The empirical design estimates the reserve map and boundary law separately across a prespecified ladder of scales. A nonlinear reserve-time relation can create apparent acceleration, while saturation, smoothing, and irregular observation can flatten or steepen it. Joint models estimate reserve-time mapping, process dispersion, and observation floor, then test whether the same exponent family transports across held-out windows.

16.3.2 — Priority Reordering and Drift Slope

Priority reordering means that the relative ordering of live demands changes as horizon and reserve change. A person may shift from long-range exploration toward emotionally meaningful contact, repair, communication, rest, or avoidance. The proposed route predicts a signed-state dependence that can be compared with ordinary horizon-driven goal selection (Carstensen, 2006).

A scientific model must specify the demand set. In a task, demands are explicit goals or penalties. In an observational study, demands may be coded from participant reports, scheduled

obligations, symptoms, unfinished tasks, or documented choices. Retrospective moral interpretation is not allowed.

The candidate prediction is not simply that important things become important. It is that the ordering changes as a function of filtered horizon, reserve, and menu constraints after controlling for baseline importance. A high-importance item may still fall if it is infeasible under low reserve.

Priority reordering can be visible in time allocation, task switching, communication attempts, search behavior, medication questions, social contact, or rest selection. Each channel has its own confounds. A phone call may reflect relationship repair, loneliness, practical logistics, family pressure, or habit.

Rivals include socioemotional selectivity, cognitive bandwidth under scarcity, fatigue-driven simplification, clinical urgency, and learned avoidance. These rivals are not hostile; they are the standard the candidate must exceed.

If reordering follows ordinary expected value, prognosis information, or social scripts with no reserve-queue interaction, the horizon-specific claim should be narrowed. The data may still teach something humane about burden under constraint.

Priority reordering should be evaluated as a trajectory. The order in which a person opens, postpones, abandons, or revisits demands may reveal more than the final action. A single endpoint choice can hide the labor of earlier attempts. Sequence models, not just outcome models, are needed if the program wants to see where burden moved.

A useful priority model may treat demands as a partially ordered set rather than a ranked list. Some tasks are incomparable: symptom relief, apology, legal deadline, last conversation, and rest may not fit a single ordering. The model should allow partial orders and ties, because forcing total order can manufacture precision and disrespect the structure of lived value.

16.3.3 — Risk Pruning and Dispersion Compression

A finite horizon may change tolerance for high-variance trajectories because it changes the time available to recover from setbacks or benefit from upside. The present candidate calls this risk and variance pruning when high-variance options leave the live menu or become less attractive. This proposed behavioral mechanism can be tested by measuring how choices change with represented opportunity, current condition, and recent experience. The clinical studies discussed nearby supply symptom and affect trajectories for that comparison (Seow et al., 2011; Vogel et al., 2013).

The prediction must be stated carefully. Some people under short horizons take more risks, not fewer. They may seek meaning, novelty, relief, or autonomy. Others become conservative because capacity is low. The model therefore predicts structured heterogeneity, not a universal shift.

The relevant variance can be reward variance, affective variance, physiological load variance, social outcome variance, or delay variance. A task must declare which variance it manipulates. Otherwise all risky options are treated as the same object.

Reserve is central. A high-reserve participant may tolerate a high-variance repair attempt because they can absorb failure. A low-reserve participant may prefer stable relief, rest, or small repair. The same horizon can produce different policies under different $U(t)$.

Rivals include loss aversion, anxiety, depression, clinical fatigue, socioeconomic scarcity, and ordinary finite-horizon expected utility. The candidate becomes interesting only if the variance-pruning pattern depends on the unresolved burden state rather than on generic risk preference.

The route-level claim fails in a setting when observed pruning is fully accounted for by baseline risk preference, disease severity, cognitive change, misunderstanding, or a reduced option set unrelated to reserve. The protocol should predeclare those comparators and retire the candidate interpretation when they explain the pattern under the same scoring rules.

Variance pruning also requires a recovery measure. A high-variance option is different when recovery is possible. In the task, the same loss can be paired with high or low reserve recovery. In field settings, recovery may come from rest, medication, support, money, or time. Without a recovery variable, the model cannot know whether risk was pruned because variance rose or because the cost of error became unrecoverable.

Risk pruning should also be compared with ambiguity aversion. A person may avoid an option not because the outcome variance is high, but because the probabilities are unknown or the institution cannot be trusted. The task should distinguish known

risk from ambiguous risk. In field settings, mistrust can be a rational response to prior burden, not a cognitive flaw.

16.3.4 — Accelerated Repair and State-Dependent Drift

Shrinking horizon may accelerate repair, but it may also accelerate avoidance. A person may attempt a difficult conversation, settle a task, forgive, plan, rest, withdraw, distract, or stop engaging. The protocol registers behavior categories and opportunity constraints before outcomes are known; it cannot preselect the noble-looking action as evidence for the route (Carstensen, 2006).

Direct repair is only one policy. Avoidance may be rational when repair is impossible, unsafe, coercive, or too costly. Blocking may protect a person from overload. Substitution may reduce a related burden when the original burden cannot be changed.

A task can distinguish repair and avoidance by offering actions that reduce a specific unresolved state, actions that suppress signals without resolving them, and actions that substitute a lower-cost route. Outcome measures can include choice, latency, post-action residual, and future reactivation.

The Law-specific prediction is conditional. If a burden is salient, repair is feasible, reserve is sufficient, and the horizon is shrinking, direct repair may rise. If reserve is low or repair has high risk, avoidance or substitution may rise instead. The hypothesis should state these branches before data are seen.

Clinical and ordinary-life interpretation must be humble. A person's apparent avoidance may be dignity, fatigue, privacy, trauma protection, communication difficulty, or refusal of

coercive meaning. Science can code behavior only within its evidence limits.

A repair hypothesis fails if it becomes a narrative that explains every action after the fact. If repair, avoidance, and no action all count as support, the prediction has no content.

This subsection should be interpreted through feasibility classes. A favorable repair signature exists only when repair is feasible, safe, and meaningful. A favorable avoidance signature exists only when avoidance is predicted under declared threat, cost, or low-probability repair conditions. Otherwise the model can explain both action and inaction too easily.

A paired design can make this test sharper. The same unresolved demand can be offered with a safe repair route, an unsafe repair route, a delayed route, and a substitute route. The candidate predicts different policies across those route types under changing horizon and reserve. If behavior does not differ by route feasibility, the repair-avoidance interpretation weakens.

16.3.5 — Reserve-Horizon Interaction

The core quantitative prediction is not a main effect of age or calendar time. It is a protocol-fixed interaction among filtered horizon, independently measured reserve, unresolved state, and the live action menu. A short horizon with high reserve may permit focused action; the same horizon with low reserve may yield rest, compression, or no observable response (Carstensen, 2006).

Emotional strengths can persist when circumstances become difficult. In 945 US adults aged 18–76 assessed during COVID-

19, older age was associated with better emotional experience even after measured risk and other covariates were considered (Carstensen et al., 2020). Sun and Sauter (2021) reproduced age advantages in 23,350 people across 63 countries, while their within-person Dutch comparison of 4,370 participants found that those advantages diminished during sustained pandemic stress. Together, these studies make context-dependent regulation a concrete research target. A reserve-horizon test should measure capacity, exposure, social support, and perceived opportunity independently, then compare a frozen interaction model with these established accounts. The empirical opportunity is to explain when resilience persists, when support changes the path, and which additional state variable improves prediction.

This interaction must be modeled within person where possible. Between-person comparisons can confuse reserve with personality, culture, resources, disability, education, and diagnosis. The strongest design observes the same person across changing horizon and reserve states.

A reserve-horizon interaction should have a protocol-fixed sign and measurement route for each task. For example, low reserve may increase the cost of high-effort repair, while short horizon increases the cost of delay. The model then predicts which action class becomes more likely.

The slope-two variance relation is conditional, not automatic. If the conditional variance of the normalized process changes with reserve, the exponent becomes an estimand rather than a fixed route consequence.

In behavioral tasks, the interaction can be tested through reserve manipulations that are safe and mild: cognitive load, time-on-task fatigue, rest breaks, or simulated capacity budgets. These manipulations must never create distress or deprivation.

If reserve does not interact with horizon after confounds are modeled, the candidate should narrow. The result may still support finite-horizon decision science, but not the reserve-coupled version of the Law-specific prediction.

The interaction should be tested in designs that manipulate or observe both dimensions independently. A task can shorten horizon while holding reserve constant, lower reserve cost while holding horizon constant, or vary both. Clinical studies cannot manipulate these states casually, but they can stratify, model natural variation, and test whether the same pattern appears under different reserve proxies.

The interaction can be visualized without overclaiming by plotting predicted choice under four quadrants: longer horizon with high reserve, longer horizon with low reserve, shorter horizon with high reserve, and shorter horizon with low reserve. The plot should be labeled simulated or estimated, not observed truth, and should always include rival curves when used in public artifacts.

16.3.6 — Nonmonotone and Heterogeneous Boundary Behavior

Boundary behavior need not be monotone, and participants need not approach a declared window through the same policy. Some trajectories may narrow gradually, others may oscillate, plateau,

reverse, or change abruptly after treatment, support, fatigue, or a new constraint. A model that permits only smooth compression can fail unfairly and can also rescue itself by averaging away the cases that contradict it.

Heterogeneity should be protocol-fixed as structure. Random effects, latent classes, mixture models, or person-specific parameters may be appropriate, but the choice should be tied to observables and tested in held-out data rather than discovered after the pooled curve disappoints. When heterogeneity cannot be predicted or interpreted, the report should widen uncertainty rather than invent a universal story.

Nonmonotone patterns can separate rivals. State-coupled control, fatigue, episodic treatment, selection, ordinary mean reversion, and endpoint-conditioned bridges imply different reversals, lags, and cross-channel signatures. The analysis should preserve individual and subgroup trajectories long enough to test those differences before summarizing them.

Mixture-induced closure is a serious alternative. A narrowing marginal distribution can arise because high-variance trajectories disappear from observation, different subgroups enter the window at different rates, or opposing local trends cancel. Component-specific and observation-process analyses are required before marginal compression is attributed to one route.

Exponent recovery is local and empirical windows are finite. A power law that is valid asymptotically may not be identifiable over the observed reserve or time range, and the reserve-space exponent is not automatically the time-domain exponent. The

reserve map, process variance, endpoint branch, and observation floor must be estimated jointly enough to show which quantity the data identify.

Irregular observation times and finite noise floors can create or flatten apparent scaling. The analysis should use the actual pair-availability and cadence structure, compare several protocol-fixed local windows, and test whether the estimate survives plausible deconvolution and calibration error. One log-log line is not a boundary law.

Candidate and rival models must be scored on the same windows, information, and missingness conditions. A result that appears only under a favorable bandwidth, after excluding reversals, or in one latent class chosen post hoc remains exploratory. Robust heterogeneity can strengthen a bounded route claim; unexplained heterogeneity should narrow it.

These trajectories describe a population, branch, and observation model; they do not prescribe how any person should feel or act near an endpoint. Nonmonotonicity is therefore both a methodological possibility and a safeguard against turning an aggregate pattern into an individual demand.

16.4 — Two-Time Covariance and Martingale Diagnostics

Marginal contraction is not a unique signature. Two processes can have the same mean and variance near an endpoint while carrying different dependence across time. The scientific leverage therefore lies in the joint law: covariance, conditional increments, quadratic variation, and how prediction errors behave when one interval is held out. These objects are demanding, but they are precisely where conditioned bridges, mean-reverting processes, and reserve-coupled routes cease to look interchangeable (Doob, 1957; Revuz & Yor, 1999).

Prospective two-time prediction must use information available at the earlier prediction time; a prespecified retrospective covariance estimand must be labeled by its actual information set. Retrospective alignment can create elegant covariance surfaces that no prospective observer could have constructed. The first display below is a candidate reserve-route covariance under its stated assumptions; the second is a Brownian-bridge rival. For this display, S_θ and $Y(S_\theta)$ are fixed, and, conditional on Ξ , U and σY are deterministic while W remains Brownian. Neither formula is evidence, and both must be evaluated under the same filtered information, endpoint uncertainty, and observation process (Andersen et al., 1993; Doob, 1957; Rizopoulos, 2012).

$$Y(t) = Y(S_\theta) + \int_{S_\theta}^t \sigma_Y(r) dW(r)$$

$$\tau_Y(t) := \int_{S_\theta}^t \sigma_Y^2(r) dr$$

$$\text{Cov}(L^{rc}(s), L^{rc}(t) \mid U, \mathcal{E}) = c_{LU}^2 U(s)U(t)\tau_Y(s), S^\theta < s \leq t$$

This is a candidate-route consequence under the stated branch, not PTVC evidence.

$$\text{Cov}(B_s, B_t) = \sigma^2 s \frac{T - t}{T}, s \leq t.$$

16.4.1 — Two-Time Covariance as a Route Signature

Two-time covariance asks how deviations at one time predict deviations at another. A route that merely shrinks marginal variance can still leave many possible dependence structures. A reserve-coupled arithmetic diffusion, a Brownian bridge, an Ornstein-Uhlenbeck process, and a hidden-state controller may all contract near a boundary, yet they need not agree on how early innovations persist, reverse, or disappear (Doob, 1957; Revuz & Yor, 1999).

The covariance object should be protocol-fixed before the surface is inspected. A primary option may be conditional covariance at two protocol times given a filtered reserve state; a secondary option may normalize by the protocol-fixed scale process. The normalization cannot be chosen after seeing which version looks most bridge-like (Doob, 1957; Durbin & Koopman, 2012).

Sampling cadence affects which time pairs are observed and how their covariance can be estimated. Sparse visits, selective pair availability, smoothing, and aggregation can distort the estimated dependence or change the observed quantity. Preserve raw timing, device versions, treatment changes, and uncertainty in the latent clock rather than treating a resampled grid as the original process.

Covariance also offers a cross-channel test. If the same route state is claimed to shape report, physiology, action, and endpoint hazard, the model should specify whether their innovations are independent, shared, or hierarchically coupled. A model that predicts each channel with an unrelated latent score has not established a common route; it has multiplied flexible explanations.

Strong rivals receive the same covariance target. A bridge model may reproduce endpoint contraction but imply a characteristic dependence on the fixed terminal boundary. A mean-reverting model may produce stationary or state-dependent correlation without terminal singularity. A frailty mixture may create long-range dependence through unobserved heterogeneity. The comparison must fit all of them through the same observation process and scoring rule.

Acceptance is conjunctive. The estimated surface must be recoverable in simulation, stable across plausible windows, predictive in held-out segments, and more compatible with the declared route than with serious rivals. A failed required recovery gate blocks the component; final verdict assignment follows §16.7.

In practice, the covariance surface should be estimated with uncertainty and tested out of sample. One route may predict long-memory residual dependence, another a triangular bridge kernel, and another near-Markov decay. The study should reserve held-out participant pairs or held-out time blocks for testing those shapes. Visual similarity is not enough. Proper scoring rules can compare predictive distributions for future pairs, while simulation

recovery checks whether the chosen design can distinguish the candidate kernels at the observed cadence and noise level (Gneiting & Raftery, 2007; Talts et al., 2018).

16.4.2 — Normalized Dependence Under Deterministic Reserve

Normalization can reveal whether shrinking scale and temporal dependence are governed by separate components. If reserve multiplies an arithmetic innovation process, dividing by a correctly specified reserve can expose a reference process whose dependence is easier to characterize. That move is legitimate only when reserve is independently estimated and the division does not amplify noise near zero (Andersen et al., 1993; Rizopoulos, 2012).

A deterministic-reserve approximation is a local model, not an assertion that human capacity follows a known clock. The approximation may be useful in controlled tasks or narrow clinical windows where reserve changes smoothly enough to estimate. Outside that context, stochastic reserve, treatment response, and abrupt state transitions should be represented rather than absorbed into residual error (Särkkä, 2013).

The normalized process should be tested for conditional mean, variance, autocorrelation, and tail behavior. A route that predicts driftless normalized innovations must say which filtration defines driftlessness and which observations are allowed into that filtration. If future endpoint information is required to make the residuals look martingale-like, the normalization has failed the prospective test.

Near-zero reserve is a numerical danger. Division can turn small calibration errors into large normalized excursions, making the process appear explosive even when the original observations are quiet. The protocol should define a reserve floor, a partial-identification region, and a rule for withholding normalized diagnostics when uncertainty exceeds the signal.

Normalization also creates a falsifier. If a single frozen transformation fails to stabilize scale across participants, sites, or windows, the deterministic-reserve route may be too rigid. Re-estimating a different reserve map for every cohort can improve fit while destroying transportability. The stronger test is whether one family of transformations survives held-out application.

If normalization removes the predicted scale while preserving the protocol-fixed dependence structure, it supports the specified route-level decomposition. The resulting coordinates allow more direct comparison of candidate and rival dynamics.

16.4.3 — Brownian-Bridge and Doob-Transform Rivals

Conditioned processes are among the strongest rivals because they can approach a boundary without positing an endogenous corrective controller. A Brownian bridge is the simplest example: conditioning a diffusion on a terminal value changes its drift so that paths are drawn toward the endpoint. That construction can imitate apparent closure while leaving a distinct covariance and singular drift structure (Doob, 1957; Karatzas & Shreve, 1991). Causal-process and predictive-scoring requirements enter the later comparison through Røysland (2011) and Gneiting and Raftery (2007).

A Doob transform generalizes the point. Conditioning on future events can produce lawful-looking pre-endpoint behavior even when the native process has no such drift. The scientific question is therefore not whether a fitted path looks guided. It is whether prospective data can distinguish native dynamics, state-coupled termination, selection, and post hoc conditioning.

The comparison must declare what is conditioned. A fixed terminal time, a random endpoint, a first-hitting event, an absorbing set, or a survival filter produces different laws. Treating all of them as one bridge rival makes the rival weak and the candidate artificially strong. Each branch should be simulated and scored under the same measurement and missingness model.

Covariance is especially informative because a fixed-time bridge has a known dependence on both observation times and the terminal time. A reserve-coupled route may instead factor scale through reserve and innovation time. Mixtures can blur the contrast, so the design should include heterogeneous endpoints and parameter distributions rather than comparing only idealized single-parameter examples.

Intervention response offers another distinction. Conditioning alone does not specify how a safe perturbation to support, information, or action availability should propagate. A causal route may predict a state update and changed future dependence. A purely conditioned bridge may fit the passive trajectory yet fail to transport under perturbation.

Rival victory is scientifically valuable. If bridge or selection models explain the held-out dependence with fewer assumptions

and equal or better calibration, the route claim narrows. The project should report that result plainly rather than preserving the favored model through metaphor.

16.4.4 — Martingale and Quadratic-Variation Diagnostics

Martingale diagnostics test whether conditional increments retain predictable drift after the declared state has been accounted for. They are attractive because they translate a verbal claim about innovation into a sequence of forecast errors. They are also easy to misuse: a transformed process may look driftless because the transformation was fitted on the same data or because endpoint information entered the filtration (Doob, 1957; Revuz & Yor, 1999).

Martingale diagnostics require a declared filtration, increment interval, predictable instruments, and sequential monitoring rule. Residual products can reveal unmodeled dependence, while e-processes or other time-uniform methods can control repeated looks without pretending that optional stopping is free. The evidential object is calibration across states and time scales, not one favorable p-value (Røysland, 2011; Ramdas et al., 2022).

Quadratic variation addresses innovation scale. In continuous-time models it can distinguish diffusion-like accumulation from smoother latent trajectories or jump-dominated dynamics. In sampled data, realized variation is contaminated by measurement error and irregular timing, so estimators must be matched to the sampling design and validated through simulation.

Jumps deserve explicit treatment. Medication changes, acute symptoms, device resets, awakenings, and care transitions can

produce discontinuities that a diffusion model will misread as extreme innovations. A jump-sensitive route may be scientifically appropriate, but it must specify whether jumps belong to the phenomenal process, the observation process, or the context process.

Martingale failure is route-specific. Predictable residual drift may indicate a missing state, a misspecified reserve proxy, an incorrect observation model, or a rival generator. The result should trigger diagnostic branching rather than a broad claim that the Law has failed or survived.

Qualification begins with known generators. The pipeline detects drift when present, controls false drift under calibrated martingales, and distinguishes jumps from noise. Passing those synthetic tests establishes which diagnostics can be interpreted in the empirical study.

A drift diagnostic and a covariance diagnostic answer different questions. A process can have approximately zero conditional mean increments while carrying route-specific conditional variance, and it can exhibit an apparent restoring drift because the sample is conditioned on a future boundary. The analysis should therefore test residual martingale properties after fitting each rival, then examine predictable quadratic variation, serial dependence, and innovation calibration. A failure in any one layer identifies where the model misses the process rather than licensing a vague verdict that the fit was poor.

Measurement noise complicates quadratic variation because high-frequency error can masquerade as process volatility.

Replicate channels, device validation, and cadence perturbations can help separate the two. If estimated variation rises without bound as sampling becomes finer, the model may be measuring sensor noise rather than phenomenal dynamics. If it collapses after smoothing, the smoothing rule may have erased real short-scale structure. Resolution invariance is therefore a diagnostic target, not an assumption.

16.4.5 — Survivor Conditioning and Pairwise Bias

Late-window covariance is observed among people who remain alive, enrolled, capable, and measurable at both times. That subset can differ sharply from the original cohort. Pairwise-complete covariance therefore mixes the target dynamics with survival, withdrawal, transfer, device tolerance, and clinical change (Andersen et al., 1993; Rizopoulos, 2012).

Conditioning on survival can induce associations even when none existed in the source population. Frailty variables that influence both measurement availability and affective trajectories create collider structures. The analysis should represent the risk set at each pair of times and state which population the covariance is intended to describe (Andersen et al., 1993; Hernán & Robins, 2020).

Weighting may recover a marginal target under strong assumptions about observation and survival. Joint models may instead connect longitudinal outcomes and event processes through shared random effects or latent states. Principal-stratum estimands can describe survivors under specified counterfactual

conditions. None of these methods is assumption-free, and their targets are not interchangeable.

Terminal observation shutdown is especially consequential. If distress, sedation, or loss of communication removes high-variance observations, the remaining data may appear to compress. Conversely, selective retention of complex cases may inflate late variance. Sensitivity analyses should include both directions rather than treating dropout as a one-sided nuisance.

Pairwise bias also affects cross-channel dependence. A physiological sensor may continue after self-report stops, while proxy reports enter only after capacity declines. Combining those channels without marking the transition can create an artificial covariance pattern. Observation marks and channel-specific risk sets belong in the model.

Partial identification or No adequate estimate may be appropriate when assumptions are weak. A result for a selected survivor population names that population and the conditions under which it was observed.

16.4.6 — Held-Out Dependence Recovery

A dependence signature should be judged by recovery, not by visual resemblance. Simulation must show that the proposed covariance, innovation, or martingale diagnostic can be recovered at the observed cadence, noise level, missingness pattern, and endpoint uncertainty, and that the same procedure does not routinely find the signature in rival-generated data.

Held-out tests should challenge the route at the level of the intended claim. Splits by participant, site, time block, endpoint

window, cohort, and device version reveal different dependencies, while random observation-level splits can leak adjacent measurements and shared preprocessing into both training and test sets. The easiest split should not determine the public verdict.

Joint prediction should be scored as a joint object. Proper scoring, calibration, and coverage should apply to the dependence structure rather than only to marginal means, and open-set cases should be included so the procedure can abstain when none of the protocol-fixed models is adequate (Gneiting & Raftery, 2007; Yao et al., 2018).

Parameter recovery and model recovery remain separate. A parameter may be estimated precisely within the wrong model, and the correct model family may be recognizable while its parameters remain weakly identified. The report should show both questions and the regions where the design cannot separate them (Talts et al., 2018; Wilson & Collins, 2019).

Adversarial simulations should be generated by the strongest ordinary rivals, including bridges, state-space mean reversion, frailty selection, treatment effects, and observation shutdown. Rival flexibility, lags, and calibration effort should match the candidate's budget. A weak rival is not a severe test.

Covariance should be inspected as a surface over time pairs, not collapsed immediately to one correlation. Irregular sampling requires pair-availability accounting, and survivor conditioning can change which pairs exist near the endpoint. A smooth surface

estimated from a changing risk set needs sensitivity analysis before it is read as a process law.

Martingale diagnostics belong to innovations after all protocol-fixed conditioning variables are included. Residual predictability may indicate a missing state, model misspecification, treatment, selection, or observation dependence rather than a special route. Cross-channel innovations can be especially useful because a route should specify which dependencies travel across reports, behavior, and physiology.

Successful recovery permits analysis of the real dependence pattern through the same frozen pipeline. Calibration, rival separation, and transport then determine how well the candidate performs.

16.5 — Terminal-Window and Intervention Signatures

A terminal-window signature is not a photograph of a final emotional state. It is a prospectively defined relation among trajectories, risks, interventions, and observation processes. Windows must be fixed by independent clinical or protocol information rather than by the point at which a preferred curve begins to look persuasive.

Interventions are included only when they are independently justified, low burden, and incapable of withholding care. The scientific objective is to perturb information, support, timing, or action availability in a way that distinguishes route predictions from ordinary learning and context effects. The protocol never induces distress to test a balancing story (World Medical Association, 2024).

16.5.1 — Prospectively Defined Terminal Windows

A terminal window is a protocol-fixed interval defined before the outcome trajectory is inspected. Its boundary must come from an independently governed protocol endpoint, a prospectively specified state transition, or another admissible event rule. The window is not the span in which a preferred curve happens to look most convincing, and it is not a photograph of a final feeling (Aalen et al., 2008).

Several clocks remain separate in the protocol: calendar time, time since enrollment, time to a protocol endpoint, disease or care-state time, and filtered subjective horizon. Each alignment defines a different estimand. A pattern that appears only after retrospective selection of one clock is an alignment finding, not a

terminal-window signature (Rizopoulos, 2012; Kurland et al., 2009).

Window boundaries use endpoint evidence independent of the candidate ledger or route estimator. The analysis distinguishes biological death, discharge, device removal, last report, treatment withdrawal, and protocol visits from the separately adjudicated stream endpoint. Uncertain endpoint status is propagated into the analysis (Fine & Gray, 1999).

Terminal-window analyses inherit the information-set rule from §13.5: filtering may support prospective claims; smoothing is retrospective and must be labeled as such. A prespecified smoothed reconstruction may be confirmatory for a retrospective estimand, not advertised as foresight.

Pseudo-endpoints and matched nonterminal cut points are candidate negative controls when the frozen route predicts no target signature there. The signature should weaken, disappear, or change in the specified way when trajectories are aligned to those events. Unexpected endpoints instead require a prospectively specified test of dependence on horizon awareness, with cause, acuity, care, and observation conditions addressed; unexpectedness alone does not make a genuine endpoint a negative control. If the same pattern appears around arbitrary salient events, the terminal interpretation loses specificity (Lipsitch et al., 2010; Hernán & Robins, 2020).

Observation intensity often changes as a window narrows. Clinical attention may increase, reports may decline, devices may be removed, sedation may alter channels, and family or staff

priorities may shift. The observation model must therefore estimate whether apparent compression, drift, or covariance change survives the changing opportunity to observe rather than treating the last visible measurements as representative of the unobserved remainder.

Prospective hospice research also documents emotionally meaningful experiences near life's end. Kerr et al. (2014) conducted 453 interviews with 59 patients; 52 reported at least one end-of-life dream or vision. Experiences featuring deceased people or animals were more comforting than other reported contents, and comforting experiences involving the deceased became more prevalent as death approached. These observations make internally generated, relationally meaningful experience a legitimate target for careful study. A participant-led observation module can record timing, comfort, sleep or wakefulness, medication, and report availability alongside usual care. This produces a richer account of late-window experience and the conditions associated with comfort.

Each window-specific estimand should state its reference class, clock, endpoint version, observation rule, treatment context, and uncertainty. Results from sudden endpoints, diffuse decline, reversible interruption, protocol censoring, and securely adjudicated terminal windows belong to different branches unless a declared bridge justifies combination. Pooling them for power can erase the very boundary distinction the study is meant to test.

A window chosen by inspecting the favored trajectory makes the evidence Unusable for the confirmatory claim. If no outcome-independent window can be defined, the target receives No

adequate estimate. The study may still report descriptive patterns, endpoint feasibility, observation loss, or rival-model performance. It may not turn an unstable boundary into evidence by choosing the interval after the result is known.

16.5.2 — Direct Repair and Support Perturbations

Direct repair is an action or support change that plausibly reduces a prospectively named unresolved state. In a bounded task, it may complete an unfinished goal; in a clinical or life-course study, it may address a reported symptom, communication barrier, practical need, conflict, or inaccessible option. The study must define the target before analysis so that almost any favorable action cannot be relabeled as repair afterward (Hernán & Robins, 2020).

A repair registry should state the burden element, the admissible action class, the expected time scale, the observable consequence, and the residual that may remain. Attempt and success are different variables. A failed repair attempt may reveal a closed menu, insufficient support, mistimed intervention, or an incorrect route prediction rather than absence of concern.

Support perturbations change information, access, safety, cost, reversibility, communication, or available time without inducing distress or withholding care. Examples include an accessible communication device, transportation, a trusted intermediary, schedule flexibility, symptom support, or a low-burden prompt that makes an existing option usable. Each perturbation must be independently justified and acceptable even if the Law-specific analysis were removed (World Medical Association, 2024).

Measurement should distinguish the offered support, actual uptake, action timing, task completion, immediate relief, later reactivation, and any burden shifted to another person or setting. A support that improves task completion but increases fatigue, family load, privacy loss, or clinical disruption cannot be summarized by one favorable outcome.

Feasibility is part of the causal object. Nonrepair cannot be interpreted as preference when access, speech, energy, safety, money, assistance, or time is missing. The model should represent which routes were live, which were blocked, and which became available only after support rather than hiding environmental constraints inside a personal reserve score.

The first human study should favor low-burden perturbations whose mechanism and stopping rules can be rehearsed in simulation. Any design that gains discrimination by delaying care, withholding rescue, provoking distress, or making support contingent on participation fails before enrollment. Lost data under humane stopping remain a limit on inference, not a reason to weaken the stop rule.

Serious rivals include ordinary goal completion, treatment response, social expectation, deadline effects, cognitive control, family pressure, and improved access. The route-specific account earns weight only when the protocol-fixed relation among filtered horizon, independently estimated reserve, unresolved state, support, and residual burden outperforms those alternatives under the same observation and scoring rules.

Direct repair supplies a concrete test of the candidate. The model specifies when change should occur and is compared with ordinary access and treatment mechanisms. Outcomes outside its prespecified relation lead to revision, narrowing, or retirement of the affected component.

16.5.3 — Substitution, Reframing, and Route Reordering

Substitution occurs when an unavailable or costly route is replaced by another action that changes a related state. Reframing changes the meaning, priority, or interpretation of a burden without necessarily changing the external event. Route reordering changes which live option is attempted first. These are distinct processes and should not be pooled merely because each can precede lower reported burden (Gerstorf et al., 2010; Vogel et al., 2013).

Substitution is not automatically lesser than direct repair. It can be adaptive, creative, evasive, socially supported, or temporarily protective. The analysis should ask what changed, including affective load, action cost, safety, future reactivation, physiological burden, and reported meaning, rather than assigning a moral rank to the route.

Reframing is difficult to identify because it may occur without visible action and may be reconstructed in later report. Experience sampling, language change, choice patterns, confidence, clinician observation, and delayed narrative can provide partial evidence, but none is transparent access to an inner transformation. Immediate and retrospective measures should remain separate.

Ordinary rivals include cognitive reappraisal, acceptance, therapy, religious coping, memory reconsolidation, social persuasion, and changing goals across a shortening future-time perspective. These mechanisms may explain the result better. A Law-specific route cannot absorb them by renaming every successful reinterpretation as completion pressure (Carstensen, 2006).

The protocol should predefine plausible substitution classes and the outcomes that would count against each one. An alternative route may repair the same target, partially repair a coupled target, provide only immediate relief, or merely distract. A classification that treats every alternative action as hidden repair has no adverse case and should not enter confirmatory analysis.

Route reordering requires a live-menu record. The study should know which actions were available, when they became feasible, what they cost, and whether support changed their order. A later choice cannot reveal that an earlier route was psychologically impossible, ethically inadmissible, or simply unavailable unless those constraints were measured independently.

Self-chosen reframing must be distinguished from pressured reinterpretation. A person may voluntarily find meaning, acceptance, or a new goal, while an institution may also demand positive meaning because actual repair is expensive or inconvenient. The former can reduce burden; the latter can transfer burden into silence. Consent, refusal, and context belong in the estimand.

The candidate route fails when substitution and reordering show no protocol-fixed relation to horizon, reserve, unresolved state, or menu change, or when ordinary rivals predict them equally well with fewer assumptions. The study may retain useful knowledge about adaptation and support while withdrawing the stronger route interpretation.

16.5.4 — Avoidance, Blocking, and Automaticity

Avoidance may protect a person from overload, danger, shame, trauma activation, coercion, or wasted effort. Blocking may keep an unresolved state outside the current control field, and automaticity may select a familiar route without extended deliberation. These action classes are not defects, and silence alone identifies none of them.

A shorter horizon does not always make repair urgent. It can make repair too slow, risky, costly, or emotionally expensive to attempt. Short-term avoidance may preserve capacity for a later safer route, while persistent avoidance may increase future reactivation. The model must represent time scale and feasibility before interpreting the same behavior as protection, habit, or unresolved burden.

Avoidance can be studied through skipped or delayed actions, task disengagement, topic shifts, physiological arousal without approach, later reactivation, and explicit refusal when available. These channels are not interchangeable. A route may be behaviorally avoided while remaining mentally active, or it may disappear from report because the observation itself became burdensome.

