneous can confuse cause and consequence. Lag sensitivity, recovery windows, and delayed effects should be tested before reserve is described as an explanatory state.

The temporal model should distinguish depletion from availability. A person may have capacity in principle but not at the relevant hour because pain, fatigue, medication, or care schedule blocks its use. The unit of analysis should therefore match the decision. A weekly reserve score cannot safely explain a ten-minute task choice unless the mismatch is modeled.

16.2.6 — Independent Estimation

Independent estimation guards against circularity. Where feasible, build reserve proxies from separately qualified physiological, functional, cognitive, or environmental channels, apart from the ledger's affective and experience-linked inputs. Validate context of use, analytical and clinical validity, responsiveness, failure modes, and version drift before entry into the route equation (FDA-NIH Biomarker Working Group, 2016; Goldsack et al., 2020).

Perfect separation is rarely possible. Pain affects mobility, mood affects sleep, medication affects cognition, and distress affects physiology. The goal is not impossible purity. The goal is to declare overlap, model shared causes, and test whether the reserve effect survives when overlapping channels are removed.

Predeclare reserve-channel tiers. One scheme uses functional and physiological capacity with minimal direct affect content, then clinical symptoms overlapping experience, then exploratory composites. Confirmatory claims should favor the least circular tier.

Independent estimation also matters for dignity. If distress lowers a reserve score and the score then predicts future distress, the model may simply be scoring suffering twice. That is scientifically weak and ethically dangerous.

Routinely remove medication-linked, mobility, autonomic, and report-linked channels to test whether the interaction persists. A signature lost after plausible channel removal lacks robustness.

Independent estimation also requires temporal separation. Reserve features used to explain an interval should be constructed from information available before that interval, with endpoint-derived summaries, later clinical deterioration, and affect-estimator outputs excluded or separately ablated. Otherwise apparent reserve coupling may be look-ahead leakage wearing a biological name.

Independence is not all-or-nothing. A study may have strong independence for physiological reserve, partial independence for functional reserve, and weak independence for self-reported energy. The status statement should name those levels. A reserve result based on a partly overlapping channel can still orient research, but it cannot carry the same claim as a result built from independently validated capacity measures.

16.2.7 — Reserve Failure Conditions

Reserve failure is a scientific outcome that clarifies the next step. Candidate components may fail to cohere, an ordinary rival may explain the pattern, a proxy may not transport, or the public-risk burden may make the object unsafe to use. Each failure updates a different proposition and should be recorded separately.

Triangulation should compare proxies from genuinely different pathways rather than stack correlated versions of one signal. Biological, functional, cognitive, social, and material capacities may constrain different menus and time scales, and no biomarker may stand for the entire reserve state. Agreement is informative only when the channels do not share the same measurement error and causal role.

Test monotonicity: reserve may recover, fluctuate, compensate, or fall abruptly, while support can expand options and increase burden. Treat social and material resources as environmental pathways, distinct from personal biology or individual strength.

Severity, clinician expectations, treatment, observation, and endpoint processes can affect both reserve proxies and outcomes. Estimate reserve prospectively, then compare prognosis, frailty, and observation-selection explanations before drawing route conclusions.

The valid output may be an identified set rather than one number. When several reserve states remain compatible with the data, exponent, covariance, intervention, and terminal-window analyses propagate that uncertainty.

Retain failed or retired proxies and their affected analyses and artifacts in the version ledger. Reanalyze, narrow, or withdraw dependent results. Publish failure and retirement conditions before inspecting outcomes.

16.3 — Boundary Exponents and Reserve Dispersion

Boundary predictions are useful only when the coordinate system is declared. A process may contract as calendar time approaches an endpoint, as a reserve proxy approaches zero, or as an action set loses reachability. Those descriptions are related only under an explicit bridge. The section therefore separates the time-domain exponent from the reserve-domain exponent and treats both as route-specific consequences rather than properties of PTVC itself (Karatzas & Shreve, 1991).

The empirical target is conditional dispersion estimated from information available before the endpoint. A local power relation between reserve and remaining time yields a time-domain exponent only under an explicit reserve-time bridge, while measurement error, heterogeneous paths, smoothing, and selection can alter the apparent slope. The protocol should fix a multiscale window ladder, error floor, random-effects structure, and rival family before any log-log relation is interpreted.

Boundary exponents also interact with behavior. Delay sensitivity, priority reordering, risk pruning, repair initiation, and avoidance can change as filtered horizon and reserve change. The candidate's cross-equation restrictions ask whether the same frozen state predicts several outcomes without retuning.