A bounded task can offer direct repair, substitution, neutral deferral, and avoidance options while varying horizon, information, cost, and support. Safety annotations should identify realistic danger, social exposure, sensory load, and clinical destabilization. When avoidance is the safer or more dignified option, the protocol must not treat lower approach as adverse evidence about the person.

Habit and automaticity are serious rivals. Familiar actions can dominate when deliberation is expensive, cues are strong, or reinforcement history is deep. Baseline habit strength, reaction time, perseveration, sensitivity to changed payoffs, and updating after route closure help distinguish automatic control from a newly reorganized priority structure.

Apply the modal distinctions defined in §§5.6.2 and 7.3.4. While positive mass remains on nonclosing continuations, stronger guidance or a more concentrated choice distribution does not establish fixed-policy probability-one completion.

The route narrows when ordinary urgency, habit, expected value of control, scarcity, fatigue, fear, or privacy explains the action pattern under equal rules. It also narrows when the feasible set cannot be identified without outcome-dependent reconstruction. A useful behavioral finding may remain, but the completion-specific interpretation should lose status.

16.5.5 — Social and Environmental Interventions

Menus are not only internal. Social and environmental support can open actions that would otherwise be closed. A communication device, a caregiver, transportation, accessible

design, medication support, or a trusted listener can change the live menu (Gerstorf et al., 2010; Vogel et al., 2013).

Late-life data also identify potentially helpful social conditions. In 2,910 deceased participants from the German Socio-Economic Panel followed for up to 27 years, social participation and valuing social goals were associated with higher late-life well-being, less pronounced terminal decline, and a later onset of decline after measured covariates were considered (Gerstorf et al., 2016). These associations provide a constructive complement to the accelerated terminal decline documented across national panels (Gerstorf et al., 2010). For this program, the useful target is whether changes in accessible support predict subsequent experience and action beyond health, care, and selection. Social participation is therefore a measurable correlate of the trajectory and a concrete focus for studying late-life connection.

Reserve is therefore not purely biological. The same bodily state can support very different action sets depending on environment. Strong support may preserve effective capacity despite low physical reserve, while isolation or poverty may sharply reduce the usable menu despite biological strength.

Support can therefore create or erase apparent queue pressure. An unresolved burden may remain invisible until someone makes a repair route possible. Conversely, social pressure can force a burden into view before the person is ready.

Social and environmental support should enter as a modifier of the available action menu. Communication access, assistance, relational safety, financial constraints, physical barriers, care

quality, and institutional rules change what actions are possible and costly. Treating those conditions as stable personal traits would mislocate the causal locus and conceal unequal option sets.

Rivals are especially strong here. Many horizon-like effects may be effects of social permission, resource availability, or family scripts. A person may act because support arrived, not because a latent queue intensified.

When environmental conditions restrict available options, the model represents those constraints explicitly. This helps distinguish social barriers from physiological capacity and identifies where changes in support could expand the available paths.

Code support as a menu intervention, not merely a covariate. It can reduce cost, increase safety, extend time, provide information, or absorb action burden. When support changes the feasible set, attribute that change to environment and person.

Formalize support as changes in cost, risk, information, or menu size, avoiding sentimental language. Rather than say support helps, specify reduced travel cost, increased route reliability, extended response time, lower risk, or a delegate action. This makes support measurable without making it mechanical.

Within a frozen route model, interventions that change time, capacity, information, cost, reversibility, or menu size may be summarized by a marginal-value diagnostic. The estimand is the local change in a declared model output when one constraint is relaxed; it is not a price on suffering, a measure of human worth, or a reason anyone should choose the model-preferred action.

Marginal-value diagnostics should be tested in simulation, reported with uncertainty, and compared with ordinary control and decision models before any human interpretation. Reader-facing copy should name the quantity that changed rather than rely on shadow-price language. If the diagnostic is unstable in simulation or adds nothing beyond established rivals, it should not enter a vulnerable-population study.

16.5.6 — Branch-Specific Failure and Residual Burden

Residual burden may persist despite action, support, reframing, substitution, or a nearby protocol endpoint. It should remain a potentially nonzero state rather than being forced toward closure, and persistence is never a defect in the person.

In bounded tasks it may appear through remaining penalty, report, conflict, reactivation, latency, or physiological load. These channels are not interchangeable; vector or set-valued representation is retained when scalarization would hide disagreement, and the measurement rule is fixed before intervention outcomes.

Persistence can falsify a route when it is independent of horizon, reserve, queue state, or the proposed control variable, or when an ordinary rival predicts it better. Operational completion such as discharge, compensation, or case closure likewise remains separate from experienced resolution.

Terminal-window analyses use fixed prospective distances, unexpected endpoints, and pseudo-endpoints. Safe intervention studies require positivity and cannot induce distress or withdraw

care; timing, treatment history, and observation marks address confounding by indication (Hernán & Robins, 2020; Pearl, 2009).

The strongest route result is conjunctive: ordered windows, survival against pseudo-endpoints, support-aware intervention response, stable calibration, adequate observation, and superiority to common-rule rivals. Failure updates the named branch and leaves the broader target unresolved absent a valid entailment.

16.6 — Compression Detectability and Observation Floors

Predicted compression is scientifically relevant only if the planned instruments and observation schedule can detect it. A process may contract below the scale of measurement, while an apparently sharp contraction may be created by sensor floors, smoothing, selective dropout, or the replacement of self-report by proxy channels. Detectability is therefore part of the estimand rather than an afterthought (Carroll et al., 2006; Little & Rubin, 2019).

The section distinguishes a scientific equivalence band from an observation floor. The former is a declared region of empirical compatibility for a measured target. The latter is the smallest pattern that the pipeline can resolve under noise, missingness, and calibration uncertainty. When the floor is wider than the band, a valid but undecided analysis yields Inconclusive evidence; No adequate estimate applies if the target cannot be identified or bounded.

16.6.1 — Additive Noise and Variance Floors

Additive measurement error contributes variance even when the latent process contracts. If the error variance remains approximately constant while the latent variance approaches zero, the observed curve flattens at the noise floor. A naive log-slope fit then underestimates the contraction exponent and can make distinct routes appear identical (Carroll et al., 2006; Little & Rubin, 2019).

The noise model should be estimated from replicate observations, calibration sessions, device comparisons, or validated measurement studies rather than inferred from the same late-window curve it is meant to correct. State-dependent error is especially important because fatigue, sedation, movement, and communication difficulty can change reliability near the endpoint (Carroll et al., 2006).

Correlated error creates a different problem. Shared preprocessing, common interviewer effects, device smoothing, and proxy-report substitution can generate apparent temporal dependence. The protocol should preserve channel provenance and estimate cross-channel error rather than treating multiple measures as independent confirmations.

A variance floor also interacts with participant heterogeneity. Some participants may remain measurable at high precision while others become effectively unobserved. Pooling them can produce a floor that is neither a property of the instrument nor the latent process. Hierarchical error models and participant-specific calibration are therefore preferable to one global correction.

Simulation should show how the proposed estimator behaves when the true exponent varies, when the floor is misestimated, and when the floor depends on state. The study should report the region in which exponent recovery is trustworthy and the region in which only bounds are available.

The contraction claim is unadjudicable when calibration uncertainty, structural error nonidentification, or inadequate statistical precision prevents the declared contrast from being

resolved. A latent variance smaller than the measurement-error variance is not, by itself, proof of nonidentification: an independently calibrated error model and sufficient suitable observations may still identify it. Report whether the limitation is structural or a finite-sample precision problem before deciding which design change could help.

Noise floors create asymmetric scientific risk. They can conceal real compression, but they can also manufacture a plateau that is later misdescribed as a finite neutrality band. Increasing sample size does not remove a systematic floor in the instrument. The study must estimate the floor from validation data, replicate channels, or controlled null periods and propagate its uncertainty into the boundary estimate. Errors-in-variables analysis is especially important because noise in both the residual and the reserve proxy can bias estimated exponents downward and distort their interaction (Carroll et al., 2006).

A useful report should include a detectability surface rather than a single power number. The surface varies the true exponent, baseline dispersion, cadence, dropout mechanism, device error, and endpoint uncertainty, then shows where the planned analysis recovers the correct branch and where it cannot. Regions of nonidentification should be visible before data collection. That honesty is more informative than a nominally powered design whose power applies only to an unrealistically clean process.

16.6.2 — Informative Observation Shutdown

Observation often ends for reasons related to the state being studied. A participant may stop responding because of fatigue,

distress, sedation, transfer, device intolerance, clinical deterioration, or a deliberate choice to protect privacy. Treating those endings as random can manufacture a smooth terminal pattern (Rizopoulos, 2012; Rubin, 1976).

Shutdown should be represented as a marked event with a time, reason, channel, and degree of certainty. The mark may indicate participant refusal, clinician stop, device removal, loss of capacity, technical failure, death, or administrative end. Each mark implies a different missingness mechanism and ethical meaning.

Joint longitudinal-event models can connect the outcome trajectory and shutdown hazard, while sensitivity analyses can vary the strength and direction of unobserved dependence. Pattern-mixture and selection models provide alternative parameterizations. No single model should be treated as a magical recovery device (Rizopoulos, 2012; Little & Rubin, 2019).

Proxy substitution requires a new observation model rather than a seamless continuation. Family and staff reports may capture behavior, distress, or function, but they are not direct replacements for first-person valence. The transition point and channel identity must remain visible in every analysis.

Shutdown can itself be informative without becoming evidence for PTVC. A rising probability of device removal may reveal burden, clinical change, or observation incompatibility. It may improve study design and care while simultaneously making the terminal signature unidentifiable.

The humane stop rule has priority. Investigators may not keep a device in place or continue prompting merely to reduce missingness. The study architecture must be capable of learning from refusal and shutdown, including the conclusion that the target cannot be estimated safely.

16.6.3 — End-to-End Detectability Simulation

Detectability should be evaluated through the entire pipeline, not through an isolated formula for statistical power. The simulation begins with a candidate or rival generator, then adds sampling cadence, channel-specific measurement error, treatment changes, endpoint uncertainty, observation marks, censoring, preprocessing, smoothing, estimation, and the final decision rule (Lakens, 2017; Talts et al., 2018).

Each component should be varied across a plausible design space. The study should include optimistic, central, and adverse scenarios for noise, missingness, event rate, reserve uncertainty, and endpoint spread. A design that works only under its most favorable assumptions is not ready for enrollment.

Simulation-based calibration tests whether the inferential procedure is calibrated when the model is correct. Model-recovery simulations test whether the procedure distinguishes candidate and rival generators. Both are needed because a computationally calibrated estimator can still be structurally non-discriminating (Talts et al., 2018; Wilson & Collins, 2019).

Open-set generators should include mixtures, abrupt jumps, nonlinear observation floors, site-specific protocols, and unmodeled treatment effects. The pipeline should be rewarded for

abstaining when none of the declared models is adequate. Forced classification is a public-risk failure because it converts ignorance into status.

Detectability maps are more useful than a single power number. They show which combinations of cadence, sample size, endpoint density, and signal scale yield adequate recovery. They can guide a staged program from low-burden feasibility to more demanding confirmatory work without exposing participants to a design that cannot learn.

The simulation archive should be frozen and versioned before real-data adjudication. Code changes, parameter-range changes, and bug fixes must be logged. A favorable real-data result cannot be used to redefine the region in which the pipeline was supposedly detectable.

Simulation scenarios should be organized as a factorial stress test rather than a single favorable world. The factors can include effect size, reserve-time relation, branch mixture, cadence, measurement floor, missing-not-at-random strength, endpoint error, and site heterogeneity. The output is a map of recovery, false route preference, no-adequate-estimate frequency, and reference-class narrowing. This map becomes part of the protocol's decision architecture, not an after-the-fact appendix.

The most informative simulations include near-equivalent models. If two routes are intentionally separated by only the amount the planned design claims it can detect, the recovery study shows whether that distinction is real. Failure to separate near neighbors is not a reason to hide them. It is a reason to narrow the

claim, collect more informative data, or choose a different first test.

16.6.4 — Deconvolution and Replicate-Channel Limits

Deconvolution attempts to separate latent variation from measurement error, but it depends on information about the error distribution. Without replicate channels, validation data, or structural assumptions, the decomposition may be unidentified. A smooth corrected curve can therefore reflect the analyst's prior more than the participant's trajectory (Carroll et al., 2006; Little & Rubin, 2019).

Replicate measurements help only when their errors are sufficiently independent or their dependence is modeled. Two instruments that share the same preprocessing, respondent, interviewer, or physiological artifact do not provide two independent views. The protocol should describe the causal pathways that create shared error.

Repeated reports can estimate short-term reliability, but repeated prompting may change the experience or the reporting strategy. The reliability study must therefore balance information against reactivity and burden. Calibration obtained in healthy participants may not transport to sedation, delirium, severe fatigue, or terminal illness.

Errors-in-variables methods, latent-variable models, and validation subsamples can narrow the problem. Partial-identification bounds may be more honest when the error law is uncertain. The choice among them should follow the scientific

question rather than the desire for a single corrected trajectory (Carroll et al., 2006).

Deconvolution becomes unstable near the boundary because small differences between observed and error variance can determine the entire latent estimate. Negative corrected variances, wide intervals, or sensitivity to minor calibration changes are signals to abstain rather than reasons to truncate estimates at zero.

Deconvolution results should be reported with the error model that makes them possible. Replicate channels can help identify noise structure, but they do not transform a latent reconstruction into direct observation. The conclusion should distinguish properties of the measured process from properties that remain conditional on channel independence, error stationarity, and the chosen observation kernel.

16.6.5 — Equivalence Bands Versus Instrument Resolution

An empirical equivalence band is a decision region for one measured estimand; instrument resolution is the smallest contrast the validated pipeline can distinguish. They are independent requirements. An equivalence conclusion requires a prospectively justified band, a valid analysis, and uncertainty sufficiently narrow to exclude both outside regions. Power is a design property; low power can leave a valid test inconclusive.

The margin is scientifically and ethically justified before outcome inspection. Its basis may be a validated measurement standard, clinically meaningful difference, or decision-theoretic loss. The declared decision determines the interpretation of practical equivalence.

Resolution should include more than nominal scale increments. Effective resolution depends on reliability, calibration drift, state-dependent error, missingness, and preprocessing. A one-point scale may have far worse effective resolution than its printed categories imply.

Equivalence analysis should include the two one-sided testing logic or another prospectively specified method appropriate to the estimand, together with sensitivity across plausible margins, calibration error, and missingness models. Nonsignificance is not equivalence, and equivalence under a wide margin does not resolve a narrower target. The report should show where the conclusion changes.

Finite-band compatibility supplies a measured result for route comparison, clinical description, or instrument development. The report specifies the target, band, and decision that the comparison addresses.

The public summary should name both numbers: the declared equivalence band and the validated observation floor. If the floor dominates, the correct conclusion is that the study could not resolve the target at the required scale.

Adjudication requires uncertainty in the declared estimand to be sufficiently narrow relative to the scientifically justified equivalence band. The error of one observation is not the same as uncertainty in an estimated mean, variance, or other model parameter. Additional suitable observations may improve precision under an identified error model; they cannot eliminate an unmodeled systematic bias or identify an unrestricted error

decomposition. Report the outcome through the verdict logic in §16.7 rather than treating an unresolved instrument floor as evidence for or against the route.

Sensitivity analysis should cross the equivalence band with plausible calibration errors and missingness scenarios. A conclusion that changes sign under a small, credible shift in the neutral origin is not robust. A conclusion that survives only after excluding difficult-to-observe windows is not a terminal finding. The final report should present a grid of verdicts across declared perturbations, making clear which conclusions are stable, which are model-dependent, and which remain unestimable.

16.6.6 — Abstention Thresholds

Apply the canonical evidence-state definitions in §24.2 and Table 27.5. This subsection specifies the terminal-window thresholds that trigger No adequate estimate, Unusable evidence, or Inconclusive evidence under those definitions (Lakens, 2017; Talts et al., 2018).

Triggers may include failed measurement qualification, endpoint leakage, unrecoverable model confusion, observation-floor dominance, excessive informative missingness, unstable calibration, insufficient event support, or a burden threshold that stops data collection. Each trigger should map to a specific component status.

The threshold is not the same as a null result. An informative near-zero result requires a qualified design and uncertainty narrow enough to support that conclusion. No adequate estimate says the study did not earn the right to make that comparison. Keeping

those categories separate prevents absence of evidence from becoming evidence of hidden closure.

Partial identification may sometimes replace total abstention. If assumptions support bounds that exclude some routes but not others, the report can narrow the model set without selecting a winner. The bounds and assumptions should be visible in the main result rather than buried in an appendix.

Public communication must resist pressure to fill the vacuum. A no-estimate result cannot be described as suggestive, mysterious, or consistent with an invisible exact law unless the same language is applied to every unidentifiable model. The protocol-fixed verdict should state the blocked gate and the next allowed action.

A program that can return No adequate estimate is stronger than one that always tells a story. It preserves the distinction between the world's complexity and the method's reach, and it protects participants from being turned into evidence by interpretive force.

16.7 — Common-Rule Rivals, Falsifiers, and Route Verdict

The final section applies one observation system, one preprocessing rule, and one scoring constitution to the candidate route and its strongest rivals. The same origin, endpoint, missingness model, reference class, and held-out partitions must govern every model.

Verdicts attach to components. Failure of a reserve exponent can retire the reserve route while leaving other PTVC routes open; failure of endpoint independence can move the program to a state-coupled branch; failure of representation or measured-to-latent transport can block the entire downstream analysis. The public record must preserve that dependency structure (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

16.7.1 — Common Observation Rules

A common-rule comparison begins before model fitting. The candidate route and every rival must receive the same observed channels, measurement versions, preprocessing rules, endpoint information, missingness treatment, and held-out partitions. A flexible candidate compared with rivals denied equivalent data is not a discriminating test (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

Representation and calibration are shared inputs rather than model-specific conveniences. The sign convention, neutral origin, unit, channel qualification, exposure clock, and uncertainty propagation must remain fixed across the tournament.

A model may not improve its fit by changing the construct it claims to explain.

Endpoint information is governed identically. If the candidate receives a filtered horizon while a rival receives only crude time to death, the comparison confounds mechanism with information. Prospective analyses use information available at the prediction time; retrospective smoothing is evaluated separately and cannot be fed back into the confirmatory state.

Observation and missingness rules are also common. Refusal, device failure, sedation, staff interruption, observation shutdown, and terminal truncation must enter each model through the same marked record or declared sensitivity family. A rival may not be penalized for missingness assumptions that the preferred route is allowed to hide.

Training, tuning, and complexity budgets should be auditable. Comparable cross-validation folds, prior or penalty budgets, stopping rules, hyperparameter searches, simulation scenarios, and calibration checks prevent a bespoke candidate from defeating deliberately rigid alternatives. Model recovery should be demonstrated before real-data ranking (Talts et al., 2018; Vehtari et al., 2017).

Candidate state variables such as queue, pressure, reserve, horizon, and admissible menu need provenance. The record should show whether each variable came from task state, report, clinical context, passive sensing, or a model-derived estimate, together with its time, uncertainty, and consent boundary.

Combining sources without provenance can make one model appear to possess information no rival was permitted to use.

Common rules support privacy minimization. When the comparison needs only activation status, feasibility, or timing, the study should not collect full narratives, dream content, family conflict, or unrestricted records. A variable definition that is too vague to limit collection is also too vague to support a fair model comparison.

The common-rule gate fails when any material difference in data access, endpoint leakage, preprocessing, tuning opportunity, or observation handling could explain the apparent winner. The result then returns design-inadequate or Unusable evidence for the affected comparison rather than route-favored. The tournament is credible only when the rules would remain acceptable if the rival won.

16.7.2 — Serious Rival Matrix

A serious rival matrix gives each alternative a mechanism, a domain in which it should fit well, a distinct prediction, and a legitimate victory route. It is not a list of names attached after the preferred model is built. The matrix is frozen before outcome inspection and updated only through a versioned, publicly visible change rule (Vehtari et al., 2017; Yao et al., 2018).

Ordinary finite-horizon and urgency models are first-line rivals. Perceived future time, scarcity, deadline pressure, fatigue, fear, and reduced planning depth can reorder behavior without any completion-specific state. These models should receive the same

horizon estimates, action menus, and contextual variables as the candidate route (Carstensen, 2006).

Regulatory rivals include mean reversion, homeostasis, allostasis, adaptation, and opponent dynamics. They can produce reduced variance, rebound, relief, and apparent return toward a baseline. The matrix should identify where their predicted time scale, channel dependence, and response to perturbation differ from the candidate conjunction.

Conditioned-path and endpoint-selection rivals can reproduce terminal concentration by construction or sampling. Brownian bridges, Doob-transformed processes, first-hitting selection, and retrospective alignment may fit a narrowing window without describing a natural completion mechanism. They must be evaluated under the same endpoint and no-look-ahead rules (Doob, 1957).

Clinical and observation rivals include frailty, medication, sedation, care intensification, survivor selection, device removal, reporting decline, and observation floors. These mechanisms can change both the latent trajectory and what remains visible. Joint longitudinal-event and marked-observation models should be allowed to win when they explain the pattern more completely (Rizopoulos, 2012; Kurland et al., 2009).

Control and learning rivals include habit, reinforcement history, expected value of control, avoidance learning, and rational privacy. Repeated or compressed action may reflect low-cost familiar policies rather than a newly activated completion route.

Baseline behavior and changed-payoff tests are therefore part of the rival specification.

The matrix should map each claimed pressure signature to its channel and time scale. Choice, latency, physiology, report, and route abandonment are different outcomes, and gradual drift, abrupt switching, oscillation, freezing, and collapse are different dynamics. A movement in one channel cannot be counted as generic confirmation of a prediction stated in another.

Equal treatment requires comparable flexibility and calibration. Rivals receive realistic observation models, relevant covariates, appropriate nonlinearities, and sufficient tuning to express their strongest known form. Absolute fit, calibration, held-out prediction, transport, and model recovery matter alongside relative score (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

Open-set inadequacy remains a required outcome. The candidate may score better than the protocol-fixed rivals while every model fails calibration, transport, or absolute predictive adequacy. That result means the present model set is inadequate, not that the best member has contacted the generating process.

A rival victory is a scientific contribution. It should identify the component explained, the evidence budget used, the candidate prediction displaced, and the scope that remains open. The matrix earns trust when the public report can state rival-favored as clearly as route-favored.

16.7.3 — Component-Level Falsifiers

A component-level falsifier is a predeclared result that removes or narrows one part of the route architecture without waiting for a verdict on the entire hypothesis. Each component should have a failure condition tied to its own object, measurement bridge, and rival set. A vague result that can be reinterpreted as support for another component is not a falsifier.

The horizon component fails when the filtered state cannot be estimated without future leakage, does not update coherently, lacks transport across prospectively specified windows, or adds no discriminating information beyond ordinary future-time perspective, prognosis, urgency, and scarcity. An unstable horizon may remain descriptive, but it cannot carry the route claim.

The reserve component fails when its proxies lack a common unit or declared measurement model, collapse into disease severity or prognosis, change meaning across sites, or add no held-out value once environmental support and treatment are represented. A reserve inferred from the residual it was built to explain is circular and receives no confirmatory status.

Boundary-rate and dispersion components fail when estimated exponents, drift restrictions, variance contraction, or reserve-horizon interactions do not survive alternative clocks, calibration versions, pseudo-endpoints, and ordinary regulatory rivals. A visually narrowing curve is insufficient when the protocol-fixed cross-equation restrictions do not hold.

Two-time and martingale components fail when covariance surfaces, innovations, quadratic variation, or dependence

diagnostics cannot be recovered in simulation, reverse under held-out intervals, or are matched by conditioned bridges and state-space rivals. First-moment movement cannot rescue a failed dependence prediction.

Terminal-window and intervention components are evaluated against prespecified windows, responses to unexpected endpoints, and models of treatment, support arrival, habit, and observation change. Each conclusion states the modality supported by its frozen policy and continuation analysis.

Detectability is itself a falsifiable prerequisite. If cadence, sensor error, missingness, sedation, response limits, or observation shutdown make the protocol-fixed signal unrecoverable at ethically acceptable burden, route the result through the canonical evidence-state rules in §24.2 and Table 27.5. The program does not manufacture power by increasing burden or relaxing the target after simulation.

Admissibility and ethical constraints are noncompensatory. The feasible action set must preserve the reason an option is unavailable, including time, capacity, information, danger, consent, and environmental access. When those constraints cannot be identified, or when the discriminating contrast would require harm, the component is blocked. These component results feed the frozen route-verdict logic that follows.

16.7.4 — Route Verdict Logic

A route verdict should be generated by a frozen decision table that links each prerequisite gate to the strongest language the evidence permits. Representation validity, neutral-origin stability, stream

and endpoint definition, observation coverage, measured-to-latent recovery, rival comparison, and held-out transport are noncompensatory. The table should identify the first gate that limits the claim, not only the model with the best score.

The protocol-fixed statuses include route-favored, rival-favored, model-ambiguous, open-set inadequate, No adequate estimate, reference-class narrowed, and route-failed. Each status has a trigger, proposition ceiling, and next action. Thresholds and labels remain fixed after the data reveal which branch is most favorable.

Route-favored requires the protocol-fixed conjunction to survive common measurement, endpoint, missingness, information-budget, and scoring rules against equal-budget rivals. One attractive exponent, covariance surface, intervention response, or terminal curve cannot compensate for failed or unidentified components.

Failure at an early gate cannot be compensated by later predictive performance. A model that predicts well with an unstable origin, an endpoint-leaking state, or an unrecoverable reserve proxy may be useful for another purpose, but it cannot carry the route proposition tested here.

Route and target-law verdicts remain separate. Failure of the reserve-coupled route can retire that mechanism while leaving PTVC unresolved; survival of a route-specific conjunction can favor the route in a declared reference class without establishing exact latent universality.

Every verdict should state the population, information set, measurement and endpoint versions, rival set, observation

assumptions, uncertainty, transport domain, and unresolved alternatives. A result outside those boundaries is a new question, not an automatic extension.

The public table should show the proposition updated, the evidence that survived, the first limiting gate, the approved status sentence, and the next scientific action. This makes narrowing, correction, replication, and retirement part of the result rather than decisions made after the narrative has formed.

16.7.5 — Public Status Labels

Every public phrase in this chapter needs a status label. Horizon may be a latent state, task manipulation, clinical belief proxy, or analogy. Reserve may be a candidate capacity construct, measured proxy, or formal variable. Queue may be a model state or illustration (Vehtari et al., 2017; Yao et al., 2018).

Status labels distinguish metaphor, measurement, task manipulation, clinical association, and identified mechanism. Keeping those roles explicit lets each contribution inform the next stage of research.

The labels also protect public communication. A social excerpt saying ‘queue pressure rises near the end’ would be unsafe unless it states the claim status, population, task, and rivals. Otherwise it invites the impression of a hidden controller.

A good status sentence is short and local. It says what is being claimed, from what evidence, under what model, and what it cannot imply. Local status should be exact enough to stand on its own.

Diagrams and tables need the same discipline. A flow from horizon to action is a candidate pathway, not evidence. A simulated trajectory is a design tool, not a finding. A fitted model is not a verdict until recovery and rival comparison are complete.

The language rule is simple enough to audit: no status, no authority. If a phrase sounds powerful but cannot say whether it is analogy, model, estimator, or result, it should not be used.

Status labels belong in captions and summaries as well as body prose. A table can overclaim through its title even when its cells are careful. Terms such as observed queue pressure, predicted horizon collapse, and reserve signature are permissible only when observed, modeled, simulated, filtered, retrospective, or exploratory status is attached to the exact object.

16.7.6 — Metaphor Retirement After Failure

Metaphors should be revised when they imply an unestablished mechanism, moral price, deserved suffering, or practical control over future rewards. A declared accounting metaphor may still explain the net remainder required by exact PTVC. Retiring a failed route removes its unsupported mechanism claim; it does not erase a conditional arithmetic consequence of the target (National Academies of Sciences, Engineering, and Medicine, 2019).

A term earns continued use only if its operational meaning, observable consequences, and failure conditions can be stated. It should be retired when it explains every outcome, cannot be distinguished from an ordinary rival, repeatedly creates moral misunderstanding, or has a clearer technical replacement.

Retirement may be audience-specific. Queue can remain inside a bounded task model while disappearing from captions and public summaries; a technical symbol can remain in an appendix while reader-facing copy uses a plainer noun. The distinction is between model utility and public authority, not between interesting and dull language. The audience-specific status should be recorded in the release registry so public materials cannot revive terminology intentionally confined to technical use.

Empirical failure also retires vocabulary. If queue pressure adds nothing beyond ordinary urgency, or reserve adds nothing beyond severity and prognosis, keeping the metaphor for intuition would continue to bias model construction. A failed route should lose both its status and the language that made it feel inevitable. Retired vocabulary should remain searchable in the audit so future authors can recognize the old concept even after reader-facing language changes.

Technical terms should identify their objects: filtered horizon, reserve proxy, admissible subset, unresolved state, marginal value, rival model, and failure condition. Public balance language can remain when its conditional net meaning is clear. Neither vocabulary establishes a personal forecast, moral obligation, or chosen future reward. Where a term has both a public and technical use, the chapter should preserve a stable mapping between them so simplified language cannot drift into a different claim.

Retirement should be recorded in the scientific decision and version ledger with the reason, permitted technical uses, prohibited public uses, dependent artifacts, and any approved

successor term. That record prevents later chapters or public materials from reviving discarded language without reopening the evidence. Successor terminology should not inherit favorable evidence automatically; it must show which formal object is unchanged and which interpretation has been revised.

The chapter's final test is whether each retained term points to an observable or formal object. Clear vocabulary gives experts a common basis for evaluation. Chapter 17 carries the resulting variables into longer records, where partial history, attrition, treatment, and observation are modeled directly. This object-level discipline makes later longitudinal tests easier to compare because a changed label cannot conceal a changed estimand.

Chapter 17 — Longitudinal and Life-Course Designs

Life-course science gains its value from following change in context. Lived records include answered and missed prompts, visits, treatment changes, device transitions, sleep fragments, transfers, consent changes, and family boundaries. A credible design preserves that uneven visibility so the resulting trajectory reflects both experience-related observations and the conditions under which they were obtained.

The value of long follow-up depends on how observations are obtained. Diaries have entry dates; devices have nonwear periods and firmware changes; follow-up may end through withdrawal, transfer, clinical decline, or death. Representing these processes gives an extended record its scientific meaning (Shiffman et al., 2008; Hernán & Robins, 2020; Little & Rubin, 2019).

Longitudinal design is where momentary measures either become interpretable trajectories or an archive of observation bias. Sampling opportunities, alignment, missingness, visit intensity, device version, site context, treatment, transport, and purpose are therefore part of the estimand and data-generating process. They cannot be relegated to clerical metadata after the curve is drawn.

The chapter protects the scale of inference. A study may estimate change within a terminal, treatment, grief, sleep-recovery, or post-diagnosis window; it may not silently reconstruct the complete ledger from the first conscious moment to the truth-level endpoint. Unknown prior history remains an initial-state identified set or sensitivity problem, not a blank that a smoother can fill.

Design follows the estimand. Within-person change, between-person difference, event response, treatment effect, forecast, transport, and pressure on a PTVC component require different eligibility rules, clocks, observation plans, and estimators. Experience sampling, passive sensing, clinical cohorts, natural experiments, target-trial emulation, N-of-1 designs, accelerated longitudinal studies, and cohort-sequential follow-up are selected only after that target is fixed.

Within-person and between-person results can differ in direction, magnitude, and mechanism. Analyses must therefore state the process, stationarity and recurrence assumptions, and limiting claim while keeping person-specific dynamics, population distributions, time averages, and ensemble averages distinct.

The first protocol, sleep designs, and reserve-horizon tests supply concrete component targets; longitudinal research asks how those targets change when follow-up extends across ordinary life. A prompt is both measurement and interruption, a device both sensor and social object, a clinic visit both care and observation, and a record both evidence source and permission boundary.

The chapter names the models needed to keep these distinctions visible, including continuous-time processes, dynamic structural equation models, Gaussian processes, functional data analysis, state-space and hidden-state models, landmarking, joint longitudinal-event models, and target-trial emulation. Its purpose is not to reteach every estimator. It is to match each question to a design, expose the assumptions that identify it, and show where a wrong design reverses or invents the result.

Longitudinal data are morally delicate because they follow people across changing vulnerability. Records can reveal pain, fear, medication, fatigue, family pressure, sleep, recovery, refusal, and location. Purpose limitation, minimization, participant challenge, secure or federated computation, withdrawal propagation, retention limits, and governed result return are therefore scientific design conditions, not downstream privacy decoration.

The technical objects in this chapter are design aids, observation models, diagnostics, and governance structures. Their purpose is to show what the study can estimate and which dependencies can overturn the result. None converts a partial record into a complete life, and no graph, formula, or data architecture acquires evidentiary authority by appearing precise.

The governing question is strict: when evidence arrives through moments, devices, visits, records, and attrition, what can science responsibly infer about a lived trajectory? The answer is a hierarchy of designs, clocks, observation models, calibration bridges, causal and predictive estimands, transport rules, and governance boundaries. Each level states what it learns and what would make the estimate unusable.

The chapter examines how longitudinal inference develops with longer follow-up. Its models represent prior history, irregular observation, state-dependent missingness, competing events, treatment changes, device and response drift, cultural translation, privacy, and transport across sites. These features determine the population and questions each result can address.

17.1 — From Moments to Life-Course Inference

Repeated diary entries, wearable readings, pain ratings, and clinical notes can inform a life-course process when the design specifies how those observations connect to its estimand. That specification guides which moments are collected and how they are analyzed (Shiffman et al., 2008; Bolger & Laurenceau, 2013).

For *The Science of Fairness*, longitudinal evidence is useful because the formal target concerns a stream. Yet the empirical record is always local. The scientific burden is to move from momentary estimates to cautious trajectory claims without converting gaps into invisible data.

Emotional development already provides an encouraging empirical starting point. Carstensen et al. (2011) sampled feelings five times daily for a week and repeated the procedure approximately five and ten years later; the three waves included 184, 191, and 178 adults. Greater age was associated with more positive and stable emotional experience and greater coexistence of positive and negative emotions. This gives the life-course program an observed pattern of affective organization to explain, extending beyond a static questionnaire snapshot. The appropriate comparison is among models of regulation, goals, context, selection, and development. The repeated observations show that increasing age can accompany meaningful emotional gains. Repeated sampling also separates the frequency, persistence, and co-occurrence of feelings within persons, providing a practical design for following major life transitions.

The design table below is a routing device, not a ranking. A design that is poor for reconstructing whole-life history may be excellent for lagged within-person dynamics. A design that helps transport across age groups may be weak for acute event response.

Table 17.1. Longitudinal design families and inferential roles.

Design family	Best question	Key strength	Main artifact	What it can update
Intensive longitudinal or ESM	How does this person change across hours or days?	Captures lag, recovery, cycles, context.	Prompt reactivity, fatigue, short windows.	Within-person dynamics and pilot feasibility.
Cohort-sequential	How do age, period, and cohort differ?	Adds overlapping age and cohort observations; separating age, period, and cohort effects still requires identifying assumptions.	Cohort confounding, invariance.	Life-stage transport and broad patterns.
Accelerated longitudinal	Can overlapping windows approximate longer development?	Reduces wait while preserving age coverage.	Assumes linkable segments.	Long-horizon bounds under linking assumptions.

Design family	Best question	Key strength	Main artifact	What it can update
Event-based or case-crossover	What changes around a specified event?	Controls stable person characteristics.	Anticipation, carryover, event timing.	Local event response and transient signatures.
N-of-1 or idiographic	What is the process law for one stream?	Centers person-specific dynamics.	Limited transport, high burden.	Individual process hypotheses.
Clinical cohort	How do trajectories change under care?	Ethically available repeated measures.	Care confounding, death truncation.	Clinical component tests.
Registry-linked	What do long institutional records reveal?	Scale, duration, event history.	Consent boundaries, coding drift.	Background rates and transport checks.

Within-between decomposition. Role: diagnostic for separating person-specific change from cross-person association; it is not a latent-ledger estimator or a score of any participant.

$$y_{it} = \alpha_i + \beta_W(x_{it} - \bar{x}_i) + \beta_B\bar{x}_i + \varepsilon_{it}$$

Here the within-person coefficient estimates how departures from a person's own usual value relate to that person's outcome, while the between-person coefficient estimates how people with higher usual values differ from people with lower usual values. The two coefficients can differ or reverse. Reporting only one slope can therefore hide the level at which the relation actually lives.

Recovery is a measurable possibility with more than one trajectory. In a prospective bereavement study, 205 people were assessed before spousal loss and at six and eighteen months afterward; the largest classified group, 45.9%, maintained comparatively low depressive symptoms, while other groups showed recovery or persistent distress (Bonanno et al., 2002). This finding gives an evidence-based reason to investigate resilience without asking every bereaved person to follow the same timetable.

Disability research further improves the question by separating degrees and kinds of adaptation. Oswald and Powdthavee (2008) estimated partial recovery in mental well-being, with illustrative estimates of approximately 30–50% depending on severity. Lucas (2007b) found substantial lasting changes in two disability-onset samples. More recently, Köhler and Vanhoutte (2024) distinguished transient from persistent functional limitations in European longitudinal data: recovery toward initial well-being was clearer after transient limitations, and the pattern differed across depressive symptoms, life satisfaction, and quality of life. Together these results support an ambitious, humane target: identify which resources and mechanisms sustain or restore well-being, while modeling persistent trajectories explicitly.

Table 17.2. Analysis plans by inferential target.

Plan	Primary target	Minimum cadence or design need	Validation that matters
Idiographic	One stream's dynamics	Enough repeated points for person-specific lag and volatility	Forward chaining within that person
Hierarchical	Shared and person-specific dynamics	Repeated measures across persons with comparable constructs	Leave-person-out and calibration checks
Transport	Generalization from source to target	Bridge variables, overlap samples, target definition	Leave-site-out, target-site calibration
Federated	Multi-site learning without pooling records	Common dictionary, local feature extraction, disclosure checks	Site-level reproducibility and audit logs

17.1.1 — Intensive Longitudinal Targets

An intensive longitudinal design begins with a process that lives within a person, not with a population curve. The protocol must name the variable, clock, lag structure, and decision it seeks to estimate, then preserve enough person-specific history to distinguish change from stable between-person differences. Repeated observations are valuable because they expose temporal order and recovery, not because their quantity automatically

converts them into a life-course law (Shiffman et al., 2008; Stone et al., 2007).

The analysis file should retain person-specific deviations from usual sleep, pain, repair, activity, and momentary valence estimates. Those fields separate lived change from changes in observation, version, care, and participation while preserving a reconstructable audit trail.

Imagine an evening prompt series in which one caregiver's sleep loss reliably precedes next-day distress, while the cross-sectional group average suggests no association. That divergence is scientifically informative. It shows why the analysis must preserve the individual's temporal sequence before pooling, and why the group result cannot be used to overwrite a process that occurs within one stream.

The most credible alternative is that between-person averages, prompt fatigue, and observation timing can reverse the apparent direction. If protocol-fixed comparisons favor that account, report the result at the level actually identified rather than as Law-specific support.

Evaluation should begin by forecasting later points within the same person before asking whether a population model generalizes. Blocked time folds and leave-person-out tests answer different questions, and both should be named. The design fails its own purpose if neighboring moments from the same person leak into the test set and make prediction look stronger than it is.

The within-person estimand must be frozen before smoothing, subgroup analysis, or population pooling begins. The data

structure should show which observations belong to the same stream, which lags were available at each prediction time, and which summaries are allowed to cross people. When those choices cannot be stabilized, the output remains descriptive or receives No adequate estimate rather than being promoted into a general trajectory.

A substantial starting resource is already available. The July 2026 openESM journal article describes 60 openly available experience-sampling datasets with more than 16,000 participants and more than 740,000 observations, accessible through searchable metadata and R or Python tools. Its authors' analysis of 39 datasets found a pooled within-person concurrent correlation of -0.49 between positive and negative affect (95% CI $[-0.54, -0.42]$) (Siepe et al., 2026). That result supplies a reproducible description of how positive and negative affect co-occur within persons.

For PTVC component research, select eligible datasets by timestamps, cadence, scale content, available context, and access conditions before examining the intended outcomes. Use one set for measurement and model development, then freeze the analysis before testing whole held-out studies. Study-specific scale meanings and timestamps guide the measurement model. The first deliverables can be replicated within-person dynamics and a shared benchmark that identifies which additional observations best distinguish the candidate routes.

17.1.2 — Sparse Windows and Unobserved Time

Repeated points reveal windows, not the path between them. The inferential problem is therefore to state what regularity, smoothness, or state-space assumptions are needed to connect those windows and how strongly the conclusion depends on them. Sparse designs can answer important questions, but only at resolutions supported by their cadence and by assumptions that remain visible to the reader (Bolger & Laurenceau, 2013; Little & Rubin, 2019).

The longitudinal record must include sampling intervals, smoothness assumptions, bandwidth, aliasing, and worst-case error. Their joint presence makes it possible to locate drift instead of absorbing it into the target trajectory.

A quarterly clinic series may miss a two-week medication crisis and still produce a visually persuasive recovery curve. The appropriate response is not to distrust every sparse record, but to represent the unseen interval explicitly through alternative smoothness classes, worst-case bounds, and interval holdouts. Uncertainty should widen where the person was not observed, even when the fitted line would prefer continuity.

A serious competing account is that sparse points can manufacture a continuous ledger by interpolation. A win for this rival is informative: the conclusion must then narrow to the measured component or be reported as a measurement finding.

Evaluation should hold out whole intervals rather than isolated observations. A model that predicts the next visible clinic point after seeing adjacent points has not shown that it recovered the

unseen path between them. The test should ask whether the assumed smoothness can survive the gaps it claims to bridge.

Interval contributions are reported only at the resolution supported by the sampling schedule and the prospectively specified regularity class. When multiple admissible paths through the same gap imply different signs, peaks, or cumulative contributions, that disagreement belongs in the identified set. No interpolation method may turn an undersampled interval into a known episode merely because the estimate is smooth.

Sparse designs are valuable when their regularity assumptions and observation limits remain explicit. They can report ranges for interval contributions, compare admissible paths through gaps, and show which additional observations would most improve the next study.

17.1.3 — Unknown Prior History

Enrollment creates an initial-state problem. A study that starts in late illness, after diagnosis, or during a treatment transition observes an increment from that point forward; it does not observe the cumulative state carried into enrollment. The protocol must decide whether it estimates post-entry change, bounds a compatible initial state, or requires a longer design, and the distinction must survive into the headline result (Hernán & Robins, 2020; Gerstorf et al., 2013).

A credible analysis must carry the initial latent state and the post-enrollment increment as separate objects, with the initial state retained as an identified set rather than silently fixed. Together they reveal whether the estimate tracks within-stream change,

between-person contrast, transport, clinical process, or sampling artifact.

Observable-window identity. Role: bookkeeping definition for delayed entry; it cannot identify the unobserved prefix or convert a late-window study into a whole-life estimate.

$$L_i(T) = L_i(t_0) + \Delta L_i(t_0, T)$$
$$\Delta L_i(t_0, T) = \int_{t_0}^T g_i(s) F_i(s) ds$$

Under its measurement model, a study beginning at enrollment estimates the post-enrollment increment. Combining that increment with an independently known or bounded initial ledger state yields the corresponding estimate or bounds for the cumulative state.

The leading rival here is that late-window evidence has been mistaken for whole-life reconstruction. When held-out checks favor that account, the conclusion contracts to the observed window and identifies the missing initial-state bridge; no rhetorical continuity may restore the larger claim.

Evaluation should preserve the initial-state uncertainty rather than hiding it in a fitted intercept. Leave-window-out checks and alternative prior bounds should show how much the conclusion depends on the unobserved past. If plausible initial states change the verdict, the study reports a window claim rather than a life claim.

Design classes should be separated before analysis: increment studies estimate change after entry, bounding studies carry a set of compatible prior states, and long-horizon studies attempt

broader coverage under stronger retention demands. If plausible initial states reverse the conclusion, the result is a window-dependent finding. More observations after enrollment cannot identify a history that was never observed.

This is the chapter's first hard boundary: a late window is not a whole life. It may constrain possible histories, estimate a visible increment, or motivate longer enrollment, but it does not erase the unknown initial state. The notation keeps that humility alive after the graph begins to look complete.

17.1.4 — Event-Time Alignment

Event-time alignment changes the scientific question. Calendar time, age, diagnosis time, treatment time, enrollment time, and time before death produce different risk sets and different conditioning. The unwarped timestamps must therefore remain available, and every aligned display should be treated as a transformation whose assumptions can be tested rather than as a neutral way to organize the page (Shiffman et al., 2008; Stone et al., 2007).

The study record needs death-alignment simulations, dynamic time-warping checks, and sensitivity to clock choice. Without them, a smooth trajectory can conceal a change in who was observed, how they were measured, or what population the estimate represents.

Backward alignment to death can create apparent convergence when the cohort increasingly consists of people with gradual, observable declines. Sudden deaths, early transfers, rapid loss of communication, and short enrollments may disappear from the

later portions of the curve. A death-aligned pattern must therefore be shown beside its changing risk set and beside alternative clocks that do not condition on the same future event.

A signature is alignment-sensitive when its direction or magnitude changes materially across prospectively allowed clocks. Such a result is not discarded, but it is classified correctly: it may describe how trajectories look relative to a chosen event without identifying a common native dynamic. The protocol should make that branch explicit rather than allowing one visually compelling alignment to carry the route verdict.

The analysis file should preserve original timestamps, the rule that generated each transformed clock, the population remaining at every aligned time, and sensitivity results under competing clocks. If the clock choice remains decision-critical, the public result should say so. Alignment is part of the estimand, not a formatting preference.

17.1.5 — Local Versus Whole-Life Claims

A local window can test local dynamics, route-specific components, and observation behavior without answering a complete-stream question. The protocol should name the beginning and end of the observed domain, the unobserved history it leaves outside, and the exact bridge required for any broader interpretation. Length of follow-up does not erase the boundary between a measured window and a whole life (Bolger & Laurenceau, 2013; Little & Rubin, 2019).

Model choice follows the scope of the claim. Fast local change may require dense sampling and short lags; transport requires

bridge variables and a declared target population; terminal-window inference requires endpoint and observation models; whole-stream language requires an independently justified initial-state and completion bridge. These are different analyses, not levels of confidence in one interchangeable result.

A final-month study may estimate variance, dependence, or intervention response during that month with considerable precision while remaining silent about childhood, adulthood, or earlier illness. That silence is not a defect. It is the accurate boundary of the design, and it allows the local result to matter without being inflated into a claim about the complete ledger.

A pipeline fails this boundary test when it declares a decisive whole-life conclusion from synthetic cohorts whose observed late windows are identical but whose unobserved initial states imply different truth-level conclusions. The negative control preserves the same cadence and terminal window while varying those hidden prior states. A valid analysis may return the same abstention across those observationally identical records; the failure is a decisive whole-life verdict that ignores this nonidentification.

The recovery suite varies hidden initial residuals across sign and magnitude while holding the visible late window and observation cadence fixed; hidden generator values are retained for evaluation, not supplied to the fitted procedure. A separate sensitivity analysis varies declared initial-state assumptions or bounds and records how conditional conclusions change. Together, these checks show whether the pipeline respects

unknown history without mistaking invariant, justified abstention for failure.

Every result should carry the domain it actually covers: momentary, interval, treatment-window, terminal-window, or complete-stream. Clearly bounded scope makes each finding answerable and usable in subsequent work.

Local questions can make substantial contributions: whether terminal-window variance changes, prompts alter a trajectory, or a medication transition shifts reports. Each result supplies a defined component for subsequent research.

17.1.6 — Transport Across Life Stages

Using the same questionnaire, sensor, or model across life stages does not establish transport. Development, aging, disability, illness, communication mode, culture, and care setting can alter item meaning, response burden, physiological baselines, and the relation between an auxiliary channel and lived experience. A transported estimate therefore requires evidence that the construct, origin, sign, unit, and measurement map remain adequate for the stated purpose (Hernán & Robins, 2020; Gerstorf et al., 2013).

Cohort-sequential and accelerated longitudinal designs can create overlap among ages or disease stages, but the overlap must contain common anchors and enough heterogeneity to test the link. A model trained in one stage should be challenged in another without silent recalibration after the result is known. If a new stage requires a new scale, the study has produced a new local claim rather than transported the old one.

Language and mode can change meaning even when wording appears simple. Cognitive interviews, bridge samples, assisted-communication records, mode-specific calibration, and participant debriefs help distinguish sincere response change from a failed linking assumption. These are inferential requirements, not accommodations outside the science.

Predictive portability is weaker than construct transport. A model may preserve rank while losing a neutral origin, interval unit, sign interpretation, or causal meaning. Reports should state which property traveled and withdraw any interpretation that depends on a bridge the data did not support.

Longitudinal designs carry distinct clocks for age, calendar, disease, treatment, enrollment, adjudicated events, and perceived horizon. Declare a primary clock and use others as covariates, realignments, or sensitivity structures. An unnamed blend can create a trajectory with no coherent estimand.

When an observational cohort emulates intervention, first define the target trial: eligibility, strategies, assignment time, follow-up, outcome, contrast, and analysis. Emulation clarifies timing and avoids preventable bias but cannot create exchangeability or recover unmeasured indications (Hernán & Robins, 2020). A clear target-trial specification also exposes which quantities remain unidentified from the observational data before causal estimates are computed.

Time-varying treatment, health status, observation, and prior experience can affect one another. Ordinary adjustment may block the pathway or create bias, so use causal language only

when temporal ordering and assumptions support it. Descriptive life-course work remains valuable otherwise. Sensitivity analyses should distinguish unmeasured confounding from measurement error and informative observation, since each requires a different repair.

Transport requires prospective overlap, common anchors, bridge evidence, mode and language records, held-out target-population performance, and a stopping point. A result may stop at a life-stage or care-setting boundary without diminishing the dignity or scientific importance of those outside it. Stopping transport at a justified boundary creates a concrete next study: test the missing bridge rather than simply enlarge the original sample.

17.2 — Active Reports and Experience Sampling

Active reporting is the closest longitudinal method to lived testimony, but closeness does not make it simple. A person answering a prompt reports from within a moment, yet the prompt itself consumes attention and may change what is being reported (Shiffman et al., 2008; Trull & Ebner-Priemer, 2020).

Experience sampling is not a moral request to confess. It is a bounded research method for estimating time-near experience with stated uncertainty. The participant should know how nonresponse, pause, and burden are treated.

The cost of being asked counts. A study of hidden burden that ignores prompt burden has already contradicted its object. Cadence should be justified by the timescale needed for the estimand, not by the researcher's appetite for dense data.

17.2.1 — Prompt Content and Cadence

Contemporary ecological momentary assessment illustrates the value of within-person, age-sensitive measurement. A 2025 study of young, middle-aged, and older adults combined repeated daily reports with an implicit measure of valence representation. Its comparison identifies age and implicit-explicit disagreement as measurement features worth examining directly (Nigam & Kar, 2025; Shiffman et al., 2008; Trull & Ebner-Priemer, 2020).

Prompt content and cadence are part of the estimand because each question selects a time scale, a comparison frame, and a burden on attention. The protocol should first decide whether it needs rapid transitions, daily summaries, event-triggered reports, or

slower adaptation, then choose the least intrusive schedule capable of resolving that process. Sampling density is justified by discriminating value, not by the availability of a phone.

A clinically grounded starting point already exists. Geeraerts et al. (2024) developed and content-validated the ESM-AC questionnaire with forty-three people living with advanced breast or lung cancer and eight health-care professionals. Its digital core contains thirty-one momentary, two morning, and seven evening items; ten participants in the usability round gave ease of use a mean rating of 4.5 out of 5. This work shows how patient input can turn intensive measurement into a practical, context-sensitive instrument. A PTVC-linked pilot could build on that development process while separately testing sampling burden, temporal validity, and the proposed valence construct.

The subsequent seven-day ESM-AC study recruited 40 of 79 people with advanced breast or lung cancer approached through two Belgian hospitals. Thirty-seven participants provided 1,703 valid assessments, 71% of the 2,400 scheduled. On seven-point scales, mean reported burden was 2.1, ease of use 5.6, and measurement reactivity 1.3 (Geeraerts, Pivodic, et al., 2026). These results provide a practical precedent for repeated measurement in comparable patients. Eligibility restrictions, including functional status, limit their extension to more severely ill populations.

A companion analysis of the same study used 1,676 assessments from 36 participants. Retrospective scores correlated with participant-level summaries of momentary ratings, with Kendall's tau values from .24 to .70, yet identical retrospective scores could

conceal different momentary trajectories (Geeraerts, de Nooijer, et al., 2026). This supports preserving temporal information when the research question concerns accumulation or recovery. The two analyses contribute complementary evidence from one cohort; their questionnaires still require separate qualification as measures of signed phenomenal value.

A naturalistic study shows what event-sensitive sampling can add. Villano and colleagues followed university students across an academic term, recording expected examination grades before results were released and sampling affect intensively afterward. The analyzed sample comprised 249 students, divided into discovery and confirmatory cohorts. Models including the difference between expected and received grades described subsequent affect better than grades alone, while modeling positive and negative emotion separately (Villano et al., 2020). This gives the program a concrete design precedent: measure expectations before outcomes, preserve separate affective components, and select a cadence that resolves their recovery. The study supports prospectively ordered observation of real emotional events.

The prompt pool, randomized windows, quiet hours, maximum daily count, burden stop rule, minimum usable cadence, and analysis of schedule effects are fixed prospectively. Planned cadence variation can estimate reactivity and fatigue. Removing inconvenient prompt periods after inspection would turn the schedule into an invisible tuning parameter.

Five prompts sent through a workday may change the day they seek to measure. A participant may silence the phone, anticipate

the next question, avoid an activity, or answer quickly to end the interruption. Those responses are not noncompliance to be punished; they reveal when the instrument has entered the process and must be modeled as an exposure.

A serious audit must test whether high cadence can measure irritation and surveillance instead of experience. If so, the conclusion must attribute the pattern to design, care, or measurement to the extent warranted and narrow the local claim.

A prompt protocol should include randomized or staggered intensity where ethically feasible. That variation lets the study estimate prompt burden and reactivity instead of guessing them after the fact. The negative control is a schedule effect that looks like an affective dynamic.

Sampling cadence should reach the slowest schedule that still recovers the protocol-fixed dynamics in simulation and pilot work. Burden, reactivity, and missingness are evaluated beside statistical resolution. Denser sampling is rejected when its marginal information is purchased by a disproportionate change in ordinary attention or routine.

Sampling error can be bounded before a smooth curve is fitted. In a declared exposure clock, suppose an independently justified constant $K > 0$ bounds rate changes by $|v(s) - v(t)| \leq K|s - t|$. For an unsampled interval of length h with exactly known endpoint rates a and b , feasibility requires $|b - a| \leq Kh$. The attainable integral interval is

$$\int_0^h v(s) ds \in \left[\frac{h(a+b)}{2} - \Delta, \frac{h(a+b)}{2} + \Delta \right], \quad \Delta$$

$$= \frac{Kh^2}{4} - \frac{(b-a)^2}{4K}.$$

The extremal paths follow the steepest allowed slopes from the two endpoints, so these bounds are sharp under the stated assumptions. Two zero samples with $K = h = 1$ permit any intervening total from $-1/4$ to $1/4$. Across exactly observed common endpoints, the interval bounds add. Equal exposure spacing minimizes the worst-case missing-area width for a fixed span and number of gaps; burden and statistical error remain separate design considerations. Noisy endpoint readings require simultaneous uncertainty bounds, and unobserved prefix remains additional uncertainty. Without an independently qualified regularity or magnitude bound, sparse samples alone cannot exclude an unseen excursion. A synthetic downsampling challenge can determine whether the proposed cadence resolves the required integral before recruitment.

17.2.2 — Momentary Versus Retrospective Questions

Momentary and retrospective questions observe different temporal objects. One asks about experience near the reporting moment; the other asks for a later construction shaped by memory, narrative, salience, and the chosen interval. A continuous-looking graph becomes misleading when those objects are merged without an explicit measurement model and a version flag identifying which question produced each point (Shiffman et al., 2008; Stone et al., 2007).

The protocol should predefine each reporting window, the wording used for current and retrospective judgments, the expected recall delay, and the analysis of their disagreement. A weekly evaluation cannot be substituted for missing momentary reports simply because both use the same response scale. The two channels remain separately versioned and may support different conclusions.

A late-night report of dread and a Sunday judgment that the week was meaningful need not contradict one another. They can reflect different moments, memory weights, and evaluative frames. Modeling the divergence can reveal recency, peak, recovery, or narrative effects that would disappear inside a single average.

An independent reviewer should be able to determine whether averaging them can erase the difference between rate and interpretation. A positive answer requires redesign or a claim limited to what survives the confound.

A useful control is disagreement by design: ask a time-near question and a later evaluation about the same interval, then model their divergence. If the result depends on merging them, the construct has been blurred. The disagreement itself may be the scientific finding.

The analysis keeps the testimony clocks separate through channel-specific estimands, lags, and uncertainty. Agreement is informative only when it survives the declared mapping between them; disagreement is reported rather than adjudicated by convenience. Neither a momentary report nor a retrospective account is granted automatic sovereignty over the other.

The distinction protects both kinds of answer. A momentary report is not morally superior to a retrospective account, and a life evaluation is not a substitute for lived time. They answer different questions, and a good protocol lets them disagree without immediately forcing one to confess error.

17.2.3 — Compliance and Reactivity

Compliance is a data-generating process, not a test of obedience. People may answer more when distressed, less when exhausted, differently when they anticipate a prompt, or only when the question feels supportive. The probability and timing of response must therefore be modeled alongside the reported value, especially when participation itself may alter attention or behavior (Little & Rubin, 2019; Nosek et al., 2018).

A reproducible data package carries response probability, prompt-induced change, randomized intensity, and compliance models. This structure allows later analysts to reproduce the risk set, measurement version, and transport assumptions at every time point.

Suppose a participant responds most often during difficult evenings because the prompt feels like contact. The observed series would overrepresent distress even though the missing intervals might be calmer. The reverse pattern is equally possible when distress makes answering impossible. Both mechanisms should be represented before the average response is treated as a trajectory.

The protocol must expose whether dropping low-compliance participants selects the easiest lives to observe. When the risk is

material, the principal result names the selected population and removes every stronger interpretation that depends on unobserved participants behaving similarly.

Cadence should be tested as an exposure. A study can randomize prompt density, vary timing within safe windows, or use planned low-intensity periods to estimate how being asked changes attention and report. If cadence changes the outcome, the prompt has become part of the model.

Response probability, response latency, prompt history, and planned cadence variation should enter the analysis before substantive dynamics are interpreted. The study should report whether conclusions survive inverse-probability, joint-process, and mark-restricted analyses. When the answer depends on treating response as random, the verdict remains conditional on that assumption.

17.2.4 — Participant-Controlled Pauses

Participant-controlled pauses make refusal visible without turning it into dropout. A pause may protect privacy, sleep, family time, clinical care, or emotional stability, and the reason need not be disclosed beyond the categories the participant chooses. The data model should distinguish temporary pause, skipped prompt, device removal, technical failure, and withdrawal because those events carry different meanings (Shiffman et al., 2008; Trull & Ebner-Priemer, 2020).

The data model needs fields for pause marks, no-estimate intervals, burden thresholds, and optional reason codes. Without

that linkage, site and instrument changes can masquerade as changes in the phenomenon.

A caregiver may suspend prompts during a family crisis and resume later when observation is no longer intrusive. Smoothing across that interval would erase both the protected event and the reason the record became silent. The pause should remain a marked boundary with an explicit no-estimate option for the interval.

Smoothing cannot erase a pause that marked the very state in which observation became inappropriate. The protocol-fixed failure rule treats that interval as a boundary or No adequate estimate rather than manufacturing continuity for public interpretation.

The pause mechanism is designed before enrollment, available without penalty, and linked to immediate stopping of prompts and sensors where feasible. Analyses treat paused time as unobserved under a declared mechanism rather than as neutral experience. A study that requires people to disappear in order to protect themselves has failed both ethically and methodologically.

A pause button is not a decoration on an intrusive design. It is an epistemic tool because it distinguishes safe unavailability from silent dropout, fatigue, fear, and refusal. A participant who can stop cleanly gives the study better information than one who must disappear to protect themselves.

17.2.5 — Language and Accessibility

Language and accessibility determine how the measurement request reaches the participant and can alter the construct being

elicited. Translation, literacy, assisted communication, sensory access, cognitive load, and cultural framing should be specified as measurement versions with their own qualification evidence. Youth and ambulatory psychophysiology reviews also show why feasibility and channel burden vary with developmental context. Identical scores do not establish identical meaning across those routes (International Test Commission, 2018; Sosa-Hernandez et al., 2024).

At minimum, the dataset must preserve translation, assistive formats, cognitive interviewing, and adaptation versioning. They are the audit trail that separates lived change from design, version, care, and participation changes.

An item that sounds neutral before illness may sound blaming after disability or treatment changes the person's reference frame. A voice prompt may be accessible but more public; an assisted response may improve participation while changing privacy and timing. These are not peripheral usability details. They can change who answers and what the answer means.

The claim should be withdrawn when the same wording can hide construct shift. The protocol should name this loss condition in advance and tie it to an explicit narrowing rule.

Time grids should accommodate communication mode and access needs. A voice prompt, screen reader, simplified item, translated question, or assisted response may require a different timing burden. The construct changes silently if accessibility is treated as a late convenience rather than a design condition.

Every change in language, modality, assistance, item set, or timing is entered in the measurement version ledger. Bridge samples and cognitive interviews determine whether data may be linked, require recalibration, or must remain separate. Accessibility is successful when it widens participation without pretending that different response routes are automatically equivalent.

17.2.6 — Calibration and Drift

Calibration can drift while displayed numbers remain stable. Treatment, grief, illness, repeated prompting, new vocabulary, trust, fatigue, and changing reference points can alter scale use, so repeated anchors and prospectively specified response-shift checks replace indefinite reliance on one baseline (Little & Rubin, 2019; Nosek et al., 2018).

The record should preserve anchor items, vignettes, overlap periods, brief debriefs, response latency, and scale-linking results. Recalibration is planned around medication change, disease progression, relocation, bereavement, new communication modes, and long participation; when meaning shifts, the protocol splits the series, estimates a bridge, widens the identified set, or withdraws the common-scale claim.

A stable number with unstable origin, sign, or unit is a stop gate. Longitudinal continuity is earned by linking evidence, not repeated use of one interface, and a wider confidence interval cannot rescue an unbridged scale change.

The prompt schedule is itself an exposure. Frequency, reminders, quiet hours, postponement, and burden-triggered reductions can

change monitoring, fatigue, rehearsal, irritation, labeling, and compliance, so invitation, opening, completion, interruption, postponement, and retrospective-entry times remain marks in the observation model.

Recent experiments make these design choices measurable. In a twenty-eight-day factorial study of 205 participants, fixed rather than random prompts produced lower measured affect variability in eight of sixteen models; associations with next-day health behaviors were not reliably changed (Langford et al., 2026). A separate fourteen-day study comparing seven-point Likert responses with visual analogue scales in 119 participants found differences in means, floor responses, and some correlations, but no reliable difference in within-person standard deviations or successive-change variability (Haslbeck et al., 2025). The practical gain is a stronger instrument: freeze the schedule and format, test their effects, and estimate transport when either changes. A smoother observed trajectory can then be assessed against measured design effects before it receives a latent interpretation. Design-effect estimates should travel with the instrument version so later studies can adjust expectations when prompt schedule or response scale changes.

When burden and ethics permit, randomized prompt density, planned schedule changes, or micro-randomized notification timing can estimate reactivity. If asking changes state or participation, that effect belongs in the estimand and interpretation rather than being dismissed as noise (Shiffman et al., 2008; Klasnja et al., 2015; Trull & Ebner-Priemer, 2020). Reactivity estimates can also inform burden limits by showing

when additional measurement begins to alter the process more than it improves information.

The final calibration verdict states which periods and populations share a defensible scale, where a bridge remains uncertain, and where only local or ordinal inference survives. Drift limits the instrument's comparative claim; it does not invalidate the participant's experience. A calibration boundary should enter downstream models as a restriction on inference rather than become a wider confidence interval around a comparison that is no longer valid.

17.3 — Passive Signals, Wearables, and Context

Passive sensing can extend temporal coverage while reducing the need for active prompts. Wearables can record heart rate, movement, sleep timing, skin temperature, oxygen saturation, or environmental context during ordinary life. Their contribution depends on a clear account of the observation gaps and device conditions that accompany those records (Onnela & Rauch, 2016; Shcherbina et al., 2017).

Device placement, sensor quality, proprietary algorithms, motion artifacts, illness, treatment, charging habits, privacy choices, firmware changes, and willingness to wear the device shape passive records.

Passive evidence can extend life-course observation when fatigue, recall, speech, delirium, sleep, or disability limit active reporting. Work with people receiving outpatient palliative care and family caregivers found wearable-triggered momentary assessment practicable in a bounded clinical setting. Building on that result, a study can record who can wear, respond, pause, and withdraw and evaluate how those patterns affect its measurements (Schuler et al., 2023).

StudentLife offers a smaller complementary benchmark combining smartphone sensing, momentary assessments, and survey outcomes across a 10-week term in 48 Dartmouth students. The original study reported associations among sensed behavior, mental-health measures, and educational outcomes, and released its dataset for reuse (Wang et al., 2014).

Its value here is to challenge the observation model. Before interpreting a candidate affective trajectory, ask how much prediction comes from recorded sleep, activity, social context, workload, and assessment availability. Fit those variables as substantive rival explanations under the same participant splits and scoring rules. A stable added contribution from a declared route variable would justify replication in a broader population. The dataset provides a local methods benchmark with a documented duration and population.

17.3.1 — Physiological Streams

Physiological streams are continuous only in a technical sense. Heart rate, electrodermal activity, movement, respiration, temperature, and sleep estimates remain partial witnesses whose meaning depends on illness, medication, posture, motion, device fit, and context. The protocol should qualify each channel for a stated use and preserve the conditions under which the signal was acquired (Onnela & Rauch, 2016; Shcherbina et al., 2017).

The relevant time scale differs by channel and estimand. A rapid autonomic response, nightly sleep summary, slow frailty change, and treatment effect cannot be placed on one clock without a model of lag and aggregation. Quality flags, treatment states, and sampling density should accompany the value so later analyses can distinguish physiology from acquisition artifact.

A wearable may show reduced arousal after medication while the participant continues to report distress. That disagreement can reflect channel lag, sedation, motor suppression, altered interoception, or genuine multidimensional experience. The

analysis should preserve the conflict rather than declare the most technical signal to be the hidden truth.

One stronger explanation is that medication, fever, motion, and device fit can mimic affective change. If this account explains the shape under equal scoring, the proper verdict is narrowing, not rhetorical rescue.