Candidate scaling relations. Role: route-specific asymptotic restrictions under a declared endpoint clock, reserve bridge, and normalized-dispersion model; they are not consequences of PTVC alone (Karatzas & Shreve, 1991).

$$U_t \asymp c_U(T - t)^\beta, \text{Var}(Y_t|U_t, \mathcal{E}_t) \asymp c_Y(T - t)^\gamma$$

$$L_t^{rc} = c_{LU} U_t Y_t$$

$$Var(L_t^{rc} | U_t, \mathcal{E}_t) \asymp c_{LU}^2 c_U^2 c_Y (T - t)^{2\beta + \gamma}$$

$$\gamma = 0 \Rightarrow Var(L_t^{rc} | U_t, \mathcal{E}_t) \asymp (T - t)^{2\beta}$$

The final display is the special case, not the general rule. The time-domain exponent equals twice the reserve-decay exponent only when normalized conditional dispersion is locally stable, or when an independently justified argument supplies the same restriction. Measurement floors, smoothing, path heterogeneity, selection, or a changing dispersion exponent can all alter the observed slope. A shrinking variance curve therefore cannot be relabeled reserve-squared behavior by visual resemblance alone.

16.3.1 — Rising Delay Sensitivity and Boundary Rate

As filtered horizon contracts, delayed outcomes may lose motivational relevance because they fall outside perceived opportunity. Socioemotional selectivity is therefore an ordinary rival. The route-specific test asks whether unresolved state and independently estimated reserve contribute a protocol-fixed interaction beyond future-time perspective, prognosis, urgency, and scarcity (Carstensen, 2006).

Naturalistic observations broaden the horizon finding beyond imagined scenarios. Fung and Carstensen (2006) observed shifts toward emotionally meaningful goals around the September 11 attacks and the SARS outbreak. These settings couple time perspective to threat, social contact, and available resources, so their contribution is ecological convergence rather than randomized causal identification. The next useful comparison tracks those variables separately and asks whether a common,

prospectively fixed horizon-by-state relation transports across ordinary transitions such as relocation, retirement, and the completion of a voluntary project. Successful transport would give a candidate mechanism a substantive constraint to explain.

Perceived time can be studied separately from a frustrated goal. Fung and Carstensen (2004) compared social motivation under foreshortened time and blocked-goal conditions, finding different patterns in social preferences and reported goals. Their design tested alternatives to socioemotional selectivity theory rather than treating all constraints as equivalent. It offers a useful template for this chapter: measure perceived opportunity and current goals separately, then ask whether independently estimated experiential history improves predictions of subsequent choice.

The prediction can be written in a task as a change in the policy for delayed repair options. When h remaining steps are high, the system may choose information gathering or delayed high-value repair. When h is low, it may prefer immediate lower-value actions if they reduce an unresolved state before the menu closes.

This can be tested without terminal pressure. A task can vary remaining trials, delay to reward, reversibility, and cost while keeping all stakes minor. The outcome is choice probability, latency, confidence, post-choice affect, and physiological control load.

The ordinary rivals are strong. Time pressure, impatience, fatigue, scarcity, stress, and reward discounting can all increase sensitivity to delay. A horizon-specific result must show the predicted

interaction with filtered horizon and reserve, not merely a main effect of deadlines.

Shortening horizons need not compress every person toward the same policy. Some people become cautious, others exploratory, generous, rigid, automatic, or more attentive to meaning. Heterogeneity should be modeled through baseline policy, available menu, reserve, culture, task framing, and belief rather than treated as error around a universal response.

Delay sensitivity confined to tired, frightened, or externally pressured participants would point toward those conditions as explanatory factors. A horizon-specific account is tested through its additional predicted interactions with filtered horizon and reserve.

A good delay experiment should include catch conditions. Some delays should be irrelevant to outcome, some should threaten route loss, and some should consume reserve. If all delays produce the same response, the effect is not horizon-specific. If only route-threatening delays matter under short H_t , the candidate becomes more precise and more vulnerable.

Delay sensitivity should be measured against a baseline delay function. Some people are generally impatient; some are generally deliberative; some delay because access is difficult. The candidate pattern is a change in delay sensitivity as H_t and U_t change, not a stable trait. Within-person estimates and task counterbalancing are therefore central.

Scaling claims need two clocks. A reserve-space exponent describes how dispersion changes as candidate capacity U

approaches a boundary, while a time-domain exponent describes how dispersion changes as observed time approaches an independently defined endpoint. If $U(t)$ is approximately proportional to $(T - t)$ raised to a power β , then the simplest reserve-coupled diffusion yields a time-domain variance exponent of approximately 2β . That relation is conditional on the reserve map, diffusion specification, endpoint branch, and observation model. Reporting one exponent as though it were the other is a category error, not a harmless notation choice.