Uncertainty should identify the channel, not merely widen the band. Motion artifact, fever, medication, sensor fit, arrhythmia, pain behavior, sleep staging error, and device removal have different meanings. The result should say which uncertainty entered the estimate before it asks the reader to trust the line.

Channel-specific confidence, artifact flags, medication timing, and device state are stored with every derived feature. Fusion occurs only after each channel has passed its own context-of-use checks. When a physiological channel cannot distinguish the target from its principal confounds, it remains an auxiliary witness or is removed from the estimand.

17.3.2 — Behavioral and Environmental Context

Behavioral and environmental context may explain a signal while also exposing intimate routines and bystanders. The smallest feature set capable of distinguishing the protocol-fixed mechanisms should be collected at the coarsest sufficient resolution. Contextual integrity and attack-surface analysis therefore belong in feature selection; more context does not automatically produce more validity (Nissenbaum, 2010; National Institute of Standards and Technology, 2020).

Activity, light, noise, care setting, social presence, and coarse location may enter as time-varying covariates, marks, or stratification variables. Each requires a declared temporal resolution and purpose. A variable gathered for one explanation cannot later become a general map of private life without new authority and a new scientific justification.

Low activity may mean restorative rest for one participant and forced immobility for another. The sensor records movement, not the reason for movement or its felt value. Active report, clinical context, and participant-defined categories may help interpret the signal, but the study should retain the possibility that the context remains unknown.

The protocol must assess whether contextual data expose bystanders or intimate routines. Record any privacy failure and its effect on permitted data use, and narrow PTVc-specific claims where those restrictions leave the estimand unidentified.

Contextual uncertainty includes both error and exposure. Location may be coarse, social interaction may be inferred, activity may be misclassified, and environmental data may reveal more than the estimand needs. The analysis records these uncertainties and collects the minimum contextual detail needed for its estimand.

Context variables are retained only when they change a prespecified model comparison, confounding assessment, or safety decision. Their privacy cost and incremental information are reviewed together. If a less revealing feature performs as well,

the more intrusive variable is removed even when it would make the visualization richer.

Context is useful because it tells the study where a signal lived. A location trace, activity summary, sound level, temperature reading, or interaction count may help explain a change, but it also raises the cost of being known. The study earns those variables only when the estimand cannot be answered by a less revealing path.

17.3.3 — Sensor Fusion Without Sovereignty

Sensor fusion is an estimation problem with a governance boundary. Multiple channels may reduce some forms of uncertainty, yet fusion can also conceal disagreement and create a composite that appears more authoritative than any constituent measure. The protocol must specify channel roles, provenance, conflict rules, and the conditions for abstention before the model is fit (National Institute of Standards and Technology, 2020; Rieke et al., 2020).

The fusion architecture, held-out channels, quality thresholds, missing-channel behavior, and conflict outputs are prospectively fixed. A model may predict a qualified target, but it may not redefine that target from whichever channels remain available. Contradictory or insufficient witness sets must be able to yield No adequate estimate.

Self-report may indicate calm while physiology shows arousal after a difficult clinical conversation. The discrepancy could reflect concealed distress, medication, physical effort, delayed recovery, social presentation, or a scale mismatch. A responsible

fusion model displays that disagreement and its competing explanations rather than compressing it into one smooth score.

One important rival is presentation authority: a technically elaborate channel may appear to overrule the person without carrying better evidence. When common-rule comparison favors that account, the result belongs to measurement presentation or channel dominance unless a later test separates the mechanisms.

The output should expose which channels contributed, which objected, and how uncertainty changed when each was removed. Held-out-channel validation tests whether one channel predicts another without being allowed to dominate it. Fusion earns use by improving a declared estimate, not by creating the appearance of a direct reader of inner life.

Fusion should make uncertainty more visible, not hide it behind a confident composite. When self-report, physiology, behavior, and context disagree, the disagreement is data. The person is not overruled by the smoothest model, and the model is not allowed to call conflict certainty.

17.3.4 — Device Removal and Nonwear

Device removal and nonwear are observation events with potentially informative causes. Privacy, discomfort, skin injury, charging, illness, delirium, family presence, care transition, and simple annoyance all produce different missingness mechanisms. The device record should preserve these causes when the participant chooses to provide them and otherwise retain an explicit unknown mark (Onnela & Rauch, 2016; Shcherbina et al., 2017).

The protocol should define nonwear detection, participant removal controls, charging windows, skin-safety checks, and the distinction between technical absence and refusal. It should also state when sensing stops automatically, how data already collected are handled, and how nonwear enters the primary and sensitivity analyses.

A person may remove a sleep tracker before discharge because it has become intrusive or uncomfortable. If the missing interval is filled from neighboring nights, the analysis erases the event that made observation inappropriate. Nonwear must remain visible as a possible indicator of burden, state change, or device failure, not as a blank invitation to interpolate.

A candidate signature that appears only after high-burden nonwear is coded as random has failed an observation-process test. The report should show how results change under cause-specific and unknown-cause missingness scenarios. When the plausible branches disagree, the appropriate outcome is model ambiguity or No adequate estimate.

Include forgetfulness among the plausible causes. A result depending on one explanation should state that explanation in the verdict.

Trajectory smoothing begins only after device absence has been modeled and the admissible missingness assumptions have been declared. The study should publish nonwear profiles by time, site, device version, and participant state. A continuous display may be used for visualization, but it may not conceal the discontinuity in evidence.

Nonwear can provide useful information about how observation fits into ordinary life. Devices may be removed for bathing, pain, delirium, privacy, fatigue, technical failure, family time, or simple preference. Recording the applicable reason, or preserving it as unknown, helps distinguish a person's choice from a device limitation or change in state.

17.3.5 — Vendor and Firmware Drift

Vendor and firmware drift should be tested as a measurement discontinuity. Overlap intervals, calibration fixtures, dual-device wear, and version-boundary negative controls can reveal whether a feature moved because the person or the sensor, firmware, algorithm, or preprocessing changed. Verification, analytical validation, and clinical validation are versioned properties; procurement history becomes measurement history when it can shift the observed variable (Bent et al., 2020; Goldsack et al., 2020; National Institute of Standards and Technology, 2020).

The auditable dataset should preserve device model, firmware, algorithm, preprocessing, bridge wear, and overlap windows. The record thereby distinguishes the scientific object from the system used to observe it.

Suppose a firmware update reduces detected awakenings at every site on the same date. Without a version ledger, this could resemble improved sleep or reduced distress. Overlap wear, calibration fixtures, and leave-version-out validation must locate the change in people or instrument.

A model that succeeds within one device version and fails across versions is not transportable merely because the vendor uses the

same product name. The result should be split, bridged with independent overlap evidence, or retired for the new version. Technology history may explain a trajectory and must be allowed to win that comparison.

Evaluation should leave out device versions and firmware periods, not just people. If a model trained on one version fails after an update, the version has become part of the observed effect. The chapter's rule is to test the machine history before interpreting the human trajectory.

Major technical changes require predeployment bridge plans with parallel measurements, version-specific quality thresholds, and a reanalysis trigger. Silent updates are incompatible with longitudinal inference. If the bridge is inadequate, segment the time series and withdraw the common-scale claim.

A device version can change the apparent life without the life changing at all. That is why vendor history, firmware, algorithms, and preprocessing belong in the scientific record rather than in a procurement footnote. Longitudinal evidence must know the machinery that helped create it.

17.3.6 — Minimization and On-Device Processing

Minimization asks what the study can learn without collecting a reconstructable portrait of ordinary life. On-device features, coarse summaries, burst sampling, and site-local analysis can reduce exposure while preserving a declared estimand, and the tradeoff is tested rather than assumed (National Institute of Standards and Technology, 2020; Rieke et al., 2020).

The database records local extraction, summary rules, sampling, and secure aggregation so a replication team can reconstruct both the estimand and its observation process.

A phone may transmit approved sleep regularity while retaining raw location and audio locally. The feature still needs provenance, quality checks, and deletion rules; local processing is a privacy architecture, not an exemption from validation.

Unspecified future collection invites post hoc fishing and weakens withdrawal. The protocol names the minimum sufficient signal for each estimand and requires new review before expansion; temporary richer audit samples validate the minimized representation without becoming permanent retention.

Permissioned comparisons with richer audit samples test whether the smaller stream preserves the needed estimand. The richer stream remains a temporary bridge, not a standing appetite for more data.

A minimized pipeline must preserve prospectively specified model comparison across relevant states, sites, and devices. If reduction removes identifying information, the question narrows rather than the surveillance surface expanding.

Long observation is proportionate only when the record remains purpose-bound, local where possible, and limited to the weakest sufficient signal.

17.4 — Marked Observation Processes

A marked observation process records not only what was measured, but when measurement occurred and what kind of measurement event it was. The distinction matters because longitudinal data are rarely collected by a neutral clock (Andersen et al., 1993; Rizopoulos, 2012).

In ordinary analysis, missing data often enter after the outcome model has been specified. This chapter reverses the order. Observation availability is part of the data-generating system, and any apparent life-course pattern should be tested against the possibility that the observation process created it.

The notation in this section is a scaffold. It does not define the Law, and it does not claim to observe the latent cumulative process. It gives the study a way to ask whether the measurement system has its own dynamics.

Table 17.3. Marked-observation model families and identification limits.

Model family	Use when	Watch for
Continuous-time state-space	Observation times are irregular and latent dynamics matter.	Do not assume regular time by inserting artificial missing rows.
Dynamic structural equation model	Lagged within-person relations and person differences are central.	Separate within-person from between-person effects.
Gaussian process	Nonlinear or nonstationary trajectories need flexible smoothing.	Smoothing can hide event timing and missingness.

Model family	Use when	Watch for
Functional data analysis	Sparse curves require functional summaries or principal components.	Regularity assumptions determine what is recoverable.
Hidden or semi-Markov model	Regime changes or state durations matter.	States can become stories if not recoverable.
Joint longitudinal-event model	Outcome, observation, death, or dropout are linked.	Define the endpoint independently of the event-model fit.

17.4.1 — Observation Intensity $\lambda_i(t)$

Observation intensity describes the rate at which a person becomes visible to the study. It may depend on prior reports, care setting, device state, staff availability, medication, distress, or participant choice, so it cannot be treated as an administrative schedule outside the outcome model. The protocol should estimate or bound that rate on the information available at each time (Andersen et al., 1993; Rizopoulos, 2012).

The analysis file carries the prospectively specified observation-intensity model, observed history, visit timing, event marks, state-dependent measurement, and version identifiers. These fields let another team reconstruct which opportunity process and estimand were actually analyzed.

Observation-intensity model. Role: candidate model for when a participant becomes observable under recorded history; it neither defines the endpoint nor reads an unobserved phenomenal state.

$$\lambda_i^{\text{obs}}(t \mid H_i(t^-)) = \lim_{\Delta t \downarrow 0} \frac{\Pr\{N_i(t + \Delta t) - N_i(t) = 1 \mid H_i(t^-)\}}{\Delta t}$$

The history available at a given time can include prior reports, device state, clinical status, medication, care setting, earlier nonresponse, site, and participant pause state. Once those variables predict observation, the record is sampled through a gate rather than simply received from lived time.

A reproducibility check should ask whether observation rate can create or hide trajectory shape. When the test is positive, the finding cannot be presented as a clean property of the latent path.

Evaluation should compare outcome models with and without the observation-rate model. If the apparent dynamic weakens once intensity is included, the result is sensitive to the observation model; an observation-artifact interpretation requires the declared identification and model checks. The diagnostic is productive because it tells the program what not to overclaim.

Observation intensity tells the study when the world decided to look. Without it, a flare in reports, a quiet interval, or a terminal decline can be mistaken for the person rather than the schedule. The rate of being observed is itself one of the variables that makes longitudinal evidence fair or unfair.

17.4.2 — Observation Marks

An observation mark records what kind of event produced a datum or an absence. Scheduled prompts, participant-initiated reports, staff-triggered assessments, refusals, device failures, removals, and clinical interruptions occupy different selection pathways. A graph that treats them as interchangeable points suppresses part of the data-generating system (Little & Rubin, 2019; Scharfstein et al., 1999).

Observation marks should distinguish scheduled opportunities, participant responses, refusals, pauses, technical failures, staff interruptions, transfers, and device removal. The mark set makes selection analyzable and permits a direct test of whether the apparent trajectory changes when the observation process is modeled. Unmarked absence forfeits that possibility.

The same pain score has a different evidential route when it is collected during a crisis, at a scheduled visit, after a device alert, or because the participant chose to report. Mark-specific analyses can reveal whether the apparent change belongs to experience or to the circumstance that caused measurement. The route to the observation remains attached to the observation.

The analysis should make it possible to test whether unmarked missingness destroys interpretability. That outcome calls for a narrower estimand or for abstention, not a reassuring footnote.

Evaluation should hold out mark types and ask whether conclusions change when refused, failed, staff-initiated, or clinically interrupted measurements are separated. A model that depends on treating all absences alike has not earned an interpretation of the person.

Observation marks remain at the datum level in a versioned dictionary, including unknown and mixed categories. Analyses compare scheduled observations, staff-triggered events, refusal, failure, clinical interruption, and device removal. Categories may be collapsed only when simulation and sensitivity analysis show that the merge cannot change the protocol-fixed interpretation.

Marks turn missingness from fog into grammar. A skipped prompt, a device failure, a nurse-initiated measurement, a participant refusal, and a clinically interrupted visit do not mean the same thing. The study that records the mark preserves the possibility of knowing why the line broke.

Once marks are defined, the analysis can model mark-specific intensities and transition probabilities instead of merely stratifying rows. A marked point process asks whether scheduled reports, self-initiated reports, clinician-triggered assessments, and device alerts accelerate or decelerate under the same modeled conditions. Goodness-of-fit checks should test event timing and mark type jointly; otherwise a model may fit measured values while missing why measurement occurred (Andersen et al., 1993).

Mark vocabularies require governance. New device states, care settings, language changes, and protocol deviations should enter a versioned dictionary rather than free text that is harmonized after outcomes are seen. Unknown and mixed marks must remain visible. The temptation to collapse them for convenience should be resisted when the collapse could hide distress-triggered sampling, staff triage, or participant-controlled silence.

17.4.3 — Informative Presence and Absence

Presence and absence are informative whenever the probability of observation depends on the state being studied or on variables related to it. A long record can therefore overrepresent lucid, supported, comfortable, or highly distressed intervals while making other states nearly invisible. Visibility profiles should be

displayed before outcome trajectories are interpreted (Røysland, 2011; Rubin, 1976).

The analysis should preserve response, nonwear, visit, transfer, and interruption processes separately, then specify which may depend on observed history and which may depend on unobserved current state. Pattern-mixture, selection, and shared-parameter formulations represent different observation worlds. Agreement across them is evidence of robustness; disagreement defines the uncertainty.

A participant who answers reliably when calm and becomes silent during severe distress creates an apparently stable series. Another who answers mainly when distressed creates the opposite distortion. The observed values can be accurate in both cases while the trajectory is wrong because the windows of visibility differ.

External reviewers need a direct test of whether observed data can overrepresent easier states. If the concern is supported, its contribution belongs in the primary interpretation and the claim must contract.

A strong analysis tests whether observed states differ from states near refusal, nonwear, missed visits, or clinical interruption. Pattern-mixture and selection-model variants should be treated as rival observation worlds. If the signature lives only in one world, the verdict is conditional.

Visibility maps, response-rate plots, nonwear intervals, and cause-specific marks should appear before any smoothed outcome figure. The result must state which states were difficult

to observe and how the conclusion changes under plausible missingness mechanisms. A missing interval is never assigned neutral experience by default.

Observation patterns help explain which experiences enter the record. People may respond differently when distressed, lucid, comfortable, alone, or assisted by staff. Modeling both presence and absence makes those differences part of the evidence and keeps unobserved intervals from being assigned neutral values.

17.4.4 — Joint Mark and Outcome Models

Joint mark and outcome models ask whether the observed values and the opportunities to observe them are driven by shared state. The outcome process, counting process, mark distribution, and any shared latent variables should be declared separately so that the model cannot use its own observation rule to manufacture fit (Andersen et al., 1993; Rizopoulos, 2012).

The chosen model must match the estimand. Forecasting the next observed report, estimating a latent trajectory under informative visits, and comparing mark-specific outcomes require different likelihoods and assumptions. Simpler outcome-only and mark-only artifact models remain in the tournament so that added complexity is not rewarded merely for absorbing the observation process.

Joint observation-outcome scaffold. Role: candidate analysis model linking measured outcomes, observation opportunities, and declared event marks to examine informative visibility.

$$y_{ij} = m_i(t_{ij}) + \varepsilon_{ij}$$

$$Pr\{dN_i(t) = 1|H_i(t)\} = \lambda_i^{obs}(t)dt + o(dt)$$

$$Pr\{M_{ij} = k|dN_i(t_{ij}) = 1, H_i(t_{ij})\} = \pi_{ik}(t_{ij}|H_i(t_{ij}))$$

No positive verdict is warranted if the model can define its own opportunity to be right. The analysis plan must state beforehand what verdict follows when this condition occurs.

The joint model should be compared with a simpler outcome-only model and a mark-only artifact model. When the mark process explains the apparent trajectory, the study has found a design dependency rather than a Law-specific signal. That result belongs in the public record.

The recorded observation opportunities remain distinct from the model for their probability or intensity. A joint observation–outcome model may allow that intensity to depend on latent experience or shared clinical state under explicit identification and sensitivity assumptions. This dependence is not circular by itself. Circularity arises when outcome-dependent inclusion, endpoint selection, or tuning forces the signature later presented as evidence.

The joint model tests whether observations and outcomes change together. Representing that dependence can improve estimates and reveal when an apparent trajectory is explained by the observation process. Either result gives the next study a more informative design.

17.4.5 — Sensitivity to Missing-Not-at-Random

Missing-not-at-random sensitivity begins from the recognition that unobserved states cannot be recovered from observed data

without assumptions. The protocol should identify clinically and behaviorally plausible mechanisms, then express them through interpretable sensitivity parameters rather than a single opaque adjustment (Little & Rubin, 2019; Scharfstein et al., 1999).

The sensitivity plan fixes model families, tipping parameters, channel-specific scenarios, and the outputs that trigger narrowing or No adequate estimate. Mechanisms tied to pain, relief, fatigue, privacy, sedation, fear, device intolerance, and family protection receive clinically interpretable parameter ranges before the preferred result exists.

A terminal prompt may be unanswered because the participant is asleep, distressed, sedated, unable to communicate, shielded by family, or simply uninterested. Those mechanisms imply different distributions for the unseen value and different ethical meanings. Treating them as one generic missing observation can create a false terminal pattern.

The result becomes nonadjudicable when plausible missingness assumptions reverse its sign, route ranking, or equivalence decision. The main report should display that dependence, identify which unobserved quantities drive it, and assign the resulting evidence state under §24.2 and Table 27.5 (Little & Rubin, 2019; Scharfstein et al., 1999).

The sensitivity parameter should have an interpretable scale, such as the change in response odds or latent outcome associated with an unobserved state after conditioning on measured history. The analysis then varies that parameter over a clinically justified region and records where sign, equivalence, model choice, or

decision status changes. A number without a plausible mechanism is not a useful sensitivity analysis.

No single missing-not-at-random model is credible enough to carry the conclusion alone. The analysis should span a sensitivity family: selection models in which observation depends on unobserved current burden, pattern-mixture models that shift unobserved outcomes relative to observed ones, and shared-parameter models that link dropout to a latent health process. Each family should be anchored by clinically interpretable sensitivity parameters rather than abstract coefficients alone (Little & Rubin, 2019; Scharfstein et al., 1999).

Missing-not-at-random sensitivity should be reported as a tipping region rather than a ceremonial appendix. The figure should display the predeclared plausible region, the boundary at which the component verdict changes, and the assumptions outside which no estimate is defended. Stability across an implausibly narrow range is not robustness; stability across a justified range is stronger but remains conditional on that range (Little & Rubin, 2019; Scharfstein et al., 1999).

17.4.6 — Observation-Process Falsifiers

Observation-process falsifiers test whether the measurement process explains the proposed pattern. Mark restriction, intensity adjustment, simulated shutdown, nonwear scenarios, staff controls, device strata, and prespecified missing-not-at-random sensitivity analyses belong in the confirmatory package (Røysland, 2011; Rubin, 1976).

Each signature is paired prospectively with a falsifier and consequence. A pattern lost after representing staff-triggered measures, device removal, or interruption is observation-dependent; analysts may not search filters until one preserves it.

Reports test high-coverage intervals, alternate marks, weighting or joint-model adjustment, simulated shutdown, device-removal worlds, and staff or site controls. These checks distinguish trajectory from opportunity to observe.

Frozen falsifiers are reported whether they preserve or destroy the interpretation. Indistinguishable observation models permit only model-ambiguous, narrowed, or no-adequate-estimate status. A falsifier that fails because the observation model is nonidentifiable should downgrade adjudicability rather than be counted as evidence for the preferred latent process.

A joint model should reproduce outcome and observation. Checks compare visit intensity, missing runs, marks, terminal dropout, and covariate-dependent response; fitting values without who was observed and when is not recovery (Little & Rubin, 2019; Rizopoulos, 2012). Posterior predictive checks should reproduce both value trajectories and contact patterns under the same fitted system rather than validate the two processes separately.

Observation failure lowers confidence in every trajectory using the same assumptions and may redirect work toward devices, workflow, visibility, or missingness. That redirection is substantive. If visibility failure is site-specific, redesign can target workflow or devices without changing the latent model unnecessarily. A useful redesign test asks whether improving

observation reliability changes the apparent trajectory while leaving the latent model fixed; if it does, the earlier pattern was partly a property of visibility.

The framework now opens ethically available clinical and institutional variation while keeping prediction, causation, and care authority distinct. This separation allows naturally occurring variation to inform mechanism tests while preserving ordinary clinical decisions as causes to model, not interventions owned by the study.

17.5 — Clinical Cohorts and Natural Experiments

Clinical cohorts give the program access to repeated measures around illness, treatment, care transitions, and sometimes the approach to death. They are indispensable because terminal and serious-illness questions cannot be answered ethically by laboratory manipulation (Hernán & Robins, 2020; Lipsitch et al., 2010).

Natural experiments are useful when some external change alters exposure or timing without being chosen by the person's underlying state. The phrase natural experiment should not be used unless the assumptions are explicit and criticizable.

This section separates predictive from causal questions and care from theory. A clinical cohort may forecast risk, describe trajectories, estimate treatment-associated changes, or test whether a candidate signature survives clinical confounds. It does not authorize treatment manipulation.

17.5.1 — Prospective Clinical Cohorts

A prospective clinical cohort can plan clocks, measurements, and observation marks before the record becomes fragmented, but standard care still determines the setting. The cohort should define the clinical population, entry criteria, baseline state, treatment context, and component estimand without implying that follow-up under care reveals a complete life (Hernán & Robins, 2016, 2020).

The analysis architecture should encode baseline state, diagnosis, treatment plan, care-process metadata, and burden budgets. The

goal is traceability across people, time, sites, devices, and analytic versions, not accumulation for its own sake.

A palliative cohort may follow sleep, pain, medication, report availability, and care transitions while leaving treatment decisions entirely with the clinical team. Its scientific value comes from prospective timing and provenance. Its main vulnerability is that enrollment, prognosis, site resources, and communication ability determine who can enter and remain visible.

Public writing supplies another observational window on terminal illness. Goranson et al. (2017) analyzed 2,616 posts from twenty-five people blogging about terminal cancer or amyotrophic lateral sclerosis. An exploratory analysis within these blogs found that positive-emotion words increased as death approached, while negative-emotion words did not show a significant increase. This supplies an observed positive pattern worth following up with direct, voluntary measures of current experience. The bloggers were a selected group able and willing to write publicly; their language could reflect coping, relationships, audience, and meaning-making as well as felt state.

Model selection into the cohort and continued observation alongside the outcome process. Compare these models under explicit identification and sensitivity assumptions to assess whether sampling, the proposed mechanism, or both can explain the observed pattern. If their observable predictions remain equivalent, report model ambiguity.

Clinical cadence follows care first, with the smallest additional research layer that can answer the estimand. The protocol names

the source population, care context, entry clock, observation window, and estimand in terms preserved in public reporting. It separates routine visits, symptom-triggered contacts, remote prompts, and emergency encounters because each creates a different observation opportunity. If those clocks or care demands make the component uninterpretable, narrow the cohort or estimand rather than adding burden.

A prospective cohort is powerful because it can plan before the record fragments. Clocks, marks, treatment variables, burden limits, and No adequate estimate routes are specified in advance, with standard care and participants' comfort governing the observation schedule.

Existing longitudinal studies show why age and remaining time should be modeled separately. Among 1,637 deceased older adults in the German Socio-Economic Panel, distance to death described life-satisfaction change better than chronological age; the estimated decline accelerated roughly four years before death (Gerstorf et al., 2008). This supplies a quantitative timing comparison for models that also include health, care, social participation, and report availability. A prospectively specified candidate can be tested for additional predictive value alongside these measured variables.

17.5.2 — Treatment Changes

Treatment changes are time-varying exposures that may alter experience, physiology, report capacity, and the probability of observation at once. Medication, therapy, procedures, oxygen, sedation, counseling, and symptom control therefore require

precise timing and role declarations as exposure, confounder, mediator, observation modifier, or competing event (Pearl, 2009; Lipsitch et al., 2010).

The versioned record needs medication, therapy, procedures, sedation, treatment-confounder history, and landmark definitions tied to exact dates. These fields allow analysts to distinguish a change in the person from a change in treatment, eligibility, observation intensity, or time origin before those discontinuities are smoothed into apparent continuity (Hernán & Robins, 2020; Rizopoulos, 2012).

A pain medication change may reduce physiological variability while also reducing active reports through sleepiness or communication difficulty. Modeling lived response and report availability separately helps explain those changes. Treatment timing and channel-specific consequences remain visible in the analysis.

The first alternative to test is that treatment can affect both experience and measurement. A favorable fit for this account is not a nuisance; it is a reason to report a rival-favored or model-ambiguous result.

Treatment models need exposure timing at the resolution of the likely effect. Sedation, analgesia, therapy, oxygen, medication taper, or procedure recovery may operate on minutes, hours, days, or weeks. A coarse time grid can make a treatment effect appear delayed, absent, or terminal when it is merely undersampled.

The analysis uses time-dependent exposure histories at the resolution of the plausible effect and compares alternative

treatment-confounder structures. Landmarking, marginal structural approaches, and joint models suit different questions. Record clinical indications separately so the interpretation reflects how treatment was chosen.

Treatment change is never a nuisance variable in this chapter. Medication, therapy, oxygen, sedation, surgery, counseling, or symptom control may change both lived experience and observability. A study that treats care as background can mistake good medicine, difficult side effects, or clinical transition for a Law-specific trajectory.

Recent studies sharpen the empirical comparison. Wang et al. (2025) followed 1,971 older adults, 1,119 of whom died, and found different terminal change points across psychological and social domains, approximately six to eleven years before death. Social-network size did not share that change-point pattern. Petkus et al. (2025) analyzed 2,411 participants and 12,574 depressive-symptom observations, finding acceleration approximately four to five years before death. In ninety-eight mortality-discordant twin pairs, the earlier-deceased twin showed a steeper terminal symptom increase than the co-twin. The twin comparison helps distinguish terminal-related change from shared age and family background, while leaving nonshared illness and environmental changes to be modeled. The paired comparison distinguishes some competing explanations. For PTVC-linked work, its value is a stronger comparison design: test any additional proposed signed-history structure against these already informative terminal models.

17.5.3 — Natural Experiments

Natural experiments use variation created outside the research assignment, such as policy thresholds, scheduling rules, phased rollouts, supply changes, or staffing patterns. Their value depends on an explicit causal graph or target-trial analogue, a defensible identifying assumption, stable measurement around the change, and evidence that the variation is not simply a proxy for unmeasured participant state or site selection (Hernán & Robins, 2020; Lipsitch et al., 2010; Pearl, 2009).

The minimum reproducible package contains policy shifts, scheduling rules, rollout timing, pre-trends, spillovers, and site differences. Those entries permit a skeptical reanalysis without asking the reader to trust an undocumented data pipeline.

A clinic may change appointment scheduling for operational reasons, shifting when observations occur without assigning participants to a research intervention. That change can help identify an observation or care-process effect only if pretrends, anticipation, spillovers, and concurrent changes are examined. The label natural does not remove confounding.

Natural-experiment cadence should be anchored around the exogenous change and its plausible anticipation window. If people know a policy, staffing, or scheduling shift is coming, the pre-period may already be treated. The design should model anticipation rather than pretending the clock begins at implementation.

The protocol should prestate the local causal or descriptive estimand, the source of variation, the exclusion or

exchangeability assumptions, the anticipation window, and the falsifiers that would invalidate the design. Results are reported as local to the setting and period that generated the variation unless transport is separately established.

The design should try to falsify its own assignment story. Pretrend breaks, anticipation, manipulation around thresholds, co-occurring policy changes, differential measurement, and negative-control outcomes can each expose a false natural experiment. When those checks fail, the result remains a descriptive association tied to the observed policy change rather than a causal estimate.

A policy shift, formulary change, device rollout, staffing change, or care-pathway transition becomes a natural experiment only when its assignment process is understood. Pretrends, anticipation, co-occurring changes, negative-control outcomes, and site-specific implementation should be examined before causal language is used. Administrative origin does not make a change random when prognosis or clinician judgment helped determine exposure (Hernán & Robins, 2020; Lipsitch et al., 2010).

The report also needs a target population and transport statement. It should show uptake, crossover, implementation fidelity, eligibility, and the covariate range shared across comparison groups. Where overlap fails, the result remains local, descriptive, or partially identified rather than being carried into the whole life-course program by narrative analogy (Dahabreh et al., 2019; Pearl & Bareinboim, 2014).

17.5.4 — Clinical Heterogeneity

Clinical heterogeneity can change both the phenomenon and the observation system. Diagnosis, disease course, treatment options, communication capacity, care setting, disability, culture, family support, and site practice may modify dynamics, measurement validity, and observation probability in different directions. The protocol should declare which axes define separate scientific strata and which may be modeled as effect modifiers (Hernán & Robins, 2016, 2020).

The protocol should preserve strata, partial pooling, site variables, diagnosis-specific clocks, and care ecologies. They expose whether the conclusion depends on survival, site, device, model version, or a hidden analytic choice.

Home hospice, inpatient hospice, intensive care, rural clinics, and chronic-pain services may produce different records before any difference in lived experience is considered. Visit density, device availability, symptom management, staffing, and family involvement shape who is observed and when. Site and clinical strata should therefore be displayed before partial pooling is interpreted.

Pooling fails when it creates an average process that no clinical group follows or when one high-observation group dominates the estimate. Hierarchical models may borrow strength, but the amount borrowed should be audited through leave-group-out checks and stratum-specific residuals. Heterogeneity that changes the verdict remains part of the result.

Sampling cadence, channel qualification, and missingness assumptions should be adapted to the clinical process rather than standardized for visual symmetry. Rapid symptom fluctuation, slow degeneration, episodic crises, and communication decline require different designs. A common protocol is useful only where it preserves a common scientific object.

Pooling should be earned through measurement invariance, overlap, calibrated partial pooling, and posterior checks that preserve subgroup failure. A pooled coefficient is unavailable when the same variable changes meaning, sign, cadence, or observation mechanism across strata. In that case, separate estimates or identified sets are more honest than a precise average of unlike objects.

17.5.5 — Causal and Predictive Questions

Prediction and causation answer different questions. A model may forecast a future report or care need accurately while remaining unable to estimate what a treatment, support, or environmental change caused. The protocol should state which task it owns and prevent performance on one task from lending authority to the other (Pearl, 2009; Lipsitch et al., 2010).

For an intervention question, the target trial should be written first: eligibility, time zero, treatment strategies, assignment procedure or emulation rule, follow-up, intercurrent events, outcome, causal contrast, and analysis. Time-varying confounding, positivity, consistency, interference, censoring, and measurement assumptions are then stated separately. Forecasting

may use the same cohort, but it remains a different estimand and validation task (Hernán & Robins, 2020).

A model may predict lower future variance after medication because medication marks disease severity, clinical attention, or survival rather than because it caused the change. Predictive success can still be useful for planning support. It becomes misleading when the result is translated into an intervention effect that the design did not identify.

The analysis report should label association, prediction, causal effect, feasibility, and component evidence at every table and figure. A model that predicts well but fails causal falsifiers remains a predictive model. A causal estimate that transports poorly remains local even when its mechanism is plausible.

Uncertainty should distinguish prediction error from causal bias. A model may forecast need accurately while still failing to estimate what treatment changed. The report should not let predictive success borrow the language of intervention effect.

Validation and decision rules are task-specific: blocked temporal tests for forecasting, negative controls and sensitivity analyses for causal claims, and held-out populations for transport. When the tasks disagree, the study reports the disagreement. No hierarchy makes causal language automatically more important or predictive language automatically safer.

Unexpected timing offers a concrete observational comparison for horizon-dependent candidates. Ito et al. (2021) followed 1,896 patients in twenty-three Japanese hospice or palliative-care units. Four definitions of sudden or unexpected death produced thirty-

day cumulative-incidence estimates between 6.4% and 16.8%. That variation makes definition choice part of the scientific question. A prospective extension could add affective and contextual observations, freeze a prognosis model using only information available before the final decline, and compare a prespecified candidate across more- and less-expected biological deaths. Clinician surprise, physiological change, care, and missingness would remain explicit comparison variables.

17.5.6 — No Care Manipulation for Theory

Chapter 3's no-harm and care-first rules remain controlling. Longitudinal designs may observe clinically justified treatment and support, but may not alter care to improve trajectory interpretability. Any datum lost because comfort medication, device removal, or a stop request took priority remains ethically unavailable and is handled through the prespecified missing-data or no-estimate branch (Council for International Organizations of Medical Sciences, 2016; International Council for Harmonisation, 2026; World Medical Association, 2024).

Any design whose discriminating power depends on care delay, induced distress, avoidable sleep disruption, denial of support, or a counterfactual that cannot be observed ethically fails during simulation and protocol review. An informative question does not become permissible because the missing contrast would be scientifically valuable.

Analysis should represent care-triggered observation marks and ask what narrower estimand remains identifiable. Clinical authority, participant refusal, comfort, and rescue outrank the

research schedule at every time. Trust is earned by accepting a smaller answer rather than engineering around humane limits.

The line is operational: if a treatment, visit, sedation decision, monitoring interval, or support change would not be justified without the theory, the study should not perform it for the theory. The chapter may learn from care as it occurs, but care never becomes an instrument for the chapter. This constraint also protects external validity, because a trajectory that appears only after research has altered ordinary care would not describe the clinical process the study claims to learn from.

17.6 — Truncation by Death and Competing Events

Death is not ordinary dropout. After truth-level stream endpoint, future felt outcomes are undefined for that stream. A study that fills post-death values or hides death inside a composite endpoint can make a trajectory look continuous after the object of observation has ended (Frangakis & Rubin, 2002; Fine & Gray, 1999).

Events that interrupt observation also matter before death. Transfer to another facility, discharge, withdrawal, loss of device access, communication loss, sedation, and family protection of quiet can end observation without ending the person.

This section draws on survival analysis and semi-competing risks because longitudinal outcomes in serious illness often depend on whether the participant remains alive and observable. The methods are tools for preventing false evidence created by survival, observation, and endpoint structure.

Table 17.4. Death-alignment artifact simulations and false-signature diagnostics.

Simulated truth	Observation rule	Naive display	Artifact risk	Required diagnostic
No terminal compression	Fewer measures as weakness rises	Backward alignment to death	False narrowing near endpoint	Compare to a null with same missingness.

Simulated truth	Observation rule	Naive display	Artifact risk	Required diagnostic
Medication dampens signals	Monitoring removed after sedation	Last observed values carried visually	Apparent neutrality from care process	Model sedation and device removal as marks.
Different diagnoses decline at different speeds	Visits cluster around crises	Dynamic time warping aligns crises	Timing differences disappear	Report warped and unwarped clocks.
Sudden and slow deaths mixed	Sudden cases lack terminal window	Only slow deaths plotted near T	Survivor-like terminal sample	Name target: observable terminal windows.

17.6.1 — Death Truncates Future Outcomes

For an outcome defined only while alive, death ends its clinical domain. The protocol defines the relevant while-alive, terminal-window, event, or joint estimand and treats the stream endpoint as a separate specified object. Values are estimated only within the domain of the chosen outcome (Frangakis & Rubin, 2002; Fine & Gray, 1999).

Stopping rules for each outcome, endpoint adjudication, last-observation handling, and the distinction among biological death, truth-level stream endpoint, and loss of observation are prospectively fixed. Figures end where the estimand ends rather than extending a line for visual completeness.

A graph that continues the final report across days after death can look stable and reassuring, but the line is an artifact of the plotting

rule. The same problem arises when zeros are inserted after death or when death is coded as an extreme symptom. The protocol should show the terminal event explicitly and remove undefined follow-up from the outcome scale.

The audit trail must reveal whether post-death imputation, survivor-only smoothing, or endpoint-aligned averaging can manufacture apparent neutrality. Simulations should replay those operations under known non-PTVC generators and show their false-signature rate. If contamination cannot be bounded, the stronger verdict is blocked (Kurland et al., 2009; National Academies of Sciences, Engineering, and Medicine, 2019).

Uncertainty after biological death includes uncertainty about pre-death records, observations, timing, and events, while the truth-level stream endpoint remains a separately specified question. The analysis should not assign post-death values to make a longitudinal method convenient.

Analysis stops the lived-outcome process at the relevant endpoint and uses event-specific methods for what follows. While-alive summaries, cumulative incidence, joint models, and survivor-conditioned quantities are labeled by the population and time they describe. None is allowed to imply an unobserved post-endpoint experience.

Death is not a missing data point after which the curve may be quietly extended. It ends outcomes defined only while alive, while the truth-level stream endpoint remains a separate question and records, memories, care processes, and survivor reports

remain different objects. The design must name which object remains before it computes anything.

17.6.2 — Semi-Competing Risks

Semi-competing risks arise when a nonterminal event can occur before death but cannot occur afterward, while death may occur without the nonterminal event. The estimand must therefore specify whether it concerns transition into the nonterminal state, death without that state, time spent alive and observable, or the joint ordering of events. Ordinary right censoring does not preserve those distinctions (Fine et al., 2001; Kurland et al., 2009).

The protocol should define states, allowed transitions, event ordering, and the clock used for each transition. Illness-death and multistate models can represent whether a nonterminal event precedes the terminal event, but their interpretation still depends on observation and endpoint qualification. The state diagram is a scientific object, not a decorative flowchart.

Sedation may end active report while biological life and clinical care continue. That transition is neither death nor ordinary missingness. The analysis should distinguish loss of report, loss of device access, change in consciousness evidence, and truth-level endpoint uncertainty rather than assigning one terminal code to all of them.

An independent review should check whether nonterminal and terminal events have been collapsed into generic dropout. Any consequential collapse triggers a documented correction in the analysis and participant-protection plan.

Uncertainty in semi-competing risks concerns both event order and dependence among transitions. A hospitalization before death, device removal before transfer, and withdrawal before communication loss imply different risk sets and different observation opportunities. The analysis should show which ordering is observed, interval-censored, or structurally impossible rather than collapsing all pre-death events into one state.

Event order is recorded and modeled explicitly, with sensitivity analyses for uncertain timing and competing definitions. A result that changes when nonterminal and terminal events are separated is reported at that event-specific level. Multistate detail is retained only when the data can support it; otherwise the study narrows to a simpler, honest estimand.

A common-clock event history should preserve the sequence of hospitalization, delirium, device removal, transfer, withdrawal, communication loss, and death. Transition intensities may depend on prior events, so the model should allow one event to change both the state process and the chance of later observation. The event history is part of the scientific object, not merely a censoring code (Aalen et al., 2008; Andersen et al., 1993).

The model family should follow the question. Cause-specific or transition-specific hazards describe movement among states; cumulative-incidence functions describe realized event probability in the presence of competing events; illness-death and joint models represent dependence under additional structural assumptions. Reporting one of these as though it answered all three questions is a category error (Andersen et al., 1993; Fine & Gray, 1999; Fine et al., 2001).

A multistate model estimates transition patterns under a declared model and population. Its scientific value lies in distinguishing those event processes and the outcome domains attached to each state.

17.6.3 — Transfer, Discharge, and Withdrawal

Transfer, discharge, and withdrawal end one observation route without necessarily ending care, life, or conscious experience. The study should preserve the reason, timing, permission status, and destination of each exit so that institutional boundaries are not mistaken for scientific endpoints (Andersen et al., 1993; Hernán & Robins, 2020).

The transport file must retain cause-specific endings, withdrawal rules, registry linkage, and context change. The resulting file supports honest transport analysis and exposes assumptions that would otherwise remain implicit.

A participant may transfer to another facility where clinical records continue but research permission does not. The study must stop the research stream unless a separately authorized linkage applies. Continuing the row because data are technically accessible would erase the difference between care continuity and research authority.

The design must answer whether separately authorized linkage can continue observation after the setting and permission change. If it cannot, inference stops at the supported window. The local result retains the status its evidence earns; any continuation claim is classified according to its remaining identification and uncertainty.

Evaluation should leave out transfer routes, discharge classes, and withdrawal categories before claiming transport across endings. If the finding disappears when one exit route is separated, the exit is part of the data-generating process and cannot be buried in generic dropout.

Every ending receives a typed mark, including transfer, discharge, voluntary withdrawal, loss of contact, site closure, device loss, and endpoint. Analyses test whether conclusions depend on grouping those routes together. When the destination or permission status is unknown, the uncertainty remains visible rather than being recoded as generic dropout.

Treat care change, burden, privacy, family decision, institutional boundary, and research fatigue as typed causes of exit rather than generic dropout or a scientific endpoint.

17.6.4 — Survivor and Immortal-Time Bias

Survivor and immortal-time bias arise when comparison requires a person to remain alive, enrolled, or observable long enough to enter a group. The apparent stability of a later cohort may therefore reflect the conditions required to survive or comply, not a common change in experience. Risk sets must be defined before trajectories are compared (Frangakis & Rubin, 2002; Fine & Gray, 1999).

The evidentiary dataset should carry landmarks, time-dependent exposure, risk sets, and survival-conditioned analyses. Such provenance is necessary to separate an effect from the infrastructure that generated the data.

Participants who complete thirty days of prompts may appear more stable simply because people with rapid decline, transfer, distress, or device intolerance could not complete them. Comparing completers with noncompleters after the fact makes future survival part of group membership. Landmark and time-dependent analyses are needed to restore a fair comparison.

The local claim collapses if the easiest lives to follow can become the apparent theory. Because the failure can mimic support, it belongs in the confirmatory gate rather than in a post hoc limitation paragraph.

Evaluation should use landmarked risk sets and time-dependent exposure definitions rather than comparing people who could not have had equal observation time. The test should ask whether the same result holds before survival has selected the sample that makes the trend easy to see.

Every comparison reports its risk set, eligibility rule, and required survival time. Immortal periods are assigned correctly, and analyses repeat at prospectively chosen landmarks. A trajectory visible only among selected survivors is labeled survivor-conditioned.

Late trajectories are most informative when their selection conditions are visible. Stability among participants who remain able to respond may reflect retained capacities, observation selection, or both. Comparing those explanations helps establish which population the finding describes.

17.6.5 — Principal-Stratum and Survivor-Average Limits

Principal-stratum and survivor-average estimands address carefully restricted questions under truncation. They may describe people who would survive or remain observable under specified conditions, but membership is usually not directly observed and requires strong assumptions or bounds. Their narrowness is the meaning of the estimand, not a defect to hide (Kurland et al., 2009; Rizopoulos, 2012).

The evidentiary record requires principal strata, survivor average effects, open-channel strata, sensitivity ranges. Their purpose is to preserve the difference between the phenomenon, its observation process, and the analyst's reconstruction.

A terminal-window analysis among people who remain communicative and device-tolerant describes that defined subgroup. The principal result names its population and selection process; separate analyses address rapid communication loss, device burden, and other care pathways.

The study should stop short of interpretation when survivor-specific answers could be mistaken for answers about everyone. The scientific cost is a narrower claim, and that cost should be paid in the headline result.

The target stratum should be defined before fitting in terms of the counterfactual survival or observability condition that gives the estimand meaning. Because actual membership is generally unobserved, point identification requires assumptions that must be named rather than hidden inside the model. The resulting claim

belongs to that latent stratum, not to all enrolled participants (Frangakis & Rubin, 2002; Zhang & Rubin, 2003).

Sensitivity analysis should vary the assumptions linking observed covariates, survival, observability, and latent stratum membership. When plausible assumptions yield materially different estimates, the study reports bounds or multiple stratum-specific results rather than selecting the most favorable specification. A survivor-average result is never translated into an average for the complete enrolled cohort.

17.6.6 — No Composite That Hides Death

Composite outcomes can simplify a table while hiding the event that determines meaning. Death, withdrawal, transfer, device failure, deep sedation, distress-triggered discontinuation, and nonresponse differ in irreversibility, information loss, and clinical significance. They should remain typed before any summary is considered.

The estimand must name whose trajectory it concerns. A while-alive mean, survivor-average quantity, composite endpoint, principal-stratum contrast, joint longitudinal-survival parameter, and component-specific cumulative incidence answer different questions. None is a neutral default, and the choice should follow scientific meaning rather than the curve that looks cleanest (Frangakis & Rubin, 2002; Kurland et al., 2009).

Multistate and competing-risk models preserve distinct pathways when the data support them. Death is represented as a terminal clinical event, while transfer and withdrawal retain the

documented routes through which observation ended (Andersen et al., 1993; Fine & Gray, 1999).

Joint models link longitudinal outcomes and event hazards through assumptions about shared random effects, functional form, and unobserved values. Sensitivity analyses should vary those links and compare selection, pattern-mixture, and joint formulations. Disagreement across plausible structures widens or changes the verdict; it should not be hidden behind one preferred model (Rizopoulos, 2012; Scharfstein et al., 1999).

A composite is interpretable only when its components share a defensible meaning and no component silently dominates. Component-specific incidence, event timing, risk sets, and leave-one-component-out analyses should appear beside the summary. If the interpretation changes when death or another event is removed, the component analysis governs. This prevents a stable composite score from concealing opposite trends in death, withdrawal, and other competing events.

Every death-truncated estimate should include a denominator panel showing the numbers enrolled, alive, observable, responding, and analyzed at each time, together with the counterfactual population invoked. The curve exists only because particular participants remained in the risk set, and that dependence should be visible (Fine & Gray, 1999; Kurland et al., 2009). Showing these denominators over time also reveals whether an apparently smooth trajectory is increasingly driven by a small selected subset.

Public language must follow the estimand. A while-alive average does not describe the unobserved experiences of those who died, and a survivor trajectory does not represent the full enrolled cohort. Precise naming prevents a mathematically valid conditional result from becoming a claim about lives the study did not observe. Where several estimands are scientifically useful, reporting them side by side can show how conclusions depend on survival conditioning rather than hide that dependence.

Models may estimate observation probabilities or bounded while-alive outcomes, but they cannot silently impute a complete phenomenal continuation after the target is no longer observable. When outcome, observation, endpoint, or target-existence uncertainty cannot be bridged, the appropriate result is narrower inference, an identified set, or No adequate estimate. Sensitivity analysis should state which unobserved continuations would be required to change the conclusion without presenting those hypothetical paths as measured experience.

17.7 — Versioning, Drift, and Transport

A life-course study is itself a life-course object. Its instruments age, staff change, sites learn, vendors update, populations shift, language versions improve, and clinical standards move. A long record without version accounting can confuse the history of the study with the history of the participant (Dahabreh et al., 2019; Pearl & Bareinboim, 2014).

Validation should follow the deployment question: forward within-person tests for future intervals, blocked temporal folds for new periods, leave-person-out tests for new individuals, leave-site-out tests for transport, and leave-device-version-out tests for technological migration. Random observation-level splits leak dependence and are outside the confirmatory rules.

17.7.1 — Measurement Version Ledger

A measurement version ledger makes the history of the instrument queryable alongside the history of the participant. Item wording, language, accessibility mode, device, firmware, algorithm, preprocessing, staff training, and consent materials are recorded at person-time resolution because each can alter the observed variable. This ledger is the provenance layer; transport analysis begins only after it can reconstruct which version produced every datum (International Council for Harmonisation, 2026; National Institute of Standards and Technology, 2020).

The ledger should distinguish changes that affect cadence, origin, unit, sign, missingness, or target population. Minor software patches and major construct revisions do not receive the same treatment. Each change is assigned a bridge, segmentation,

recalibration, or retirement decision before the post-change data are merged with the earlier series.

A wording update that reduces apparent burden halfway through follow-up may reflect improved clarity rather than improved life. Without the exact version dates and overlap evidence, the curve cannot tell the difference. The ledger lets analysts reproduce which question, device, and algorithm produced every value.

The hardest competing account is that unmarked version boundaries can create false path continuity. If it explains the data better, the result should be presented as evidence for the rival or as an unresolved model comparison.

A version ledger should include a null feature expected not to change with the person, such as a technical quality metric or calibration fixture. If that feature shifts at the version boundary, the study has detected the measuring system moving under its feet.

Measurement history must be retrievable for any observation, table, model, or public figure. Analysts should be able to rerun results by version and identify which claims depend on a superseded instrument. Longitudinal evidence is not reproducible when the measurement system has no memory of its own changes.

A version ledger should be paired with a dependency graph. Each change in question, language, device, firmware, preprocessing rule, feature extractor, endpoint classifier, or analysis package should point to the estimates, figures, and public artifacts it may affect. Long evidence needs this propagation map because the

measuring system changes while the cohort is still being followed.

17.7.2 — Site and Era Effects

Site and era effects include care philosophy, staffing, referral patterns, technology, population composition, language, and historical practice. They may change observation and outcome together, so a site intercept alone is often insufficient. The protocol should describe the setting as part of the scientific object (National Academies of Sciences, Engineering, and Medicine, 2019; Särkkä, 2013).

Site and era variables should enter the design at the level where they operate, with site-specific clocks, device ecosystems, care processes, and calendar changes preserved. Partial pooling is evaluated against leave-site-out and leave-era-out performance. A stable average does not establish that the same process generated each setting.

One hospice may protect quiet and collect few terminal measurements, while another documents every monitor reading. The resulting trajectories differ before any difference in participants is considered. A transport analysis must decide whether it is moving a person-level relationship, a care-system relationship, or a mixture of both.

The design must distinguish the target from the possibility that site effects can be care ecologies rather than nuisance intercepts. The analysis must be capable of returning this rival as the winner, with the target claim narrowed to the residue it actually explains.

Site checks should include leave-site-out prediction, era indicators, and at least one site-level negative control. If a hospice, clinic, or device vendor can predict the trajectory better than the substantive variables, the result belongs first to place and era.

Claims of transport are withheld until site and era effects have been modeled, stress-tested, and reported. If the signal is local to a care ecology, that locality becomes part of the finding. Place is not a nuisance when place helps generate the evidence.

Site and era effects should be modeled as potential interactions, not only as nuisance intercepts. A quiet hospice, crowded ward, home-care program, and technology-rich clinic may alter observation cadence, treatment pathways, device wear, family presence, and endpoint adjudication differently over time. Transport requires evidence that the mechanism and measurement bridge remain stable across those changes.

17.7.3 — Response and Device Drift

Response drift and device drift are distinct sources of nonstationarity. Participants may change standards, vocabulary, trust, or reporting habits while sensors age, firmware changes, and algorithms update. The study should include anchors and technical diagnostics capable of separating those movements (Shcherbina et al., 2017; Bent et al., 2020).

Anchor-stability tests, device-quality controls, overlap requirements, residual diagnostics, and thresholds for splitting or relinking a series are prospectively specified. Drift is adjudicated before substantive interpretation of the affected interval, and the

bridge method cannot be chosen because it preserves the preferred trend.

A participant may rate pain differently after learning the illness vocabulary, while a wearable update changes the apparent sleep score in the same month. A stable combined trajectory can therefore hide two moving scales. Parallel anchors and version-specific residuals are needed to locate the change.

An equal-status rival is that stable numerical scores conceal changing construct meaning. When the protocol-fixed comparison favors that account, the result is measurement-version or response-shift evidence, and Law-specific interpretation is withdrawn from the affected analysis.

Drift analysis should separate changing response standards from changing device behavior. Anchor items, overlap samples, device holdouts, and residual checks can show whether the person, the instrument, or both moved. The result should name the source of movement before it interprets direction.

When drift is detected, the series is segmented, bridged with independent evidence, or carried as an identified set. Uncertainty is widened only when it honestly represents the remaining ambiguity. A common scale is withdrawn when the person and device movements cannot be separated.

Drift monitoring should specify thresholds, detection delay, and action. Prompt learning, changing response standards, trust loss, vocabulary growth, sensor aging, and algorithm updates can produce gradual shifts that evade a single overlap check. The

study should test both abrupt and delayed drift before calling the pattern a human trajectory.

17.7.4 — Bridge Samples and Overlap

Bridge samples create evidence for linking old and new measurement systems. They require overlap in time, participants, states, or calibration fixtures and should include difficult cases where the mapping is most likely to fail. A bridge learned only from stable, high-quality observations may not apply at the states that matter most (Dahabreh et al., 2019; Pearl & Bareinboim, 2014).

The bridge plan should freeze parallel-device periods, dual items, overlap sample sizes, subgroup coverage, link functions, and acceptance criteria. The old and new systems are analyzed separately until the bridge passes held-out checks. Continuity is an empirical result, not a consequence of deploying the replacement on the next day.

Old and new wearables worn together during a transition can reveal systematic offsets, state-dependent error, and loss of sensitivity. The overlap should include motion, illness, sleep disruption, and other challenging conditions, not only quiet calibration periods. A bridge that works only in easy states cannot carry the full longitudinal series.

Linking fails when bridge error changes sign or scale across clinically relevant subgroups, devices, or states. The study should then retain version-specific estimates or narrow the target population. A single correction factor is not allowed to conceal differential transport failure.

Overlap is the honest price of merging old and new systems. A bridge period should be analyzed as its own estimand: how close are the two systems, for whom, under what contexts, and with what residual bias? Without that answer, a merged line is only a visual convenience.

Merged analysis begins only after the bridge meets prospectively declared accuracy and invariance criteria. Raw version-specific values remain available for audit and sensitivity analysis. When overlap is inadequate, the record contains an explicit break rather than an invented continuity.

Bridge samples should estimate more than a mean offset. Old and new instruments must be compared for nonlinear distortion, variance change, threshold movement, differential missingness, and subgroup-specific error. When those structures do not transport, the program reports a version break rather than hiding incompatibility under a merged line.

A bridge is useful only within its support. If the overlap sample contains healthy, highly connected users while the post-change cohort includes advanced illness or limited digital access, calibration may not transport. Transportability analysis should therefore compare covariate support, reweight the bridge where justified, and report regions with no overlap rather than extrapolate silently (Pearl & Bareinboim, 2014; Dahabreh et al., 2019).

17.7.5 — Transportability Analysis

Transportability analysis states where the model was learned, where it is intended to apply, which variables link the settings,

and which mechanisms are assumed stable. Performance in the source population is only the starting point; the target population supplies its own calibration, observation, and construct challenges (National Academies of Sciences, Engineering, and Medicine, 2019; Särkkä, 2013).

The reproducibility package should preserve source S , target T , bridge variables Z , selection, effect modification, and external-validity assumptions. The package should permit a skeptical reader to follow every transformation from observation to estimate.

Transport scaffold. Role: declaration of the source setting, target setting, and bridge variables required for a specific estimand; it is not evidence that the estimand travels.

The source setting S supplies the fitted relation, the bridge variables Z encode measured differences relevant to selection or effect modification, and the target setting T defines the population and observation conditions to which the claim is proposed to move.

The transport question is component-specific: after accounting for Z , measurement version, observation process, care context, and common-support limits, does the same estimand retain its meaning and calibration in T , or must the result remain local (Dahabreh et al., 2019; Pearl & Bareinboim, 2014)?

Numerical performance can travel while meaning does not. A model may preserve prediction rank but lose neutral origin, response unit, channel validity, or the relation between proxy and

lived experience. Transport claims should therefore report both predictive transfer and construct-level bridge evidence.

Transportability checks should ask whether the time grid itself travels. A cadence tolerated in a research hospice may be unsafe in home care, too slow for acute illness, or too intrusive in a work setting. If the original observation schedule cannot ethically be used in the target setting, transport requires a validated observation bridge for a permissible schedule.

Every transported result names source and target populations, estimand, bridge variables, overlap support, measurement and observation versions, and assumptions about effect modification. Extrapolation beyond common support is labeled model-dependent. When the target lacks the required bridge, the study reports nontransport rather than universalizing the source estimate.

A transport audit should return component-level outcomes rather than one global pass. Predictive ranking may travel while neutral origin, response unit, observation cadence, or reserve validity fails; a site effect may be transportable within one care system but not another. The final report therefore states which bridge passed, which failed, and which claim remains source-bound (Dahabreh et al., 2019; Pearl & Bareinboim, 2014).

17.7.6 — Reanalysis After Major Change

Changes in site, device, instrument, language, care practice, population, schema, or endpoint rule trigger reanalysis, not cosmetic updates. The change record should identify affected estimands, models, figures, public claims, validation layers, and

withdrawal conditions, plus the person or body authorizing the change (International Council for Harmonisation, 2026; National Institute of Standards and Technology, 2020).

Validation must match the new use. Forward-chaining, blocked-time, and person, site, era, or device-version holdouts expose dependencies hidden by random row splits. A lower honest score for that split supersedes a higher leaked score.

Reanalysis starts with the affected clock and context. Changes may alter sampling interval, time since event, device lag, burden, care workflow, or prompt meaning without changing the script. Label results confined to the old cadence or setting accordingly.

A measurement-version graph identifies each node's instrument, language, device, firmware, scoring rule, preprocessing pipeline, schema, and context. Bridge evidence must support every edge. Otherwise the graph remains disconnected, and earlier values cannot be silently standardized to the new version.

Bridge studies use prospective overlap when feasible, running old and new versions in parallel long enough to estimate differences in meaning, thresholds, error, burden, and order effects. A bridge established in a low-burden population does not automatically transport to serious illness or low-access states and must be retested when the intended claim reaches them.

Schema migration is scientific work. Renaming variables, collapsing categories, revising missing-value codes or units, and altering derivations can change an estimand without visible code changes. Machine-readable data dictionaries and derived datasets

should preserve source-schema provenance (Little & Rubin, 2019; National Institute of Standards and Technology, 2020).

Evaluate transport component by component. A measurement bridge may travel when a clinical prediction model does not; a state representation may travel when an endpoint classifier fails; a treatment contrast may require reweighting. Reports should identify which components crossed the boundary and which stayed local (Dahabreh et al., 2019; Pearl & Bareinboim, 2014).

The version ledger enables correction. If a calibration, instrument, code path, or public interpretation proves defective, the program should identify dependent estimates and artifacts, reanalyze where possible, and withdraw unsupported claims. Long-running studies earn trust by making changes and reversals inspectable, not by pretending every edition was always current.

17.8 — Purpose Limits and Participant Return

Life-course data are unusually revealing because time itself is identifying. A record of sleep, movement, prompts, medication, visits, pauses, transfers, and family context can describe a person more intimately than a single sensitive variable ever could (Nissenbaum, 2010; National Institute of Standards and Technology, 2020).

Longitudinal design is not complete until it states what data may be used for, what may not be linked, what may be returned, what can be challenged, how long records persist, and what happens when the study ends.

Federated analysis, secure computation, provenance, and minimization are part of scientific validity. They shape who participates, who remains observable, what can be audited, and how safely sites can collaborate.

17.8.1 — Operational–Research Firewall

The operational-research firewall separates data created for care or administration from data collected under a research purpose. Availability inside a clinical system does not supply consent, lawful authority, construct validity, or permission for secondary modeling. The protocol should document the route by which each data class enters the study and the purpose that limits its use (Nissenbaum, 2010; National Institute of Standards and Technology, 2020).

The technical file should make visible separate permissions for observation, linkage, sharing, publication, model training, and

reuse. These variables anchor the comparison to the actual participants, windows, instruments, and decisions that produced it.

A clinical note written to treat pain is not automatically permission to train or apply a momentary-valence estimator. The note may use shorthand, reflect a care decision, include bystanders, or be shaped by billing and workflow. Research use requires a separately approved purpose, minimization plan, access boundary, and validity assessment.

A replication team should be able to evaluate whether record linkage can create a cross-domain dossier. The finding is not portable until this question can be answered from the record rather than from investigator memory.

The firewall should specify the cadence of permission as well as the cadence of measurement. Consent for one extraction, one linkage, one analysis window, or one return of results does not silently authorize ongoing observation. Permission itself has a time structure.

Operational data cross into research only through a documented authority, context-of-use qualification, provenance record, and revocable access path where feasible. The transfer is auditable and does not expand the original record into a general-purpose archive. When those conditions are absent, the scientific question does not inherit the data.

The purpose, permission, and provenance route define whether a clinical, City, government, religious-community, or Workgame record is eligible for a particular research question.

17.8.2 — Participant-Facing Results

Participant-facing results are communications, not private scientific verdicts. Returned information should be valid for the individual, requested or consented to, understandable, and consistent with the study's clinical and ethical plan. Group findings and unstable research constructs are not personalized merely because a dashboard can display them (Rieke et al., 2020; National Academies of Sciences, Engineering, and Medicine, 2018).

The core record must include return classes, uncertainty labels, desired feedback levels, and challenge routes. They make the claimed object recoverable rather than leaving it implicit in a polished figure.

A sleep summary may help a participant when it clearly identifies missing nights, device changes, uncertainty, and the difference between an observation and a research inference. Comprehension testing should confirm that the display does not imply diagnosis, prognosis, or a hidden reading of the person's inner life.

The participant-protection review must test whether returned graphs can feel like diagnoses. If the answer is yes, participant protection takes priority and the scientific claim must narrow accordingly.

Participant return has its own timing rule. Immediate feedback may change behavior, delayed feedback may lose relevance, and no feedback may be safest for some measures. The design declares when return is useful, optional, or withheld because validity is insufficient.

The return plan states which outputs may be shared, who reviews them, how questions are answered, and when nonreturn is the safer choice. Results that are invalid at the individual level remain in aggregate research reporting. Desire to be transparent does not justify returning an interpretation the study cannot support.

Participant return must be modest enough not to become a verdict. A person may want understandable summaries, data errors corrected, or aggregate findings explained; they may also want no feedback at all. Return is a relationship of respect, not a delivery channel for hidden judgment.

Participant-facing summaries should separate collective findings from individual interpretation. A clear summary can explain what the study measured, which groups were represented, what uncertainty remains, and what changed because of participant contributions. It should not return a personal ledger estimate, endpoint forecast, route classification, or claim about inner truth. The difference between gratitude and overreach is often one sentence, and the protocol should write that sentence before recruitment.

Return formats should also be accessible and revisable. Plain-language text, large-print versions, translations, audio, and supported discussion may be needed, while some participants may prefer no return at all. If a published result is corrected or withdrawn, the return plan should define how participants are notified without creating alarm or implying that their care or identity has changed.

17.8.3 — No Individual Ledger Verdict

The no-individual-verdict rule established in §14.8.3 applies unchanged to longitudinal records. These data may support bounded population or measurement inferences, but they do not determine whether a particular life balanced or how a person should be judged.

Individual-facing outputs may describe observed periods, missingness, device quality, and uncertainty within the qualified context of use. They may not convert a local estimate into a complete-stream conclusion or use it for eligibility, care priority, trust, worth, truthfulness, or spiritual interpretation. Those prohibitions are enforced in schemas, permissions, interfaces, and publication templates.

When a family asks whether a final graph proves that a life reached balance, the answer is that the graph cannot carry that conclusion. The study observed a bounded and imperfect record under specific conditions. Respect for the family includes giving a clear boundary rather than softening an unsupported verdict with technical uncertainty language.

The public record should permit scrutiny of whether individual outputs can become self-surveillance or social judgment. Any unresolved risk should remain visible in the public summary and block overgeneralization.

Uncertainty should not be used to soften an individual verdict that should not exist. The correct output is not a low-confidence judgment about a person's life. It is no individual ledger verdict,

with any usable information returned only in the limited form the protocol permits.

No individual ledger judgment is generated, stored, returned, or made available for secondary use. Any feature or interface that invites such an interpretation is removed or redesigned before deployment. The protocol's value lies in testing scientific components, not administering a hidden account of persons.

17.8.4 — Access, Retention, and Deletion

Access, retention, and deletion are specified separately for identifiers, raw signals, derived features, linkage keys, provenance, code, and aggregate results. Each layer receives the smallest audience and shortest duration compatible with the approved purpose. Retention for unspecified future value is not a scientific justification (Nissenbaum, 2010; National Institute of Standards and Technology, 2020).

Data architecture should distinguish what must remain at the site, what may be shared, what can be computed locally, and what should never be centralized. Federated analysis may reduce transfer of raw data, but it still requires controls for model leakage, reconstruction, local deletion, and audit. Governance follows the information, not merely the file location.

A multisite project may keep identifiers and raw traces within each institution while transmitting approved features or model updates. That arrangement reduces exposure only when the features cannot readily reconstruct the private record and when sites retain authority to stop participation and execute deletion. Aggregate movement is not automatically anonymous movement.

The evidence is not adequate when indefinite storage turns research into an archive of private life. When this condition holds, the affected evidence is Unusable; any narrower descriptive use requires its own valid permissions and protocol.

Uncertainty should include future reidentification and future misuse. A dataset that seems safe today may become identifying when combined with later records or models. Retention policy should therefore be justified by the approved purpose, not by the hope that future analysis might someday want everything.

Retention decisions are linked to named analyses, replication obligations, legal or ethical requirements, and deletion triggers. The record should show why each layer still exists and who can access it. Data that survive only because storage is inexpensive have outlived their approved scientific purpose.

Retention is itself a burden when the record is intimate and long-lived. The study should keep only what its approved purpose requires, separate identifiers from features, and give withdrawal a practical route. A record that cannot end has already begun to behave unlike research.

Table 17.5. Federated-analysis workflow, provenance fields, and minimum data dictionary.

Layer	Minimum fields or action	Scientific purpose	Dignity control
Local capture	person key held locally; time; clock; channel; value; unit; confidence	Keeps time-indexed evidence analyzable.	Identifiable linkage stays at source site.

Layer	Minimum fields or action	Scientific purpose	Dignity control
Observation mark	scheduled; refused; paused; failed; removed; clinical interruption	Models why data exist or vanish.	Refusal and care interruptions remain meaningful.
Version ledger	instrument; firmware; item version; language; pipeline	Separates person change from system change.	Participants can challenge the version that interpreted them.
Feature extraction	approved features, quality flags, burden flags	Reduces raw exposure while retaining estimand inputs.	Minimization before transfer.
Federated analysis	site-local models, disclosure checks, aggregate summaries	Enables multi-site learning without central dossier.	No individual-level pooling by default.
Return and closure	participant choice, deletion status, archive decision, future-use flag	Completes the longitudinal record responsibly.	Study ends without indefinite claim over the person.

17.8.5 — Breach and Reidentification Response

Time-indexed data can reidentify people even after direct identifiers are removed. Rare clinical transitions, sleep rhythms, location patterns, transfer dates, and combinations of events may become unique when linked to external records. Breach planning

therefore covers both unauthorized access and inference from ostensibly deidentified trajectories, with reidentification risk reassessed as variables, sites, publications, and auxiliary datasets change (Rieke et al., 2020; National Academies of Sciences, Engineering, and Medicine, 2018).

The incident plan specifies detection, containment, access suspension, forensic review, required participant and site notification, support, public-artifact review, and criteria for withdrawing or rerunning affected analyses. It also records whether the incident changed completeness, provenance, consent, or permitted access. Silence is not a privacy remedy.

Evidence repair follows the same record. The program may suppress or coarsen features, withdraw affected artifacts, revise minimization and retention, and reassess whether participants can still exercise correction or withdrawal. Impermissible data are Unusable; repaired data may remain Inconclusive or yield No adequate estimate under the canonical evidence-state rules. Privacy failure therefore propagates into scientific validity rather than remaining a separate security note (National Academies of Sciences, Engineering, and Medicine, 2018; Nissenbaum, 2010).

17.8.6 — End-of-Study Closure

Closure determines when the research relationship, datasets, instruments, models, and public claims end. Protocols must specify result communication, unresolved analyses, retention and deletion, future-use limits, correction channels, and responsibility for retired artifacts. This prevents indefinite interpretive power

after completion (World Medical Association, 2024; Council for International Organizations of Medical Sciences, 2016).

Before enrollment, the closure plan fixes archive contents, deletion events, participant communication, failure memory, code and model status, derivative-data handling, and prohibited future uses. The study's ending is part of consent and purpose limitation; it cannot wait until the dataset becomes valuable. The plan should also identify who has authority to certify each closure obligation and what evidence shows that the obligation was actually completed. This turns closure from an administrative date into a verifiable state of the research system.

Participants should receive clear notice of what was learned or unresolved, what will be retained or destroyed, what future use is barred, and where corrections will appear. They should not infer the relationship ended merely because contact stopped. Closure communication should remain understandable and reachable after active data collection ends, especially when a later correction changes how an earlier result should be interpreted. A durable contact route gives participants a practical way to ask about those changes without reopening participation.

Closure should assign final status to usable findings, inconclusive analyses, unusable data, unresolved access questions, and future-use prohibitions. A completed record cannot support stronger claims through reinterpretation without a newly approved analysis, consent basis, and status review. Any later reopening should therefore create a new versioned analytic record rather than silently modifying the closed one. This preserves the

distinction between what the original study established and what a later investigation newly inferred.

Site reconciliation, incident review, fulfillment of retention and deletion commitments, public result registration, retirement notices, and a durable correction contact are completed before closure is certified. Null results, failed recovery, deviations, and rival-favored outcomes remain in scientific memory even when sensitive data are deleted. Reconciliation should verify completion across sites rather than assume that a centrally issued instruction was carried out uniformly. Differences in retention, deletion, incident handling, or version status should be resolved or recorded explicitly before the study is treated as closed.

Every retired dataset, instrument, model, and public artifact should receive a tombstone recording what existed, why it was retired, which successor replaced it if any, and which claims it can no longer support. The tombstone preserves provenance without preserving unrestricted access to private information.

A responsible program ends observation without erasing failure or extending authority beyond consent.

Part VI — Candidate Mechanisms and Causal-Locus Tests

Part VI makes the mechanism program experimentally answerable. Earlier Parts fixed the terminal target, separated latent and measured objects, established stream and endpoint rules, and built the first study families. This Part now asks which mathematical, causal, and embodied processes could generate the discriminating signatures, which ordinary processes could imitate them, and what evidence would support, narrow, or retire each candidate.

The Part begins with completion geometry because possibility precedes explanation. From a declared state and prefix, some future contributions may be reachable and others may not. Reachability sets, viability regions, completion kernels, committers, and boundary-value problems make that distinction explicit. They show what a model permits before anyone claims that nature uses the model.

Path-space methods then expose a second distinction. A process can end in a target set because its native dynamics drive it there, because analysts condition on that endpoint, because a controller steers it, because the endpoint is defined by first hitting, or because selection removes trajectories that do not fit. Doob transforms, Schrödinger bridges, absorbing boundaries, and related constructions are therefore tools for discrimination, not ornaments that confer truth (Doob, 1957; Léonard, 2014; Chetrite & Touchette, 2015).

The Queue model remains as one bounded, partially observed control architecture for unresolved demands, priority, blocking, reactivation, repair, and residual influence. Its value is that each suggestive element becomes a typed state, observation, action,

transition rule, rival prediction, recovery test, and retirement condition. Components that survive earn a clearer scientific role; components that fail can be removed without weakening the wider mechanism program.

Chapter 19 moves from construction to causal location. A model earns scientific force only when it says where an intervention enters, what continuation law changes, and which observable divergence should occur first. Interventions on reports, physiology, action support, medication, information, assignment, or endpoint rules are not interchangeable. The representation gate must remain intact before causal language begins (Hernán & Robins, 2020; Pearl, 2009).

Sections 7.3.4 and 19.4.5 establish the modal distinctions and policy-mixture condition. Here, an observed action sequence counts as completion support only under a frozen continuation regime, adequate support, and the corresponding modal guarantee.

Shadow price enters as a dimensioned sensitivity quantity within constrained optimization. Properly specified, it shows how a local objective changes when a declared constraint is marginally relaxed, with units and regularity conditions that can be checked. That analytic use ends at the model boundary and supplies no moral exchange rate, human price, or permission to tolerate harm.

Chapter 20 brings the body into the mechanism tournament. Interoception, allostasis, salience, stopping, pain, fatigue, medication, disability, trauma, illness, autonomic regulation, endocrine dynamics, and wearable signals may carry, constrain,

or confound route-specific signatures. Each receives a declared channel, lag, baseline, rival, perturbation, and no-inference zone so bodily evidence can become more informative without being mistaken for direct access to lived valence (Khalsa et al., 2018; Barrett & Simmons, 2015).

Three achievements organize the Part: construction, identification, and evidence. Mathematical coherence establishes that an object can be defined; identification asks whether the relevant quantity is determined by the available law and observations; evidence asks whether realistic data recover and transport the promised difference. Keeping those achievements separate prevents elegance, estimability, or reproducibility in one channel from standing in for causal support.

Prospective information discipline protects the Part's strongest tests. Endpoint information stays outside state construction, filtering, feature selection, action choice, and model training unless the declared design permits it. Every information set is time stamped, every outcome-dependent transformation is labeled, and cross-fitting reduces data reuse without excusing a representation that already contains the answer.

Mechanisms operate within lived opportunity. Transportation, care access, medication, fatigue, family obligations, communication, disability, cost, and institutional permission can open or close continuations before any internal controller acts. These conditions enter support, selection, and transport models as causal determinants, allowing the science to distinguish blocked opportunity from preference, motivation, or latent route failure. Opportunity variables should be measured independently of the

candidate mechanism when possible so blocked access is not inferred from the same behavior the route aims to explain.

The Part is designed for mathematicians, causal researchers, neuroscientists, clinicians, engineers, and serious general readers to inspect the same objects at different depths. Equations, tables, and design aids state their role, assumptions, units or type, nearest rival, failure condition, and permissible interpretation. Technical density earns its place when it makes a mechanism easier to recover, compare, perturb, transport, or retire. A technical object that cannot state its failure condition should remain illustrative rather than enter the evidentiary tournament.

Each outcome advances a different scientific task. A route-specific pattern that survives representation, observation, causal, recovery, transport, and equal-budget rival tests earns route-level support and opens a stronger target test. Ambiguity identifies the information or intervention still missing. Rival-favored and Route-failed results retire specific queue rules, path-space constructions, or embodied bridges while preserving the methods, data, and negative knowledge they produced. A route-level update should name the specific discriminating result that moved status, not merely the chapter or mechanism family that was studied.

By Part VI's end, completion appears as distinguishable scientific possibilities. Readers can separate conditioning from native dynamics, steering from selection, absorption from first hitting, belief-state from omniscient control, and embodied mediation from measurement artifact. The map identifies the observations that distinguish these cases. This taxonomy also prevents one

successful construction from being mistaken for evidence that every mathematically similar path arises through the same cause.

The movement is from mathematical possibility to empirical discovery. Mathematical constructions widen the explanations; causal, recovery, and brain-body tests compare them using common information, realistic observation, humane intervention, and equally treated rivals. The mechanism program's promise lies in making these possibilities precise enough for evidence to identify which processes nature actually uses. The strongest mechanism is the one that survives these comparisons with fewer untestable commitments, not the one that can reproduce the widest range of paths.

Chapter 18 — Completion Geometry

Chapter 18 turns a shared terminal appearance into a tournament among path laws. Native dynamics, selection, terminal conditioning, first hitting, absorption, reflection, stickiness, and active control can approach the same boundary while differing in hazard, reversibility, dependence, and perturbation response. Those preterminal differences carry the scientific information that the endpoint picture alone cannot supply.

The chapter advances through five answerable questions. From the current prefix, which future contributions remain attainable? How does a frozen law distribute probability across them? Which information state supports the forecast? What change of measure or control constructs the path? Which held-out observation would distinguish mathematical construction from natural realization? Each question receives its own object so possibility, probability, construction, mechanism, and evidence remain separate.

The primary objects have distinct jobs. A reachability set describes what remains possible. A committor gives event probability under a declared law. A Doob transform constructs a changed path law. A policy changes transitions through an action rule. A boundary implementation specifies approach, contact, dwell, return, and stopping. Their existence establishes coherent mathematics; scientific realization requires identification, recovery, transport, and held-out discrimination.

The distinction between history and state is central. A continuation law may depend on the complete observed prefix. It may be reduced to a state-indexed law only after state sufficiency is justified. Compressing history into a convenient state without

testing that sufficiency can hide the memory or path dependence the program is supposed to measure.

Finite-band completion and exact singleton closure require different conditioning constructions; §18.4 develops the zero-probability-target case and its tightness and uniqueness requirements.

Reachability makes route-level impossibility visible. When the negative of the current residual lies outside the attainable future-contribution set, exact completion is unavailable under the declared continuation class. That finding narrows or defeats the route on its own terms and identifies which horizon, action, information, or ownership restriction produced the obstruction.

Ordinary alternatives enter as full competitors. Viability control, safe reinforcement learning, homeostatic regulation, scarcity, planning, and conditioned Markov processes can all create boundary-sensitive paths. A PTVC-linked route earns priority only through a prospectively specified difference that those rivals fail to recover under the same observations, flexibility, tuning budget, and scoring rule.

Partial observation prevents the mathematics from becoming omniscient. Researchers observe reports, physiology, behavior, context, and missingness, not the phenomenal state itself. A belief-state model can organize uncertainty, but its posterior is a model output, not a private truth and never a human-worth object.

Path-space constructions can look explanatory before they are causal. A bridge ending at zero may display smooth convergence because the terminal event was built into the changed law; an

absorbing process may stop at zero because the boundary rule says so; a selected sample may concentrate near zero because other paths disappeared. The chapter treats each construction as a generator of discriminating preterminal predictions, not as a certificate of natural mechanism.

Consider two models with the same terminal distribution. One uses a local controller responding to the current state. The other mixes endpoint-conditioned bridges. Their one-time marginals may nearly coincide, yet a safe midcourse perturbation, an unexpected endpoint probe, or a held-out action changes the controller's path law and the bridge mixture differently. The experiment belongs at that divergence, where a shared endpoint no longer hides causal structure.

Model recovery is the chapter's empirical gate. Simulated and benchmark data must show that the analysis can recover the correct generator or model family under the planned noise, missingness, cadence, and heterogeneity, and can return an open-set unknown when the generator is absent from the library. A pipeline that confuses native control with conditioning is not ready to interpret human data, regardless of apparent fit.

The chapter leaves the reader with a map of path-space possibilities and a stricter appreciation of elegant endpoints. Even if PTVC narrows or fails, the distinctions among reachability, committers, conditioning, hitting, absorption, partial observation, and recovery remain durable scientific tools. The mechanism program advances by preserving those tools while withdrawing the interpretation that loses.

18.1 — Completion Geometry and Reachability Sets

Let the current signed residual be $L(t) = l$ and let $A_{fut}(t, z)$ denote the set of future signed contributions attainable from the declared state z under ownership-preserving continuations. Exact completion is directionally reachable only if

$$-l \in A_{fut}(t, z).$$

The condition is necessary, not sufficient evidence that a route is realized. The geometry can also be expressed through a residual-solvency set

$$S_{res}(t, z) = \{l: -l \in A_{fut}(t, z)\}.$$

A prefix outside that set is an explicit counterexample for the declared route and continuation class. It cannot be rescued by changing the stream, endpoint, or allowable continuations after inspection.

Convex approximations permit support-function tests. For a closed convex attainable set A , membership of $-L(t)$ can be checked through inequalities against $h_A(a) = \sup_{x \in A} a^\top x$. Nonconvex sets require richer geometry, and a convex relaxation must be labeled as a relaxation rather than the true continuation support.

For several active streams or coupled resources, joint reachability must preserve coordinate provenance. A shared resource can constrain several streams, but one stream's phenomenal contribution cannot cancel another's unless a separately named junction or transfer theory is under test. The geometry must not reintroduce cross-stream trading through notation.

Empirical use requires estimating the attainable set without outcome leakage. Training data, policy restrictions, care context, and action availability define the set; held-out prefixes then test whether observed continuations remain inside it. A set widened until every history becomes reachable has no discriminating power.

18.1.1 — State Prefixes and Future Cones

A state prefix is the complete information object declared at analysis time: the stream-owned residual coordinate, route state, observation history, action history, endpoint-information state, and uncertainty carried forward from earlier measurements. Its future cone is the set of continuations still admissible under the protocol-fixed dynamics, ownership rules, action support, and care constraints. Both objects must be fixed prospectively, because a cone reconstructed after the endpoint can silently import the outcome it is supposed to predict (Aubin, 1991).

The prefix is not the person and it is not the person's entire life. It is a model state built for one scientific question. A richer prefix may improve prediction while making identification worse, especially when it includes variables that are descendants of the endpoint or of the intervention being evaluated. A defensible model therefore distinguishes what is known, what is latent, what is estimated, and what remains outside the representation.

A future cone is broader than the path that eventually occurs. One realized continuation cannot be used to declare every unrealized action or environmental change impossible. The scientific task is to estimate how the cone contracts or changes shape as

information arrives, then test whether the observed continuation obeys restrictions that were visible before the outcome. Retrospective pruning makes any path look inevitable and therefore destroys discrimination.

Action support belongs inside the cone. Transportation, communication, care access, symptom burden, institutional permission, family obligations, and physical capacity can open or close continuations independently of any candidate completion mechanism. A geometry that assumes unavailable actions will misclassify structural deprivation as a property of the latent route.

The cone must also preserve route ownership. A shared resource may alter several streams, but one stream's future phenomenal contribution cannot be inserted into another stream's cone. Junctions, partition, fusion, and continued-stream branches require their own typed routing rule. These rules preserve per-stream accumulation within the multivariate model.

Partial observation turns a single cone into a family of plausible cones indexed by the current belief state. A narrow point estimate may hide radically different futures that remain compatible with the data. Robust analyses report an inner cone supported across declared uncertainty and an outer cone that includes all plausible continuations, rather than presenting one estimated frontier as known fact.

A concrete test begins with held-out prefixes. The team freezes the state representation and dynamics on training data, computes the admissible cone for each held-out prefix, and asks whether observed actions, state changes, and endpoint-independent

outcomes remain inside it. Systematic cone violations are evidence against the route or representation, not a reason to widen the cone after inspection.

The central payoff is prospective vulnerability. Once a prefix and cone are frozen, the model can be wrong because it excludes an observed continuation, includes almost everything, depends on future labels, or changes materially under reasonable uncertainty. A future cone that cannot fail is not geometry for science; it is a retrospective story drawn around the path that happened.

18.1.2 — Signed Reachability Under Finite Opportunity

Signed reachability asks whether the continuation set contains enough contribution in the direction required by the current residual. Large remaining variability is not sufficient. A process may still fluctuate widely while lacking the sign, magnitude, timing, or route ownership needed for completion. The relevant condition is directional inclusion of the required opposite-signed contribution, not generic capacity or emotional intensity (Aubin, 1991).

Finite opportunity makes this condition sharp. Remaining time, physiological reserve, action access, reportability, social permission, and environmental support jointly bound what can still occur. The bound is model dependent and uncertain, but it cannot be replaced by the statement that something helpful might happen. A route must identify a feasible continuation under the declared horizon and constraints.

Reachability should be computed on phenomenal contribution rather than on an untyped behavioral proxy. A conversation,

medication change, rest period, or institutional remedy may alter future experience, but the action itself is not a signed valence increment. The model needs a separately validated transition from action and context to the distribution of future phenomenal contribution.

Direction matters most near constrained boundaries. A strongly positive residual requires access to sufficiently negative future contribution on the additive branch, while a strongly negative residual requires the opposite. That formal statement is not a prescription to create pain or pleasure. Harm induction is outside the admissible action set, and ordinary care continues regardless of what the reachability calculation returns.

Uncertain opportunity yields an identified set rather than one answer. Some prefixes may be reachable under every plausible horizon, some under only a subset, and some under none of the declared continuations. Reporting these classes is more informative than averaging over endpoint scenarios and calling the mean reachable.

Ordinary rivals can explain directional asymmetry. Goal structure, avoidance learning, symptom limits, opportunity cost, social support, and treatment response may make one sign of future change more available than the other. A PTVC-linked route earns support only if its signed reachability restrictions outperform those alternatives under the same state and action information.

A held-out failure is decisive for the declared route class. If the required contribution lies outside the estimated continuation

support and the endpoint still occurs under the declared branch, the route cannot be rescued by revising the endpoint, reassigning ownership, or inventing unobserved capacity after the fact. The appropriate result is Route-failed, reference-class narrowed, or No adequate estimate.

18.1.3 — Viability, Solvency, and Closure Regions

Viability, solvency, and closure answer different questions. A viability region contains states from which at least one admissible policy can respect declared constraints. A solvency region adds the requirement that the current signed residual can still be offset by attainable future contribution. A closure region is stronger still and must specify whether closure is possible under one policy, probable above a threshold, supported under every admissible policy, or guaranteed on a declared branch (Aubin, 1991; Aubin et al., 2011).

These regions should be nested only when the assumptions justify nesting. A state may be viable because safe functioning can continue while being insolvent for the signed completion target. Another state may be solvent under one narrow policy but not under ordinary policy variation. Collapsing the regions hides which part of the argument is doing the work.

Solvency is direction-specific and route-specific. A positive and negative residual of equal magnitude need not have symmetric continuation sets, because available actions, bodily reserve, context, and endpoint support may differ by sign. A single radial distance from zero can therefore conceal the geometry that matters most.

Uncertainty creates nested reachability regions. The inner region contains prefixes that satisfy the criterion across every declared parameter, state, and horizon compatible with the data. The outer region contains prefixes that satisfy it under at least one admissible specification. Their difference is an identified uncertainty region, not a smooth probability gradient, and the final display should preserve that distinction.

A clinical example separates ethical permission from geometric identification. A participant may remain within comfort and consent constraints while the candidate route is not estimable because the observation channel has shut down. The protocol may remain ethically permissible while geometric viability and solvency remain unidentified. That uncertainty should stop the affected inference without changing care or implying anything about the person's life.

The region boundary can be tested through safe perturbations that change action support or information without changing the endpoint definition. Opening a communication route, correcting an institutional barrier, or observing a clinically indicated treatment transition may move the estimated state. A route-specific model should predict which boundary moves and by how much.

Approximation error belongs beside the region. Numerical grids, convex relaxations, surrogate dynamics, and finite samples can shift a narrow frontier. If classification changes under reasonable discretization or model uncertainty, the result is a band or no estimate, not a crisp geometric verdict.

A closure region built by excluding nonclosing paths is circular. The scientific object must be derived from independently specified dynamics, constraints, and observations, then evaluated on held-out continuations. Otherwise the region proves only that the analyst encoded the desired endpoint.

The practical value of these distinctions survives PTVC. Viability theory clarifies when safe action remains possible, solvency analysis clarifies directional capacity, and closure regions clarify which additional assumptions turn possibility into stronger modal claims. Their scientific discipline lies in naming exactly which region has been estimated and which stronger region has not.

18.1.4 — Geometry Under Uncertain Endpoints

Endpoint uncertainty changes the geometry of completion before it changes any estimate. A fixed horizon gives one future cone, but a distribution over possible endpoints gives a family of cones indexed by stopping time, branch, and information state. The relevant object is therefore not one attainable set but a set-valued map from each prefix and endpoint scenario to the signed continuations that remain possible. A route that is reachable at one generous horizon may be impossible at a shorter horizon, and that difference cannot be repaired by averaging the two cases (Aubin, 1991).

Several geometric summaries are possible, and they answer different questions. The union across endpoint scenarios asks whether completion remains possible somewhere. The intersection asks whether it remains possible under every declared scenario. A probability-weighted region asks how much endpoint

mass lies over solvable continuations. None of these objects is equivalent to exact closure at the truth-level endpoint, and each should carry its own status label rather than being collapsed into a single shaded region.

Consider a longitudinal clinical cohort in which remaining observation time is uncertain because illness trajectories differ and follow-up can end for several reasons. A participant may have many future actions under one prognosis and very few under another, while the scientific team knows only a calibrated distribution. The geometry should preserve that uncertainty instead of treating the most favorable horizon as available to every path. Comfort, treatment, and withdrawal remain outside the optimization target and are never adjusted to make the geometry easier.

Uncertain endpoints also create leakage hazards. A model trained with realized time-to-end can learn a future label that was unavailable at the prefix being evaluated. It may then appear to identify narrowing reachability when it is merely reading hindsight. Prospective estimation must use only information available in the declared filtration, and endpoint models should be cross-fitted or frozen before they are used to construct a future cone.

Ordinary rivals can create the same apparent contraction. Frailty, age, disease progression, medication changes, resource loss, and institutional closure can all reduce available continuations without any fairness-specific route. The test is not whether options shrink, but whether the signed, route-owned geometry shrinks in the pattern jointly predicted by the candidate

mechanism after those rivals receive the same endpoint information and action constraints.

A useful result may be a bounded statement rather than one boundary. The analysis can report prefixes that are solvable across all plausible endpoints, solvable only under some horizons, or nonadjudicable because endpoint support is too uncertain. If the apparent empirical result depends on using retrospective endpoint knowledge as a prospective input or on choosing a favorable horizon after inspection, the confirmatory comparison fails its information or protocol gate and the affected evidence is Unusable. A route that necessarily requires unavailable future information is inadmissible under the declared information constraints; an empirical Route-failed verdict requires a valid test.

18.1.5 — Topology, Disconnected Supports, and Hidden Barriers

Reachability is not determined by distance alone. An attainable set can be disconnected, folded around forbidden states, or concentrated on a lower-dimensional support. Two states that are numerically close may be separated by an action barrier, a routing rule, a safety constraint, or a zero-probability transition. Topology therefore decides whether a seemingly short path is actually available (Aubin, 1991; Aubin et al., 2011).

Convex relaxation is useful but dangerous. Filling the gaps between disconnected components can create synthetic continuations that no admissible dynamics can realize. A relaxation should be labeled as an outer bound and tested against

the original nonconvex support, especially when the conclusion depends on a narrow bridge between components.

Hidden barriers can be material. A treatment exists but is inaccessible, a communication device is unavailable, an institution has no appeal route, or a person cannot safely take the modeled action. Those restrictions belong in the action support. Omitting them makes the model attribute externally imposed barriers to the stream or its policy.

Barriers can also be informational. Two latent states may produce nearly identical observations while permitting different futures. The apparent connection between their estimated cones may disappear once the belief state is represented. State aliasing is therefore a topological problem in the inferred state space, not merely a measurement nuisance.

A route may cross a barrier only through a junction event such as partition, fusion, return, or a change in endpoint branch. Such events require typed rules and prospective evidence. They cannot be invoked as invisible tunnels whenever ordinary reachability fails.

Concrete simulation should include obstacles rather than only smooth landscapes. A model can compare Euclidean distance, geodesic distance on the admissible set, and actual hitting probability under the protocol-fixed dynamics. Divergence among those quantities reveals when a simple residual norm is an inadequate summary.

Ordinary models may explain the same disconnected support. Habit, learned avoidance, legal restrictions, symptom thresholds,

finite resources, and safe-control constraints can all carve the action space. A fairness-specific route must therefore predict a distinctive change in connectivity or transition probability, not merely observe that barriers exist.

The public boundary is exact: a state outside a model's connected component is not a person declared trapped, doomed, or deficient. It is a statement about one formal system under assumptions. The repair may be to change the environment, expand access, revise the representation, or retire the model.

Topology earns its place when it produces a falsifiable consequence. The model should identify which observed transition would cross a forbidden barrier, which safe intervention should open a passage, and which held-out paths should remain impossible. If every surprise is explained by adding a hidden tunnel, the topology has stopped constraining the theory.

18.1.6 — Testable Consequences of a Reachability Map

A reachability map becomes scientific when it predicts more than terminal compatibility. It should identify prefixes that will lose sign-specific options, actions expected to reopen or close a route, uncertainty changes that move the frontier, and observations that falsify the estimated dynamics. Those predictions are frozen before the continuation is observed, then evaluated with the same recovery and scoring rules applied to rival geometries (Aubin, 1991; Aubin et al., 2011; Wilson & Collins, 2019).

One consequence concerns boundary crossing. If a prefix is classified outside the outer solvency region, then no continuation in the declared class should achieve the required signed

contribution. An observed qualifying continuation is a counterexample to the map or its assumptions. The analysis cannot preserve the map by moving the boundary after the fact.

A second consequence concerns intervention sensitivity. An action that genuinely changes opportunity, reserve, or route state should alter the attainable set in a specified direction. A sham action matched for attention or expectation should not. The contrast separates structural change from generic reactivity.

A third consequence concerns calibration. Predicted inner-region membership should correspond to conservative empirical coverage, while outer-region membership should not be treated as a guarantee. Reliability diagrams, set coverage, and false exclusion rates are more informative than one global accuracy score.

Transport tests whether a geometry retains its declared invariants when the observation system, action menu, site, or population changes within a defined transport class. The target state and ownership rule remain fixed, while only the declared destination components may be recalibrated. Failure narrows the route to the conditions in which the geometry was learned instead of supporting a universal mechanism.

Model recovery must precede interpretation. Simulated paths from viable control, ordinary scarcity, endpoint-conditioned bridges, and the candidate route should use the same estimator. If the pipeline cannot recover the generating geometry under realistic noise, missingness, and state aliasing, real-data frontier labels are not trusted (Villaverde, 2019; Wilson & Collins, 2019).

Negative controls are equally important. Variables that alter reporting cadence without changing action support should not move the true reachability map. If they do, the map may track the observation process rather than completion geometry.

A public artifact shows uncertainty, assumptions, and prohibited readings beside the frontier. It does not display a person-level dashboard or a countdown to solvency. The map is a research object for comparing models, never a private balance display.

Retirement is a normal outcome. Persistent held-out violations, unstable frontiers, circular dependence on endpoint labels, or equal performance by simpler rivals should narrow or retire the map. The remaining contribution is then methodological: a clearer account of which futures were and were not identifiable.

18.2 — Completion Kernels and Boundary Values

A completion kernel asks for the probability of finishing inside a declared band under a declared continuation law. With current state x and residual ℓ , a state-indexed committor can be written as

$$h_{g,K}(x, \ell, t) = P_g \left(\ell + \Delta L_{t:T_g} \in [-K, K] | X(t) = x, L(t) = \ell \right).$$

The regime g , endpoint branch, band, and reference law are part of the object. A history-indexed kernel is more general. Reducing it to a state function assumes that the chosen state is sufficient for the future event. That assumption should be tested by residual history dependence, held-out prediction, and rival state augmentations rather than asserted because a Markov model is convenient.

Under regularity, a committor solves a backward boundary-value problem. The boundary conditions reveal what counts as completion and failure; the generator reveals the assumed native dynamics. Changing either after seeing the data changes the hypothesis.

The kernel is useful because it transports a quantitative object across actions, tasks, horizons, and cohorts. A single potential trained on one module can be frozen and evaluated on transition, action, and endpoint modules. Retuning a new potential for each module tests only local fit.

Uncertainty in the kernel should remain visible. Posterior bands, conformal regions, or identified sets may be more appropriate than a single surface when the state is partially observed or the

generator is weakly identified. A colorful heat map should not conceal uncertainty.

A high committor is not a personal forecast or moral status. It is a model-conditional probability of an event under specified assumptions. Its public artifact must name the model, band, time, uncertainty, and prohibited interpretations.

18.2.1 — Completion Kernels as Conditional Forecasts

A completion kernel is a conditional forecast of a declared terminal event given the information available at a prefix. It maps a state or belief state to a probability distribution, not to a metaphysical degree of fairness. The event, horizon, branch, policy class, and observation filtration must be stated before the kernel is estimated (Kallenberg, 2002).

The kernel differs from reachability. Reachability asks whether at least one admissible continuation exists; the kernel weights continuations under a specified law or policy. A state can be reachable and still have very low completion probability, or unreachable under one policy while reachable under another.

Forecasting requires a baseline law. Native dynamics, selected cohorts, endpoint-conditioned samples, and intervention policies induce different kernels even when they share the same state coordinates. Every reported probability therefore identifies the law under which it is computed; probabilities from incompatible laws are not placed on one scale or interpreted as competing estimates of the same object.

Partial observation replaces a state kernel with a belief-state forecast. The input is then a distribution over latent states, and

uncertainty in that distribution must propagate to the completion probability. A sharply reported scalar is unjustified when several latent states with different futures remain observationally equivalent.

Calibration is evaluated prospectively. Binned or distributional calibration, proper scoring rules, and held-out endpoint branches can test whether the forecast behaves as declared. A kernel fitted and assessed on the same terminal event is a description of the sample, not evidence of transportable completion dynamics.

Ordinary rivals receive their own kernels under the same information budget. Homeostatic control, finite-horizon planning, conditioned bridges, selection models, and observation artifacts may forecast the event as well as the candidate route. The kernel's scientific role is comparative rather than confirmatory by itself.

A kernel is withdrawn when its event is ill-defined, support is inadequate, calibration fails, or its output is used outside the declared research purpose. The reported quantity is a model-conditional forecast with uncertainty and an available no-estimate branch.

18.2.2 — Committor Functions and Boundary-Value Problems

A committor gives the probability of reaching one declared set before another under a specified stochastic process. In Markov settings it solves a boundary-value problem for the generator, with boundary conditions fixed on the competing sets. The mathematical object is powerful because it turns a path question

into a state function, but only after the state, generator, sets, and law are justified (Metzner et al., 2009).

The forward committor asks what is likely to happen next from the current state. A backward committor asks where a trajectory most likely came from under a stationary or appropriately defined ensemble. These are different questions. Using a backward object as a prospective forecast can import information unavailable at the decision time.

Boundary conditions carry substantive assumptions. Setting the committor to one on a completion set and zero on a rival set does not show that either set is a truth-level endpoint. It defines the event being forecast. The sets must be independently motivated and prospectively specified.

Generator misspecification can dominate the result. Sparse observations, hidden variables, non-Markov memory, state-dependent diffusion, and informative sampling can make an estimated committor look smooth while representing the wrong dynamics. Recovery simulations should test whether the boundary-value solution remains valid under the actual observation process.

A concrete comparison can use several models with identical terminal sets. A first-hitting diffusion, a conditioned bridge, a homeostatic controller, and a queue candidate may yield similar one-time completion probabilities but different transition-path densities and intervention responses. Those differences create the discriminating work.

Uncertainty should be represented as a band or distribution over committors when the generator or state is uncertain. Reporting only the fitted mean hides whether classification changes under plausible dynamics. If a valid treatment contrast remains too uncertain to determine its sign, report Inconclusive evidence; if adequate route models remain inseparable under a qualified analysis, report Model-ambiguous.

Committors support rare-event sampling and transition-path analysis. Preferentially sampling successful transitions changes the sample law, so likelihood weighting and support checks connect those paths to the intended population.

The committor is retired as a route object when it fails calibration, cannot transport across held-out actions or endpoints, or depends on a state representation that cannot be recovered. It may remain valuable as a descriptive forecasting tool even after its causal interpretation is withdrawn.

18.2.3 — Action-Specific Committors

An action-specific committor asks what happens if one declared action is taken now and the continuation policy thereafter is fixed or prospectively specified. It separates the immediate causal fork from the larger policy value. Written conceptually, the object is the conditional probability of reaching the declared completion set after action a , given the current state or belief state and the declared continuation rule. This is narrower than a personal forecast and more informative than a single state-level completion probability (Metzner et al., 2009).

The action index matters because two interventions can have identical short-term observations and different future geometry. One action may open a repair route, another may reduce measurement burden, and a third may merely change what is reported. A state committor that averages across those actions can hide the divergence. The model should therefore declare the action version, timing, eligibility set, and continuation policy that define each surface.

A low-burden laboratory example can use unfinished but harmless tasks. Participants may receive information, an opportunity to resolve one task, or a matched control cue. An action-specific committor predicts which intervention should change the probability of a later route-relevant state under the candidate model. This tests controllable continuation structure where the action is safe and observable.

Identification requires support. If participants with a particular belief state never receive one action, its committor is extrapolated rather than learned. If action choice depends on unmeasured urgency, the surface may encode selection. Randomization, sequential exchangeability assumptions, or partial-identification bounds are needed according to the design. A smooth heat map cannot supply missing positivity.

The most severe comparison gives ordinary decision and control models the same action set, observations, and fitting budget. A standard model may predict that information, effort, or safety explains the action effect without any completion-specific state. Held-out intervention modules should score the competing

action-specific surfaces on calibration, discrimination, and transport rather than on visual resemblance to a desired endpoint.

An action-specific committor is retired when it is unstable across folds, fails calibration, does not transport across matched tasks, or gains apparent performance only after its action or endpoint definition changes. A successful result identifies its action, state representation, reference class, and continuation model.

18.2.4 — Calibration, Transport, and Uncertainty

A completion kernel must be calibrated for the event and population in which it will be used. Calibration in one simulated process, site, endpoint definition, or action regime does not establish calibration elsewhere. Transport requires an explicit bridge across state definitions, observation systems, policies, and endpoint branches (Gneiting & Raftery, 2007; Hernán & Robins, 2020).

Uncertainty enters at several levels: latent-state uncertainty, generator uncertainty, finite-sample error, endpoint ambiguity, policy variation, and numerical approximation. These components should not be compressed into one standard error when they have different consequences. Some widen the forecast; others invalidate the event or state entirely.

Cross-fitting can reduce optimistic evaluation, but it does not solve semantic leakage. If the state representation contains realized time-to-endpoint, post-treatment information, or labels derived from the terminal event, held-out scoring still tests a future-informed model. The information audit precedes the split strategy.

Transport should be modular. A kernel may transport across sites while the observation model does not, or across devices while the action policy changes. Reporting which module moved and which was re-estimated prevents a successful local recalibration from being described as mechanism invariance.

Calibration curves need enough support. Near a rare boundary, a small number of events can make a smooth curve look precise. Effective sample size, event counts, censoring, and selection weights should be reported beside the result. When support is thin, a wide identified set is more honest than a polished probability.

Ordinary rival kernels should be recalibrated with the same budget. Granting the candidate route bespoke recalibration while freezing rivals at their source-site parameters would turn transport into a hidden advantage. Equal-treatment comparison includes tuning, uncertainty, and failure rules.

A public forecast must remain population- and model-level. It should not be returned to a participant as a personal completion probability, care forecast, or interpretation of their life. The number is not clinically validated merely because it is calibrated for a research event.

Failure to transport is informative. It can reveal missing state, changing observation, treatment heterogeneity, or a mechanism limited to one setting. The route should narrow to the domain where calibration and support are demonstrated, with the failed transport preserved as part of the scientific record.

18.2.5 — Flexible Baselines and Rival Kernels

A candidate completion kernel should be compared against flexible ordinary baselines, not against a constant risk or weak regression. Baselines may include nonparametric survival models, state-space forecasts, homeostatic controllers, finite-horizon planners, conditioned bridges, and selection models. Their flexibility must be sufficient to reproduce ordinary nonlinearities without being so unconstrained that none can be interpreted.

Common observation is the first fairness rule. Each model receives the same prefix information, missingness indicators, endpoint definition, and action history unless the scientific question explicitly tests an information advantage. A model that wins because it was given future labels or richer sensors has not identified a mechanism.

Common tuning and scoring follow. Hyperparameter search, calibration, regularization, and stopping criteria should be budgeted prospectively across models. Proper scoring rules, recovery tests, and held-out interventions are chosen before the winning family is known, so the comparison rewards calibrated predictive content rather than a metric selected after inspection (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

Flexible kernels can mimic route signatures through different mechanisms. A bridge can condition on the endpoint, a hazard model can exploit frailty, a recurrent network can memorize site patterns, and a homeostatic process can concentrate near a set

point. The comparison therefore examines transition structure and intervention response, not only forecast accuracy.

Open-set inadequacy remains a first-class result. If every prospectively specified model fits poorly under a qualified analysis, the result is Open-set inadequate. If, in the prespecified simulations, the pipeline exceeds its allowed rate of confidently assigning unknown mechanisms to known classes, it fails the open-set recovery gate and cannot support the affected confirmatory comparison. Residual structure and challenge generators then define the next model-building task. This option prevents the least-wrong candidate from receiving a scientific victory it did not earn.

Complexity penalties are useful but not decisive. A simpler model that predicts as well may be preferred for explanation, while a more complex candidate may still be retained for a prospectively specified distinctive prediction. Predictive ranking, causal interpretation, and theoretical scope remain separate judgments.

Rival victory is a substantive result. If ordinary planning, regulation, or selection kernels match the candidate under common rules, the route-specific interpretation narrows or retires. The result strengthens the surrounding science by identifying which ordinary structure was sufficient.

The baseline library should be versioned and reproducible. Code, simulation seeds, observation models, and parameter priors become part of the artifact. A later stronger rival triggers reanalysis rather than being excluded because it was not present when the first favorable result appeared.

18.2.6 — When a Kernel Must Be Retired

A completion kernel is retired when its event, input state, reference law, calibration, or intended decision cannot be defended. Endpoint leakage, poor transport, unsupported extrapolation, unstable numerical solutions, state aliasing, or failure against flexible ordinary rivals each triggers a typed disposition. The result may be recalibration, reference-class restriction, descriptive-only use, or retirement. A more persuasive heat map is never a repair.

State aliasing yields a scientific identified set. When materially different latent states remain compatible with the same observations and imply different completion probabilities, the data do not determine one scalar forecast. The defensible output is a bounded range, an assumption-indexed family, or No adequate estimate, together with the additional observation or intervention that would separate the compatible states.

Event failure occurs when the completion set or competing boundary changes after outcomes are known, or when the event is defined by the same estimator the kernel is asked to validate. Such circularity cannot be repaired by cross-validation because the target itself was manufactured.

Law failure occurs when selection or conditioning changes the probability measure without proper accounting. A kernel estimated among paths that already reached the target cannot be interpreted as the native probability of reaching it. Likelihood ratios and support checks are necessary, and sometimes insufficient, when the event is probability zero.

Transport failure is not solved by silently recalibrating every new site. Recalibration may produce a useful local predictor, but it withdraws the claim that one mechanism-level kernel transported. The record should distinguish local salvage from preserved structure.

Model recovery is the gate before human interpretation; §18.7.5 gives the full recovery and confusion-matrix standard. If realistic synthetic generators cannot be recovered, real-data route probabilities remain exploratory rather than confirmatory (Villaverde, 2019; Wilson & Collins, 2019).

A kernel can retire partially. Its ranking may remain useful while its absolute probabilities fail, or its descriptive calibration may survive while its causal interpretation disappears. Narrowing the role is preferable to discarding every useful property or protecting every original claim.

When a kernel narrows or retires, record the affected version, surviving role, failed diagnostic, and successor test; Chapter 28 governs downstream artifact correction. A successor kernel begins as a new version and must pass recovery and calibration rather than inherit the predecessor's status.

Retirement should distinguish sharpness from calibration. A kernel can separate cases confidently while assigning wrong probabilities, or be calibrated yet too uninformative for the protocol-fixed decision. Either failure may be decisive, and neither should be hidden inside one performance score.

Coverage should be checked across state regions, actions, endpoint branches, and observation-quality strata. A global

average can conceal failure exactly where completion is most difficult or data are least available. The retirement packet should identify the failed region and preserve only any narrower calibrated domain.

Calibration should be evaluated under policy change as well as under passive observation. A kernel that is accurate under the behavior that generated the training data may fail when a safe intervention changes which states are visited. Such failure withdraws causal interpretation even if ordinary forecast calibration remains acceptable.

Rare completion events require special care. A visually smooth probability surface can appear calibrated because almost every case is a non-event. Event-specific calibration, precision-recall behavior, uncertainty under low counts, and synthetic recovery should accompany global scores before the kernel is used as a route object. Calibration plots should condition on event prevalence and decision-relevant regions so abundant easy negatives do not dominate the assessment.

A kernel may also lack decision relevance. Even a calibrated probability is unsuitable for a decision role when it adds no information relevant to the protocol-fixed scientific decision, or when no lawful and safe action can depend on it. Its decision or deployment role should then retire; its descriptive or mechanism-testing role may remain if separately validated. This distinction preserves a useful scientific object without granting it operational authority simply because it is statistically well calibrated.

18.3 — Belief-State and Partial-Observation Realizations

Partial observation replaces hidden state with a probability law over compatible states. The update combines a prior, transition law, action, observation likelihood, and missingness model. It becomes sufficient for control only inside the declared model and information set. The belief is therefore an analytic state for decision and recovery, not evidence that an organism, investigator, or device has direct access to phenomenal state.

A POMDP realization separates latent route state, observed channels, actions, and policy. Reports, physiology, behavior, context, and missingness update the belief with different lags and biases. Conflicting channels should widen uncertainty rather than be forced into one score.

Belief-state models make circularity inspectable. If endpoint outcomes help train the observation model and the resulting posterior is then used to predict those endpoints, the apparent completion signal may be outcome leakage. Endpoint-blind fitting, cross-fitting, and held-out modules reduce reuse, but none repairs a state representation that omits the variables needed for the declared transition law.

Action selection introduces another distinction. The action taken changes future observations and possibly future state. A model of observed trajectories must therefore account for policy, support, and selection rather than treating actions as passive measurements.

Observation garbling provides a discriminating negative control. The route-specific posterior should lose information when channels carrying its proposed state signal are permuted, delayed, masked, or degraded in a way that preserves generic time and severity cues. If predictive performance remains unchanged, the model may be using chronology, prognosis, or endpoint proxies rather than the claimed latent state.

Belief-state methods remain valuable if PTVC fails. They provide disciplined language for uncertain clinical and behavioral dynamics, while the no-score rule prevents a posterior from becoming a dossier, eligibility rule, or claim about inner truth.

18.3.1 — Latent State, Belief State, and Observation

A latent state is the modeled condition that governs future transitions under the declared dynamics. A belief state is a probability distribution or identified set over possible latent states given the information available at the current time. An observation is one channel output used to update that belief. Treating these three objects as interchangeable would erase the uncertainty that partial-observation models are built to represent (Kaelbling et al., 1998; Särkkä, 2013).

The latent state is not the person and it is not a complete description of lived experience. It is a task-specific representation chosen for one mechanism question. A route state may include residual position, bodily variables, opportunity, context, and action support while omitting dimensions that matter morally or phenomenally. The omission should limit the interpretation rather than be hidden by a broad label.

State sufficiency is an empirical claim. If the earlier path still predicts future observations or actions after conditioning on the proposed state, then the representation is incomplete or non-Markov. Residual-history tests, state augmentation, and held-out transition prediction should decide whether a compact state is defensible.

Belief states depend on the transition and observation models that generate them. Two teams can observe the same record and obtain different posteriors because they assume different latent states, priors, channel errors, or missingness laws. The posterior therefore carries a model identity and cannot be presented as a model-free fact about the participant.

The observation layer should retain channel provenance. Self-report, behavior, physiology, contextual records, and device-quality indicators may each contribute, but none is the latent route state by itself. Correlated channels should not be counted as independent witnesses merely because they arrive from different devices.

A useful realization separates three kinds of uncertainty: uncertainty about the world state, uncertainty introduced by measurement, and uncertainty about the model family. A narrow posterior under one misspecified model does not resolve the third kind. Sensitivity across plausible state and observation models should accompany the estimate.

A concrete validation task uses simulated latent paths passed through the actual cadence, missingness, and device-quality process. The fitted pipeline should recover the known state

distribution and forecast held-out transitions. Failure in simulation stops person-level interpretation before real data are given a vivid label.

The scientific payoff is corrigibility. A belief can widen, split across alternatives, or be withdrawn when evidence conflicts. That behavior is not weakness. It is the formal expression of not claiming possession of an inner state that the study can only infer indirectly.

18.3.2 — Filtering Without Phenomenal Identification

Filtering updates uncertainty about a declared latent route state as observations arrive. It does not identify phenomenal value merely because the state variables have affective names. Threat, fatigue, action readiness, or route position can be estimated for predictive purposes while the felt quality of experience remains a different target connected only through a separately validated bridge (Särkkä, 2013).

This distinction matters because an accurate filter can still be accurate about the wrong object. A model may predict the next heart-rate sample, movement transition, or report response without measuring valence, cumulative exposure, or the terminal residual. Predictive success licenses the task that was tested, not a broader inner-life interpretation.

State aliasing is the central identification hazard. Distinct latent states can induce nearly identical observation distributions, especially when channels share medication, activity, context, or device confounds. Adding more correlated channels may tighten the posterior while leaving the underlying states unresolved.

Filtering also depends on time scale. A fast sensor can respond within seconds while a report integrates minutes and a contextual record updates only after an event. Aligning all channels to one timestamp can manufacture apparent agreement. Lag models and channel-specific kernels should be included before posterior conflict is interpreted.

Endpoint-blind training is necessary but not sufficient. Cross-fitting can prevent direct leakage from terminal labels, yet the state representation may still be selected because it produces the desired terminal pattern. Representation choice, preprocessing, and model-family search should therefore be versioned and separated from the confirmatory sample.

A useful negative control filters a state that should not carry the candidate route information, or permutes the channel expected to be distinctive while preserving generic time and severity. If the posterior remains equally predictive, the model is likely exploiting background structure rather than the proposed mechanism.

Phenomenal identification requires its own evidence: defensible representation, origin and sign, channel qualification, measured-to-latent transport, and uncertainty that permits withdrawal. The filter can contribute to that program, but it cannot skip the bridge by relabeling a hidden control state as experience.

When aliasing, channel conflict, or model dependence remains large, the correct output is a broad belief set or No adequate estimate. The data may still teach where the observation process

failed. Refusing a scalar posterior is preferable to producing a precise route score that the evidence cannot support.

18.3.3 — POMDPs and Information-Constrained Control

A partially observable Markov decision process provides a grammar for latent state, observation, action, transition, reward or cost, and policy under incomplete information. Its relevance here is structural: it forces the mechanism to declare what the controller can know and which actions are supported at each decision time (Kaelbling et al., 1998).

The belief update uses only the current prior, protocol-fixed transition law, action, and observation likelihood. Future endpoint labels, later narratives, and the true latent residual are outside the decision-time information set. A model that sees them is a retrospective reconstruction or conditioned law, not a prospective controller.

The Markov assumption belongs to the chosen state, not automatically to the observed record. If memory, unresolved history, or delayed physiology affects future behavior beyond the state, the representation must be augmented or treated as non-Markov. Convenience is not a justification for discarding path dependence.

Action affects both state and observation. Avoidance can reduce exposure while hiding the unresolved cause; disclosure can increase short-term arousal while opening repair; treatment can change physiology and the measurement gain at once. A valid realization models these pathways rather than treating actions as passive covariates.

Information-constrained control should use the action set actually available. A laboratory button, a clinical option, an institutional appeal, and a private coping action are not interchangeable treatment versions. If transportation, safety, consent, disability, or authority removes an option, the model must remove it too.

Exploration has a burden. An algorithm may value an action because it reveals the hidden state, but research cannot expose participants to harm merely to improve identification. Safe information-gathering actions, ordinary care transitions, and natural variation define the admissible exploration set.

Equal-treatment rivals should receive the same belief state, observations, actions, and tuning budget. Model-free learning, model-based planning, homeostatic control, and a completion-specific route can then be compared on held-out choices and interventions rather than on unequal information.

A POMDP realization remains a candidate construction. Successful simulated trajectories illustrate the encoded controller's behavior; a policy-level feasibility or probability-one guarantee requires a separate proof or justified bound. Neither establishes that brains, bodies, or institutions implement the policy. Empirical relevance begins with recoverable state, prospective prediction, and causal contrasts not guaranteed by the construction.

The policy output is a distribution over actions inside a declared scientific model, interpreted according to its specified task and continuation regime.

18.3.4 — Sensor Placement, Missingness, and State Aliasing

Sensor placement determines which latent distinctions can be recovered. A channel observed only during low movement, clinic visits, or periods of high adherence may confound state with availability. The study should describe where each sensor can operate, where it fails, and which parts of the target population those failures remove.

The observation model must be channel specific. Reports, heart rate, respiration, movement, sleep, speech timing, contextual records, and device-quality indicators have different lags, noise, floors, and causes of absence. One generic measurement-error term is rarely adequate for a dynamic mechanism study.

Missingness can itself be informative. A participant may remove a device during discomfort, lose reportability during illness, or skip prompts when institutional or caregiving demands are highest. Treating absence as random can make severe or poorly observed states appear calm and well regulated (Little & Rubin, 2019; Hernán & Robins, 2020).

State aliasing occurs when two latent states generate similar channel patterns. Pain and exertion may share autonomic features; sedation and low distress may share reduced movement; danger and cultural restraint may share silence. Context and alternative channels can reduce aliasing, but sometimes the states remain only partially identified.

Active sensing can help when a low-burden prompt or quality check separates plausible states. The value of that observation should be evaluated prospectively and compared with participant

burden, privacy, and reactivity. A channel that narrows a posterior without improving held-out decisions may add confidence rather than information.

Sensor redundancy should be tested, not assumed. Two devices derived from the same optical signal or two models trained on the same labels do not provide independent confirmation. Shared error sources and preprocessing should be represented in the observation graph.

Recovery simulations should place sensors according to the real protocol, including outages, drift, device changes, and state-dependent missingness. If the pipeline cannot distinguish known latent states under that deployment, the real-data posterior is not interpretable as a mechanism estimate.

A no-estimate region can be local to a sensor configuration. The study may continue to describe observed channels while withholding the latent-state claim for a subgroup, setting, or time window. That narrow abstention is more useful than a global confidence label that hides where the observation geometry failed.

18.3.5 — Policy Under Model Uncertainty

Policy under model uncertainty begins with a declared family of plausible latent states, transition laws, observation models, and admissible actions. Robust, Bayesian, and set-valued approaches organize disagreement differently, but none can compensate for an omitted model family or an action set defined after the outcome is known (Manski, 2003; Kaelbling et al., 1998).

Section 7.3.4 defines almost-sure and limit-sure attainability. Here the additional burden is epistemic: the protocol must state the information-adapted policy class and belief state under which any such guarantee is claimed (Chatterjee et al., 2016; Asadi et al., 2025).

Apply §7.3.4: an empty admissible policy class returns RouteStatus: unavailable, empty admissible policy class. A missing action system, safety exclusion, or modeling error does not establish almost-sure or limit-sure failure of the candidate mechanism.

Partial observation changes the guarantee. A policy conditions on the declared observation history or belief state, not on the hidden history that the investigator wishes it could see. Posterior probability-one completion requires probability-one action-specific completion for almost every live history-action pair under the declared posterior model; a robust guarantee over all compatible histories is stronger.

Section 7.3.4 gives the general partial-observation intersection result. Here it functions as a construction test: a belief-state route is robust only if all histories compatible with the observation share at least one structurally admissible completion action and the resulting correspondence admits a measurable, time-consistent selector. Otherwise this realization fails at the available information level.

The policy class must respect the participant's real support. Disability, cost, danger, consent, institutional authority, language, care duties, and environmental access can remove an action that

appears in an abstract model. Including inaccessible actions makes the controller look more capable than the world permits.

The value of information is conditional on burden and decision relevance. A prompt, test, or sensor may narrow the belief state, yet its scientific value also depends on time, fatigue, symptom risk, privacy loss, reactivity, and whether the result could alter the protocol-fixed decision. Information that cannot change an admissible action or verdict may remain descriptively useful without justifying additional participant burden.

Candidate and rival policies must receive the same information, action support, missingness pattern, and computational search budget. A completion-specific route that receives privileged state access can win through information rather than mechanism. Recovery, calibration, transport, and open-set adequacy remain separate from average reward.

When model disagreement is material, the scientifically honest output may be a set of admissible actions, a request for safer information, robust-route unavailability, or abstention. The policy is an analytic object for a declared research task. Participants, care professionals, and lawful decision-makers retain authority over real action, including the authority to refuse the model entirely.

18.3.6 — Belief-State Failure and Abstention

Belief-state failure begins when the posterior cannot be connected reliably to the latent state it names. Causes include state aliasing, misspecified transitions, overconfident likelihoods, omitted context, correlated channels treated as independent, endpoint

leakage, and informative missingness. Numerical stability does not protect the model from these failures.

Parameter recovery and state recovery should precede interpretation. Synthetic data generated from known hidden states are passed through the actual cadence and observation process, then refit. If the pipeline cannot recover state probabilities, transition timing, or uncertainty coverage, real-data posteriors remain exploratory (Särkkä, 2013; Villaverde, 2019).

Posterior predictive checks should target temporal structure rather than only marginal fit. The model may reproduce the overall distribution of reports while missing order, dwell time, lag, action dependence, or the pattern of missing observations. Those failures identify which part of the realization is wrong.

No-omniscience is a separate gate. The state update and policy may use only information available at the protocol-fixed decision time. A model that relies on future endpoint labels, later treatment response, or retrospectively selected histories is a smoother or conditioned reconstruction and must be labeled accordingly.

Abstention can be local. The pipeline may estimate one region of the state space while returning No adequate estimate under severe channel conflict, unsupported transport, rare actions, or endpoint ambiguity. Local no-estimate regions preserve useful analysis without pretending uniform coverage.

Policy sensitivity supplies another failure test. If small plausible changes in the posterior, transition law, or utility reverse the proposed action, the action is not stably identified. A robust set or

no-action output is preferable to a brittle recommendation presented with confidence.

Model-family uncertainty should remain visible after parameter uncertainty narrows. A posterior under one POMDP may be sharp while alternative state representations fit equally well. Open-set challenge generators and none-of-the-models options prevent the chosen family from becoming a protected theory.

Failure can be role-specific: a belief state may remain predictive while losing causal or measured-to-latent status. Record the surviving role, failed diagnostic, affected reference class, and successor plan. Artifact correction follows Section 18.2.6 and Chapter 28; a successor model does not inherit the withdrawn interpretation.

The model separates hidden variables, observations, and assumptions before inferential use. The next section asks how the whole path law changes when a terminal event is imposed or conditioned on. Keeping those layers separate lets a later conditioning result be attributed to the path law rather than to unrecorded changes in what the agent was assumed to know.

Model disagreement can itself guide measurement. When plausible belief models diverge on which observation would be informative, a low-burden channel or timing change can be selected prospectively. The design should record the expected information gain and the possibility that the new observation changes behavior rather than merely revealing state. Expected information gain should be discounted by burden and reactivity, so the most informative observation in theory is not automatically

the best observation to collect. That tradeoff can be evaluated prospectively by comparing candidate observation plans on expected uncertainty reduction, participant burden, and induced behavior before deployment; if the preferred plan changes across plausible belief models, the study should preserve that design uncertainty rather than select the channel favored by one model after outcomes are known.

18.4 — Path Conditioning and Bridge Constructions

Conditioning begins with a reference path law P_0 and an event A . For a positive-probability event, the conditioned law is $Q(B) = P_0(B|A)$. The resulting paths exhibit A by construction. Their existence demonstrates mathematical compatibility, not that an unconditioned system contains a native completion mechanism.

A Doob h -transform uses a positive harmonic or space-time harmonic function to alter transition probabilities or drift. When h is a committor, the transform can generate paths biased toward the completion event. The object is scientifically useful because its likelihood and generator differ from the baseline in a calculable way.

For exact singleton targets of probability zero, ordinary conditioning is insufficient. A bridge kernel, regular conditional law, disintegration, or shrinking-band limit must be justified. Tightness and uniqueness matter: different subsequential limits can define different candidate bridges.

Schrödinger bridge formulations choose a dynamically admissible path law close to a baseline while satisfying endpoint constraints. A representative objective is

$$J_{path}(K, \alpha) = \inf_{Q \in Q_{dyn}: Q(A_K) \geq 1 - \alpha} D_{KL}(Q \| P_0).$$

The objective quantifies steering relative to a declared baseline path law; it supplies no evidence that nature pays, minimizes, or even represents that cost. Conditioned and native processes can instead be compared through likelihood, reciprocal structure, intervention response, and transport. A bridge mixture may be

reciprocal without being Markov, while a local controller may become Markov only after the state is augmented. Those distinctions create the testable content.

The endpoint event, baseline law, topology, and admissible class must be fixed before fitting. Otherwise the construction becomes an after-the-fact explanation of whatever path occurred.

18.4.1 — Conditioning Events and Changed Path Laws

Conditioning on a terminal event changes the path law. A process observed under the event is not distributed like the unconditioned process with a fortunate final value; earlier transitions, dependence, and likelihoods are reweighted throughout the path. This distinction is the starting point for every bridge or selector construction (Doob, 1957; Chetrite & Touchette, 2015).

The conditioning event must be explicit. Reaching a set before another, lying in a terminal band at a fixed time, surviving to an endpoint, or matching a terminal distribution are different events and induce different laws. A phrase such as conditioned to complete is too vague for scientific use.

Positive-probability events permit ordinary conditional probabilities. Probability-zero targets require a separately justified bridge, limiting sequence, or change of measure. Treating an exact-zero event as though it were an ordinary observed subgroup can hide singularity and create a formal object with no recoverable data analogue.

Conditioning can imitate mechanism. A selected cohort of paths that end near zero may display preterminal drift, variance compression, or reciprocal dependence even when the native

process has no closure controller. Those induced signatures become serious rivals to any route-specific interpretation.

The observation process may create another conditioning layer. Requiring complete terminal records, surviving device coverage, or reportability near the endpoint selects paths before the formal model is fitted. The sample law must include these filters rather than treating them as harmless inclusion criteria.

A useful analysis compares likelihoods under the native law, the explicitly conditioned law, and candidate causal dynamics. Held-out actions or unexpected endpoint probes are especially valuable because conditioning fitted to one terminal event may not predict them.

Conditioned constructions remain scientifically valuable. They provide exact countermodels, rare-event tools, and benchmarks for what terminal appearance can arise without a native law. Their role is to make the candidate route harder to protect, not to supply evidence by mathematical resemblance.

18.4.2 — Doob h-Transforms

A Doob h-transform constructs a new Markov law by reweighting transitions with a positive harmonic or space-time harmonic function. Under suitable conditions, the transformed generator describes the reference process conditioned or biased toward a declared event. The function h , its domain, and its boundary behavior are therefore part of the model, not decorative notation (Doob, 1957; Chetrite & Touchette, 2015).

The transform changes transition probabilities before the endpoint. It can generate local drift toward regions with higher

completion potential while preserving Markov structure. That local appearance can resemble a controller even when the transformed law was obtained from conditioning rather than from a physical feedback mechanism.

Scientific use requires an independent route for h . Estimating h from the same terminal outcomes later used to claim prediction creates leakage. A defensible program estimates or specifies one completion potential, freezes it, and tests transport across held-out transitions, actions, endpoints, or terminal-support modules.

Action-indexed transforms require further typing. A separate h for every action can absorb any policy difference and lose causal content. The model should state whether h is common across actions, how interventions alter the reference generator, and what invariance is predicted under shared information.

Support matters. The transform is not valid where h vanishes or where the transformed measure is not absolutely continuous with respect to the reference on the relevant sigma-field. Apparent success outside support is extrapolation, not a conditioned-law result.

The transform loses as a mechanism when an equal-budget endpoint-conditioned rival fits just as well, when h fails held-out transport, or when the required reference dynamics cannot be recovered. It may remain a formal bridge or simulation device after its causal interpretation is retired.

18.4.3 — Schrödinger Bridges and Entropic Steering

A Schrödinger bridge finds the path measure closest in relative entropy to a reference process while matching declared endpoint

marginals. It is an entropy-regularized path-space transport problem and can be written as a stochastic control problem. The construction shows how a distribution can be steered between boundaries with minimal change relative to a baseline, not that nature uses that steering law (Léonard, 2014; De Bortoli et al., 2021).

The endpoint objects are distributions rather than a single realized terminal value. Choosing them already encodes the target population and resolution. A narrow terminal distribution around zero, an atom at zero, and exact pathwise closure are different constraints and should not be collapsed into one bridge picture.

Soft constraints define a different object. Instead of forcing the terminal marginal to equal the target, a soft-constrained bridge permits mismatch and penalizes it through a divergence term. That construction can improve robustness when a finite band or noisy target is scientifically appropriate, but it cannot be presented as exact endpoint matching; the tolerance, penalty, and resulting terminal distribution remain part of the claim (Garg et al., 2024).

The reference process carries most of the scientific meaning. A Brownian, homeostatic, learned-control, or clinically stratified baseline yields a different bridge even with the same endpoint marginals. Comparison therefore asks whether the inferred control is stable across plausible references and whether one reference explains the data without special steering.

Entropic cost is a divergence on path laws. It is not effort, suffering, moral cost, or phenomenal burden unless a separately

justified bridge is supplied. In exposition and diagrams, the relative-entropy objective is described as a distance-like control penalty between probability laws, never as a price paid by a person.

Finite-sample algorithms can fit bridges that reproduce marginals while missing transition structure. Validation should include two-time dependence, intervention response, likelihood-ratio diagnostics, and recovery under the actual observation cadence. Matching the start and end distributions is a weak test of the interior law.

Table 18.1. Path-space constructions and distinguishing evidence.

Construction	What is fixed	How the path law changes	Distinguishing evidence
Native Markov route	Generator, state, action law, and endpoint branch	Evolves prospectively without selecting on the terminal event	Held-out transitions, interventions, and unexpected endpoints
Doob h-transform	Reference law, event, and positive completion potential h	Reweights local transitions toward the declared event	Frozen-h transport, support, and likelihood-ratio checks
Schrödinger bridge	Reference law and endpoint marginals	Finds a minimum-relative-entropy steering law on path space	Interior covariance, reference sensitivity, and intervention response

Construction	What is fixed	How the path law changes	Distinguishing evidence
Brownian or reciprocal bridge	Starting law, terminal condition, and horizon	Conditions trajectories on boundary information by construction	Known reciprocal dependence and absence of an independently recovered native mechanism

Partial observation complicates steering. The algorithm may operate on measured features while the target concerns a latent phenomenal object. A bridge in sensor space is not automatically a bridge in latent state, and the measured-to-latent transport must remain explicit.

The strongest rival interpretation is selection. A population assembled by endpoint status can have the same apparent endpoint marginals without any steering mechanism. Inverse-probability weighting, generative selection models, and held-out sampling branches should enter the comparison.

Schrödinger bridges are valuable because they make a precise quantitative comparison available. If a minimally changed conditioned law reproduces the candidate signatures, the route needs additional evidence. If the bridge fails on held-out interventions or unexpected endpoints, that failure becomes a discriminating result.

18.4.4 — Brownian Bridges as an Explanatory Baseline

A Brownian bridge is the clearest baseline for understanding why terminal appearance can be created by conditioning. Starting from a diffusion, the bridge law conditions the path on a specified

endpoint. The resulting process acquires a time-dependent drift that pulls trajectories toward that endpoint and a covariance structure that contracts as the horizon closes. Exact arrival is specified by the construction; comparison with an unconditioned process therefore examines additional predictions, such as pre-endpoint dynamics and responses to changed conditions (Doob, 1957; Chetrite & Touchette, 2015).

The bridge is valuable because its preterminal signatures are explicit. Conditional means, two-time covariance, an increasing restoring coefficient, and variance contraction can all resemble route-specific closure. Those similarities make the bridge a serious rival rather than a classroom curiosity. Any proposed completion mechanism should be compared against a bridge that receives the same endpoint information and observation noise.

The baseline also exposes the endpoint-information problem. If the analyst selects only trajectories known to end in a band, then fits a contracting process to the selected sample, bridge-like behavior is expected. The sample has been conditioned even when no bridge equation was written. Selection diagrams and prospective cohort definitions are therefore part of the mathematical comparison.

A useful simulation compares the observable laws produced by unconditioned diffusion, endpoint selection, and explicit bridging under the same observation kernel. Endpoint-selected paths and explicitly bridged paths can have the same conditional law; recovery must then return model ambiguity rather than distinguish labels unsupported by the data. Additional hazard,

intervention, or endpoint-regime measurements discriminate only when the models specify different predictions for them.

Brownian motion is not assumed to be a literal model of consciousness or valence. Its role is explanatory and adversarial: it identifies the additional path information needed to interpret an average that approaches a terminal boundary. More realistic diffusion, jump, and hidden-state rivals can be added after the baseline has made the logic visible.

A cumulative ledger requires a path-class-matched comparator. For an explicit Gaussian illustration, fix a deterministic $T > 0$ and fixed initial values L_0 and V_0 , and start from

$$dL_t = V_t dt, \quad dV_t = \sigma dW_t, \quad \sigma > 0.$$

Here L is an accumulated coordinate and V its stochastic rate. Conditioning the reference law on $L_T = 0$ through its Gaussian regular conditional distribution gives, for $t < T$,

$$dL_t = V_t dt, \quad dV_t = -\frac{3\{L_t + (T - t)V_t\}}{(T - t)^2} dt + \sigma dW_t.$$

The Brownian driver in this conditioned equation is defined under the conditioned law. The derivation uses $\text{Var}(L_T | L_t, V_t) = \sigma^2(T - t)^3/3$ under the unconditioned reference law. The accumulated coordinate remains finite variation even though its rate is stochastic. This supplies a linked residual–rate–horizon prediction for recovery benchmarks and matches the path class of an accumulated rate. The coefficients of the conditioning drift become singular as t approaches T , making resource requirements an explicit problem for biological implementations. Comparisons should give each model the same endpoint, selection, and

observation information (Doob, 1957; Chetrite & Touchette, 2015).

For the zero-initial-value case $L_0 = V_0 = 0$, Gaussian conditioning also gives

$$\text{Var}(L_t \mid L_T = 0) = \frac{\sigma^2 t^3 (T - t)^2 (4T - t)}{12T^3}, \quad 0 \leq t \leq T.$$

Writing $\tau = T - t$,

$$\frac{\text{Var}(L_{T-\tau} \mid L_T = 0)}{\tau^2} \rightarrow \frac{\sigma^2 T}{4} \quad \text{as } \tau \downarrow 0.$$

The same integrated Gaussian example therefore supplies both a conditional drift and quadratic preterminal variance contraction. These linked predictions can be assessed together when comparing candidate dynamics.

18.4.5 — Likelihood Ratios, Support, and Endpoint Leakage

A change of path law is interpretable only where the transformed measure has adequate support relative to the reference. Likelihood ratios quantify the reweighting on declared sigma-fields; they do not create information where the reference assigns zero probability. Support failure is therefore a structural limit, not a numerical inconvenience (Jacod & Shiryaev, 2003; Chetrite & Touchette, 2015).

Extreme likelihood ratios reveal practical nonoverlap. A small number of heavily weighted paths can make a conditioned estimate unstable even when absolute continuity holds formally. Effective sample size, tail behavior, and weight truncation sensitivity should be reported before route claims are made.

Endpoint leakage occurs when realized terminal information enters state construction, feature selection, imputation, or model tuning. A model can then appear to forecast completion because it has already encoded the answer. Splitting observations into training and test sets does not remove leakage if the feature definition used both.

Time-to-endpoint requires an explicit clock. Retrospective alignment describes a terminal trajectory; prospective filtering uses information available at the prediction time. Every plot identifies whether its coordinate is calendar time, clinical prognosis, filtered horizon, or realized remaining time.

Selection through observation is another leakage route. Complete-case analyses, device-quality thresholds, and reportability windows may condition on variables caused by state or proximity to the endpoint. The resulting law can resemble a completion bridge even when the native process does not.

A leakage audit follows every derived variable from raw observation to final score. It records which timestamps, endpoint labels, future summaries, and adjudication decisions were available at each stage. Any feature whose construction uses future information is restricted to retrospective analysis.

Held-out endpoint modules help but do not solve support. A potential trained on one terminal event can be tested on a different event or unexpected probe, provided the state and observation bridges are common. Failure indicates that the original transform may have learned event-specific selection rather than a general route.

When support cannot be established, the result is No adequate estimate or Model-ambiguous as appropriate; when leakage invalidates the comparison, its evidence is Unusable. A large likelihood-ratio-weighted effect is not strengthened by its extremity. It is often a warning that the comparison is being carried by a few incomparable paths.

18.4.6 — Native Dynamics Versus Retrospective Conditioning

Native dynamics specify how the process evolves before any terminal event is selected. Retrospective conditioning specifies the law of paths after restricting or reweighting by that event. Both can produce the same endpoint distribution, and sometimes the same one-time marginals, while disagreeing on transition probabilities, reciprocal dependence, and response to intervention (Doob, 1957; Chetrite & Touchette, 2015; Léonard, 2014).

The distinction requires a reference law. A route claim should state the unconditioned generator or transition kernel, the information available at each time, and the way the endpoint enters. If the native law is never estimated, the analyst cannot determine whether a fitted bridge represents a mechanism or merely a conditional description.

Preterminal covariance discriminates only when the declared models imply different observed kernels. A Brownian bridge is itself Markov and admits a time-dependent feedback representation; reciprocal structure alone does not distinguish conditioning from a native implementation. If the path laws agree, passive observations cannot separate the causal accounts. A

proposed intervention must specify different responses before it can do so (Çetin & Danilova, 2016).

Intervention response is stronger. A native controller should react when a safe action changes state or support. A retrospective bridge fitted only to terminal membership may not transport to that intervention unless the conditioning model explicitly includes it. Earliest-divergence tests in the next chapter are designed for this distinction.

Unexpected endpoint probes provide another test. A transform learned from one planned terminal event may fail when an independently occurring probe samples the path. A genuine native route should state what remains invariant across those probes and what changes with the endpoint branch.

Selection models must be included. Frailty, survival, device retention, reportability, and site-specific follow-up can select terminal-compatible paths without changing individual dynamics. Equal-information comparison asks whether selection explains the apparent preterminal signature as well as the route.

Model recovery precedes empirical ranking. Simulations from native controllers, conditioned bridges, hitting-time models, and observation-selection mechanisms should pass through the same pipeline. If the method confuses them under realistic sampling, real-data labels are not interpretable and no preference should be inferred from fit alone (Wilson & Collins, 2019; Villaverde, 2019).

The route can be evaluated through a joint prediction involving transition law, two-time structure, intervention response, endpoint support, and the observation process.

A route may survive only as a conditional representation. That is still useful. It can organize terminal-compatible paths and generate tests while losing the claim that it describes causal dynamics. The record should preserve that narrowed role rather than oscillate between total endorsement and total deletion. A conditional representation can be judged by descriptive calibration without receiving causal credit for the process that generated the paths.

The section ends with a strict wording rule: conditioned path law, candidate native mechanism, selector, and observation artifact are different statuses. A diagram or equation must name which one it depicts. Mathematical equivalence at one boundary does not grant causal equivalence through the path. Status labels should survive cropping and reuse, especially when a transformed path visually resembles a naturally generated one.

A direct diagnostic compares forward simulation from the estimated native law with endpoint-conditioned reconstruction. If only the conditioned reconstruction reproduces the data, the result favors that description over the fitted native candidate; it does not exclude other native laws or identify selection as the cause. If both fit, the mechanism remains ambiguous until intervention or unexpected-endpoint evidence separates them. Unexpected endpoints or interventions are especially valuable here because they can expose whether the apparent bridge effect persists when the conditioning event changes.

The comparison should include reciprocal structure, two-time dependence, action response, and likelihood ratios under the same observation process. Matching one terminal histogram is too weak because many conditioned and selected laws can share it. Shared observation models are essential, since different smoothing or missingness assumptions can create apparent differences between native and conditioned laws.

A public diagram should show the unconditioned law, the conditioning event, and the transformed law as separate objects. Its caption should state that conditioning changes the path distribution by construction and that natural realization remains an empirical question. Showing the transformation explicitly also teaches readers which patterns are consequences of conditioning and therefore cannot independently count as evidence for a natural mechanism.

18.5 — Absorbing, Hitting, and Bridge Routes

Absorption, first hitting, stickiness, reflection, state-coupled stopping, endpoint atoms, and bridges can all produce terminal concentration. They differ in what happens before and at the boundary. The protocol must name the implementation branch rather than call them all closure.

A first-hitting implementation stops at the first entry into a declared set. Choosing the zero-residual surface makes closure part of that stopping definition. Prospective approach, hazard, and perturbation signatures then supply empirical comparisons with other mechanisms.

An absorbing boundary keeps the process at the boundary after contact. A sticky boundary allows positive occupation time there. Reflection returns the process to the interior. Each produces different local time, dwell, and return signatures that can be estimated when the state and observation resolution are adequate.

Endpoint atoms require their own branch. Sudden biological events, administrative censoring, scheduled protocol stops, device shutdown, and discrete adjudication rules can place mass at particular times or states. Density-based arguments do not automatically extend to those atoms. A model that smooths them away can generate a false theorem, a distorted hazard, and misplaced confidence about terminal concentration.

Integrated-rate bridges are often more path-class appropriate than bridges placed directly on an accumulated finite-variation ledger. The rate process can remain stochastic while its integral is

conditioned on a terminal band. The construction must specify the path space and limiting mode.

A model tournament should simulate all branches through the actual observation pipeline. The question is not which ideal process resembles a plotted average, but which branch can be recovered and predicts held-out path features, endpoint hazards, and perturbation responses.

18.5.1 — First-Hitting and Zero-Surface Termination

First-hitting implementations define an endpoint as the first time a process enters a declared set. For the zero-residual surface, closure follows from the stopping rule whenever the surface is reached. The empirical questions concern the justification of that state and stopping relation and the preterminal observations that distinguish the route from alternatives (Doob, 1957).

A zero surface can be crossed, touched, approached without contact, or reached by a jump. Those possibilities imply different local signatures. Continuous diffusion may accumulate local time near the boundary; a finite-variation path may approach monotonically; a jump process may cross without ever occupying zero. The implementation must specify path class and boundary regularity before a hitting-time theorem is invoked.

A first-hitting candidate specifies a stopping mechanism and compares its timing with an independently defined endpoint. Keeping those definitions separate makes their relationship testable. The same model can also generate route-level predictions about trajectories before the stopping event.

A low-risk model-recovery study can compare simulated first-hitting paths with fixed-time bridges, absorbing processes, and state-coupled hazards. The observation pipeline should include realistic sampling and missingness. Distinguishing features may include return behavior before stopping, hazard spikes near the surface, and response to safe perturbations that shift the state without altering endpoint definition.

Ordinary processes can also generate first-hitting behavior. Threshold decisions, failure limits, physiological triggers, and institutional stop rules all create hitting times. Those rivals should be represented in the same state space before a fairness-specific mechanism is credited. The fact that a stopping surface exists says nothing about why that surface is relevant to experience.

The route fails when the surface is unreachable for observed prefixes, when stopping occurs away from the declared surface, when endpoint labels are required to recover the state, or when ordinary threshold models explain the data as well. A first-hitting construction is useful because it makes those failure conditions sharp.

18.5.2 — Absorbing and Killed Processes

An absorbing implementation keeps a process in a boundary state once that state is reached. A killed process instead terminates the path or transfers probability mass to a cemetery state. These constructions may share a first entrance time and differ completely afterward. The distinction matters whenever post-contact observation, return, or continued consciousness is possible (Champagnat & Villemonais, 2016).

Absorption creates a persistent atom at the boundary in later-time distributions. Killing removes the path from ordinary state space and changes denominators. A dataset that treats missing post-boundary observations as zeros can make killed trajectories look absorbed. The observation and retention processes must therefore be modeled alongside the state dynamics.

In terminal research, an administrative stop, device shutdown, loss of reportability, and truth-level endpoint are not interchangeable. Each can produce an apparent killed process. A comfort-first protocol may correctly stop collection while experience continues. The model should record that as observation termination rather than infer an absorbing phenomenal state.

Quasi-stationary behavior supplies another diagnostic. Among paths not yet killed, the conditional state distribution may stabilize even as survival probability declines. That pattern can resemble regulation or terminal concentration and should be compared directly. The route's predictions concern both the surviving distribution and the exit process, not one terminal histogram.

Simulation should preserve denominator flow. Analysts should report how many paths remain at risk, how many are absorbed, how many are killed, and how many become unobservable for other reasons. Recovery succeeds only if the pipeline can distinguish those branches under the actual cadence and noise floor.

An absorbing or killed route is retired when post-boundary returns are common, when the apparent atom disappears after observation correction, or when endpoint status cannot be separated from dropout. The construction remains a useful rival even when it loses as a PTV mechanism, because it teaches how terminal samples are shaped by state and observation together.

18.5.3 — Sticky and Reflected Boundaries

Sticky and reflected boundaries preserve continued dynamics after contact. Reflection pushes a process back into the interior, while stickiness allows positive occupation time at the boundary before movement resumes. Both can create repeated near-zero observations without terminal absorption. Their local-time structure is therefore central to discrimination rather than a mathematical detail.

A reflected process can touch the boundary many times and immediately return. A sticky process can produce a visible pile-up at zero even when the eventual endpoint is elsewhere. Finite-resolution instruments may confound both with absorption because small excursions are rounded away. Sampling frequency and measurement floor must be included in the simulation.

The distinction has a concrete analogue in regulated systems. A controller may repeatedly correct deviations from a constraint, creating reflection-like behavior, or dwell in a low-activity state before reactivation. Neither pattern implies a complete-stream boundary law. It may be ordinary homeostasis, task design, or instrument censoring.

Useful tests examine dwell time, excursion distribution, return frequency, and sensitivity to safe perturbation. Reflection predicts immediate direction change at the boundary; stickiness predicts excess residence. An absorbing model predicts no return. These features can be estimated from preterminal data when cadence is sufficient and the observation process is not itself sticky.

Hidden state complicates the picture. A measured channel may appear stuck while the latent state moves, or appear reflected because a bounded scale truncates values. Cross-channel comparison and latent-state recovery should therefore precede a mechanism verdict. A zero-heavy report scale is not evidence of a zero-heavy phenomenal process.

The route is narrowed when local-time or dwell signatures fail, and retired when the boundary behavior is produced entirely by scale limits or preprocessing. Sticky and reflected models earn their place by offering precise alternatives to the vague claim that a path simply converges.

18.5.4 — Endpoint Atoms and Singular Carriers

Endpoint atoms place positive probability on particular times or states. Singular carriers concentrate endpoint mass on sets that need not possess an ordinary density. Both can defeat arguments requiring an independent endpoint law with a positive Lebesgue density on the declared support; singular continuous laws, however, remain non-atomic. The model must declare whether atoms or singular carriers arise from biology, protocol, scheduling, state-coupled stopping, or observation design before applying the relevant obstruction.

Atoms can be mundane. A study may end at a scheduled visit, a device may shut down at a battery threshold, or a protocol may stop at discharge. Those events can produce repeated endpoint times unrelated to the truth-level endpoint. Treating them as natural terminal structure would import the study calendar into the hypothesis.

State atoms are equally important. Rounding, censoring, and bounded scales can produce a pile-up at zero. A latent mixture can also include a true atom, a narrow continuous component, or both. The analysis should compare those possibilities through an observation-kernel model rather than declaring exact neutrality from repeated zero readings.

Singular endpoint supports require topology as well as probability. If endpoints lie on a lower-dimensional manifold or a discrete state graph, density-based tests may be inappropriate. Support-aware methods should ask which neighborhoods carry mass and whether the proposed route predicts the carrier independently of the terminal observations used to discover it.

A rigorous design uses negative controls for administrative atoms and simulated observation floors. It also separates the time atom from the state atom: many paths can end at the same scheduled time without sharing a terminal state, and many can share a recorded state because the instrument has coarse bins. Each factor receives its own model component.

The route fails when its atom disappears under finer measurement, when the support is determined by protocol rather than process, or when alternative endpoint models reproduce the

same concentration. An atom is a property to explain, not a shortcut around endpoint discipline.

18.5.5 — Continued-Stream and Endpoint-Inclusive Branches

Continued-stream and endpoint-inclusive branches change the domain of the claim. If experience continues after the observed endpoint, then the recorded terminal residual is a prefix, not the complete object. If a phenomenal contribution is assigned exactly at the endpoint, the strict-pre-endpoint and inclusive ledgers differ by that contribution. These branches are non-equivalent and must be specified separately before outcome inspection.

Return and resuscitation make the distinction concrete. A protocol may close a window when report ceases and later observe recovery. The original stop cannot be treated as the truth endpoint. The stream-routing and endpoint records should reopen or mark the earlier object as provisional rather than forcing the returned experience into a new stream for convenience.

Endpoint-inclusive models also require a rule for what belongs at the boundary. A final conscious event, a transition with uncertain duration, and a biological event without experience are different. Assigning all terminal physiology to phenomenal value would collapse mechanism and target. The inclusion rule must be independently justified and sensitivity-tested.

Observation shutdown is a strong rival. Sedation, delirium, device removal, caregiver burden, or comfort-first stopping can end measurement while lived experience remains uncertain. A no-

estimate outcome is scientifically stronger than treating silence as zero or as a completed stream.

Comparisons across branches should use the same pre-endpoint data and explicitly different remainder models. One analysis can estimate strict-pre-endpoint compatibility; another can bound an unobserved terminal remainder; a third can remain nonadjudicable. The branch choice should not be changed to rescue an unfavorable result.

The route is retired when continued experience is systematically misrouted, when inclusive contributions cannot be identified, or when branch switching occurs only after inspection. Scientific clarity begins by allowing the endpoint domain to remain unresolved.

Endpoint-branch adjudication uses a frozen event packet that withholds the terminal ledger estimate. The packet records the protocol endpoint, clinical state, evidence of continuing or returning consciousness, measurement-shutdown reason, routing decision, and uncertainty. A blinded panel then classifies the event as strict-pre-endpoint, continued-stream, endpoint-inclusive, provisional, or nonadjudicable. This ordering prevents the favored terminal value from deciding which endpoint branch is said to have occurred.

An unobserved terminal remainder can sometimes be bounded even when it cannot be point estimated. The bound may use the last observation meeting the declared qualification criteria, maximum plausible exposure under the chosen clock, duration uncertainty, and branch-specific limits on the measured-to-latent

bridge. The full interval enters the route verdict. When a valid finite bound spans outcomes that reverse the conclusion, the result is Inconclusive evidence rather than a midpoint presented as terminal truth (Little & Rubin, 2019; Manski, 2003).

Return events require versioned reanalysis. The original endpoint classification, all decisions made under it, and the evidence available at that time remain preserved; the later return creates a successor record rather than erasing the earlier uncertainty. Analyses that used the provisional stop are rerun under the corrected routing and endpoint object. This makes error visible and allows recovery without pretending that a protocol can know the truth-level boundary in real time.

Recovery simulations should include branch misclassification. Synthetic paths can continue after observation shutdown, include an endpoint atom, return after a provisional stop, or carry an unobserved inclusive contribution. The complete pipeline is then asked to recover the correct branch and to abstain when the evidence is insufficient. A route estimator that appears accurate only when the endpoint branch is supplied by the simulator has not solved the adjudication problem.

Detachable figures and tables should carry the branch label with the estimate. A curve described only as terminal can be mistaken for complete-stream evidence even when it ends at report loss or a protocol window. The caption therefore names the endpoint object, the strict or inclusive domain, the treatment of return, and the remainder status. This compact provenance is scientific content because it determines what the displayed trajectory can and cannot adjudicate.

18.5.6 — Distinguishing Identical Endpoints by Preterminal Data

Different mechanisms can produce the same terminal value. A fixed-time bridge, first-hitting route, absorbing boundary, sticky process, state-coupled hazard, and endpoint-selected sample may all place mass near zero. Terminal concentration alone therefore has weak discriminating value. The scientific burden is to use preterminal dynamics and intervention response to separate the branches (Doob, 1957; Champagnat & Villemonais, 2016).

The most useful differences concern path law. Candidate branches imply different covariance, hazard, dwell, return, jump, and local-time signatures. They also differ in how a safe perturbation changes future trajectories. A bridge conditioned on the final event can absorb an intervention differently from a native state-coupled controller.

Observation models can erase those differences. Sparse sampling may miss returns; a floor may hide excursions; informative dropout may remove unstable paths. Simulations should therefore pass every candidate through the protocol-fixed measurement cadence, censoring, and missingness process before model recovery is assessed.

A common-rule tournament can begin with identical state information and endpoint labels, then withhold endpoint labels in a prospective module. If a route succeeds only when the final event is supplied, it is a conditional reconstruction rather than a discovered mechanism. Held-out unexpected endpoints are

especially valuable because they prevent the model from relying on a known horizon.

The comparison should include a none-of-the-models option. If all branches miss preterminal structure, the result is open-set inadequacy rather than a victory for the least-wrong implementation. Residual diagnostics and challenge generators should be reported beside classification accuracy.

This subsection closes the implementation family with a strict rule: identical endpoints do not imply identical mechanisms. A route earns support only from prospective, recoverable differences that survive the observation process and equal-treatment rivals.

Dwell and return behavior can be especially informative near a boundary. Absorption predicts no departure after entry; reflection predicts immediate return; stickiness predicts positive residence; first hitting links termination to initial contact; a fixed-time bridge can cross the target repeatedly before the horizon. Sampling cadence must be high enough to observe the distinction.

Hazard and local-time signatures should be modeled together where the implementation permits. A rise in endpoint hazard near the target, repeated grazing without termination, and long residence at the boundary are different phenomena. Collapsing them into one terminal-zero indicator destroys the mechanism information.

Unexpected safe perturbations provide a final check. A native boundary controller should respond according to its local rule, whereas a cohort selected by terminal outcome may show no

prospective response once endpoint information is removed. The perturbation module should be scored without access to the eventual terminal label.

Boundary-contact data should retain exact timing at the resolution the sensor can support. Rounding several contacts into one terminal observation can make reflection, stickiness, and absorption indistinguishable. The analysis should model interval censoring rather than pretend the contact time is known.

Endpoint atoms and continuous hazards should be compared explicitly. A mass point at a scheduled or administratively defined time can mimic terminal concentration while following a different law from first hitting or state-coupled stopping. Mixture models and branch-specific simulations should test whether the data can separate those components.

Recovery benchmarks should include identical terminal histograms generated by different preterminal laws. The task is successful only when the pipeline distinguishes those laws from the path before the endpoint. Classification based mainly on the terminal value would fail the mechanism question by construction.

When cadence is insufficient, the verdict should name the lost distinction. The study may establish that several implementations remain compatible while being unable to tell which one generated the data. That is a mechanism-ambiguous result, not weak support for all of them.

A path-law comparison should score one-step and multi-step predictive densities before the endpoint, not only classify the

implementation after the full trajectory is visible. Transition residuals can reveal whether the fitted process places probability on the observed sequence of approaches, retreats, and returns. Cross-validated likelihood or proper-score differences should be reported by distance from the boundary so a final segment cannot dominate an otherwise poor preterminal fit (Gneiting & Raftery, 2007).

State normalization matters when comparing intervention response. Two branches may appear to react differently only because one cohort begins closer to the target surface or with less remaining action support. The perturbation analysis should condition or match on the declared preintervention state, then compare the timing and shape of divergence. A branch that requires post hoc state redefinition to recover its expected response has failed the prospective mechanism test.

Channel-ablation tests can expose observation dependence. The mechanism should be refitted or rescored after removing the channel most directly tied to endpoint ascertainment, while retaining the same state definition and verdict rule. If discrimination collapses only when that channel is withheld, the result may reflect endpoint leakage rather than a path-law difference. A robust branch should preserve at least its prospectively specified qualitative ordering across independent observation routes.

18.6 — The Queue Model as an Illustrative Candidate

The Queue model is retained as one illustrative state architecture for unresolved demands, partial observation, priority, blocking, reactivation, repair, and residual influence. Its scientific value lies in the distinct transition and intervention patterns those modules predict.

A scientific queue declares state variables, observation channels, actions, transition rules, costs, constraints, policy classes, recovery tests, and retirement conditions. These specifications turn the architecture into a model with observable consequences.

This section develops the model's POMDP, belief-state, recovery, and public-language analyses. It should be read as a bounded candidate family inside the wider path-space chapter, not as the mechanism of PTV C.

18.6.1 — Candidate Mechanism Status

The queue-style route is a midlevel candidate mechanism. It asks whether explicitly represented unresolved demands, blocking, reactivation, and repair improve prediction and causal localization beyond ordinary rivals. Its components can be refined through source specification, measurement, recovery tests, and prospective comparisons (Kaelbling et al., 1998; Sutton & Barto, 2018).

A midlevel mechanism can be measured, compared, revised, or retired separately from the wider program. Its role is to explain specified observations.

The working claim is conditional. If unresolved demands have queue-like dynamics, then attention, action, physiology, and report should show structured priority, blocking, reactivation, and repair sensitivity beyond what simpler rivals predict under the same observations. That sentence is stronger than a metaphor and weaker than validation. It says exactly where the model might matter.

A candidate mechanism also has a narrower reference class than the Law. It may apply to some burdens, some developmental periods, some cultures, some clinical states, or some task settings and not others. A caregiver's recurring vigilance after months of night alarms may have queue-like features, while a transient mood shift after bad weather may not. The model must allow partial domain.

The model also needs a negative space. Certain experiences should not enter the queue simply because they are vivid. Joy, boredom, fatigue, ordinary desire, routine planning, and benign memory may affect lived experience without becoming unresolved demands. If every salient state becomes queue material, the model loses its shape and becomes a name for mental life in general.

Candidate status disciplines the prose. A queue-style route may represent state, assign model quantities, specify a selection rule, or generate closure under stated assumptions. Those are mathematical operations, not evidence that an unseen agent knows a person's balance, punishes them, or distributes morally owed rewards. Describe what the model computes and predicts without turning it into an intentional actor.

18.6.2 — State, Demand, and Control

The queue illustration begins with three explicit objects: a state describing active and latent demands, a demand representation that can be multidimensional, and a control process that changes future state or access. None of the objects is a person, a moral account, or a direct phenomenal ledger.

State and control are defined on real opportunity. Transportation, money, energy, care access, physical capacity, communication, permission, and safety determine whether an action is actually supported, and those constraints may change over time. Recording them lets the model distinguish an inaccessible repair route from an internal transition failure.

One candidate input is an unresolved mismatch between expected and actual affective consequence. A person expected an apology to feel safe, but it did not. A long-sought achievement produced relief for a day and dread afterward. A harmless-looking letter triggered fear because past letters carried danger. These mismatches can update beliefs and keep demands active (Kaelbling et al., 1998; Sutton & Barto, 2018).

Prediction-error language is useful because it gives a rival its strongest form. Predictive processing and active-inference accounts can explain salience, attention, avoidance, and reappraisal without invoking a Law-specific queue. The Queue model must therefore ask whether unresolved affective mismatch produces priority and reactivation patterns beyond those rival accounts.

Affective prediction error should not be treated as a single scalar surprise. It may involve valence, threat, bodily cost, agency, meaning, memory, and social expectation. A person may be surprised by relief, harmed by anticipation, or unsettled by numbness. The queue entry rule needs to specify which feature is unresolved.

A simple entry indicator might include magnitude, persistence, action relevance, and repair availability.

One candidate operational rule admits a demand when mismatch exceeds a declared threshold, persists, and continues to influence attention, action, or expected future cost. The record separately identifies whether a repair-relevant action is available, blocked, or absent. Lack of a repair route can sustain a demand rather than prevent its entry.

The rule should allow no entry. A large emotional change that resolves quickly may not enter. A surprising joy may alter the measured cumulative estimate without becoming an unresolved demand. A brief irritation may be real feeling but not queue material. The model becomes more credible when it refuses some cases.

Some demands enter through relationship. Attachment, betrayal, obligation, shame, apology, exclusion, caregiving, conflict, and unspoken fear can continue to shape attention and action after the visible interaction ends. A Queue model can represent these as relational demands embedded in context rather than private defects (Shenhav et al., 2013; Kaelbling et al., 1998).

A realistic example is a caregiver who smiles during a clinic visit because the parent is present, then cannot sleep after reading the discharge instructions alone. The demand is not simply anxiety. It may involve responsibility, uncertainty, role conflict, lack of respite, fear of making the wrong call, and no safe route to transfer the load. A queue entry rule that sees only mood misses the social structure.

Relational demands require careful observation because bystanders have privacy. A participant may report conflict with a spouse, child, colleague, or clinician. Those reports can enter as participant experience, but the other person does not automatically become research data. The demand can be modeled without building a dossier on everyone around the participant.

Social entry rules also need culture. Silence, indirect speech, apology, obligation, and repair differ across settings. A model trained on one social grammar may misclassify another. A delayed reply may be threatening in one context and ordinary in another. The entry rule should include contextual priors and transport checks.

Relational repair has been studied as a time-dependent process. McCullough and colleagues followed 337 people after a recent interpersonal transgression, using repeated reports over approximately three weeks. Reported conciliatory gestures, including apologies and offers of compensation, were associated with increasing perceived relationship value and decreasing perceived exploitation risk. The longitudinal model linked rising relationship value to faster reductions in vengeful and avoidant motivation (McCullough et al., 2014). This gives a relational-

demand model concrete variables to track: what the person remembers, what the partner does next, how future safety and relationship value are appraised, and how motivation changes over time.

Relational demands often interact with material constraints. A person may remain in contact because housing, care, immigration status, work, or family obligation narrows alternatives. The queue cannot treat continued contact as evidence that the demand is low. Sometimes the action set explains behavior better than preference.

The model's ethical boundary is clear: it may represent relational pressure only to understand hidden burden and compare mechanisms. It may not prescribe forgiveness, reconciliation, exposure, confession, or public testimony. Repair remains voluntary, contextual, and safety-dependent.

A large intervention study demonstrates that emotional responses to past interpersonal harm can change through a self-directed practice. In the International REACH trial, 4,598 adults across sites in Colombia, Hong Kong, Indonesia, South Africa, and Ukraine were randomized to receive a forgiveness workbook immediately or after a two-week delay. At two weeks, the immediate group had lower unforgiveness, depression symptoms, and anxiety symptoms, with standardized mean differences of -0.53 , -0.22 , and -0.21 , respectively (Ho et al., 2024). The measured changes provide a concrete basis for studying how voluntary reflection alters the continuing influence of relational events. Longer follow-up and active comparison conditions would help identify durability and the most effective ingredients.

18.6.3 — Unresolved Demand and Continuing Influence

Unresolved demand language is especially vulnerable because the word unresolved can sound like unfinished payment. This chapter rejects that reading at the point of definition. A demand is unresolved when its generating condition, expected cost, blocked action, or state uncertainty continues to influence the system. It is not unresolved because reality is asking the person to suffer until a moral balance is paid (Shenhav et al., 2013; Kaelbling et al., 1998).

Consider a person who keeps checking the mailbox after months of medical appeals. The demand may be unresolved because the institution can still deny medication, the person lacks reliable information, and prior letters have carried real consequences. Calling that state queue-like does not say the person owes vigilance. It says a system of uncertainty, material consequence, memory, and limited control may be keeping a demand active.

The same rule applies to relationship repair. After betrayal, trust may remain difficult even after apology. A queue model can represent remaining uncertainty, risk estimation, memory salience, and the cost of future vulnerability. It cannot tell the injured person that they must forgive, must reopen access, or must suffer until the relationship is balanced. The action set includes refusal and protection.

This distinction matters for empirical design. If the model confuses unresolved demand with moral debt, it will treat distress as useful signal no matter how obtained. A scientifically admissible task must instead ask how demand features change

under safe, consented, low-burden conditions. It can study response to information, option availability, or symbolic repair without creating harm to fill a queue.

Relief after a move, treatment, apology, or safe housing may reduce estimated demand. The queue records those changes according to its stated transition model.

Unresolved means still exerting influence under the model.

18.6.4 — Priority, Blocking, and Reactivation

Priority, blocking, and reactivation are the queue family's distinctive dynamics. Priority allocates limited control, blocking reduces current influence or observability, and reactivation predicts a specific return when context or action support changes. These claims should be separated so one vague recurrence does not count as all three.

Priority can be represented as a function of expected cost, controllability, time sensitivity, context, and resource availability. It should not be represented as moral importance. A demand can be high priority because it threatens safety, because repair is possible now, because delay increases risk, or because context makes it salient (Manski, 2003; Jacod & Shiryaev, 2003; Tao et al., 2018).

Table 18.2 specifies an illustrative sequence for a future simulation. It shows the intended entry, blocking, reactivation, repair, and residual-state transitions; it does not report an executed simulation or a finding about a patient or institution.

Table 18.2. Queue-model simulation steps and test functions.

Toy step	Queue state change	What the simulation tests
1. Entry	A hospital-billing cue adds a demand with high uncertainty and moderate controllability.	Does a specific cue increase belief in an unresolved administrative-threat demand beyond general stress?
2. Blocking	A childcare deadline consumes attention and temporarily suppresses message-opening behavior.	Can blocked access occur without treating the demand as resolved?
3. Reactivation	A reminder email restores the demand and raises avoidance latency.	Does reactivation depend on cue specificity rather than any unpleasant event?
4. Repair attempt	A caseworker call lowers uncertainty and changes available actions.	Does priority fall because state changed, not because the model declared closure?
5. Residual	Future portal cues retain some salience after the bill is fixed.	Can the model represent partial repair while allowing rivals to explain residual vigilance?

An illustrative priority score can make the candidate dynamics inspectable:

$$P_i(t) = \beta_C \hat{C}_i(t) + \beta_U \hat{U}_i(t) + \frac{\beta_H}{H_i(t) + \varepsilon} + \beta_R \hat{R}_i(t) + \gamma^T X_i(t).$$

Here the left-hand side is the modeled priority of demand i at time t . The hatted C term is estimated future cost, the hatted U term is uncertainty, the inverse-horizon term captures urgency as remaining opportunity narrows, the hatted R term is available resources or repair capacity, and $X_i(t)$ records context. The positive constant epsilon prevents division by zero. This is a candidate priority equation, not a definition of worth, severity, truth, or deservingness.

The sign and units are declared for every use. A high value may mean high action priority, high monitoring priority, or high expected control cost, depending on the model. Keeping those meanings explicit makes the equation interpretable.

Priority should also be stochastic. Demands may fluctuate with sleep, medication, pain, context, social safety, and observation. A deterministic priority rank may be useful in a task, but real systems will need uncertainty. The model should report posterior priority distributions where possible.

Rivals can copy priority shifts. Scarcity increases attention to immediate needs. Fatigue narrows control. Threat conditioning raises salience. Active inference reduces expected uncertainty. A Queue model must specify a distinctive priority pattern, such as reactivation after apparent resolution when a repair-relevant action becomes available, not merely urgency under pressure.

The priority rule becomes scientifically useful when it can be wrong. If high predicted priority demands do not affect action, report, physiology, or memory under prospectively specified

conditions, the rule weakens. If low predicted priority demands dominate, the model must update or retire.

Reactivation occurs when a demand that had low current influence returns to shape attention, report, physiology, memory, or action. Triggers may include sensory cues, similar contexts, relational contact, institutional notices, bodily states, anniversaries, treatment changes, or new repair opportunities. The trigger supplies a structured observation (Wilson & Collins, 2019; Manski, 2003).

A letter from an insurer can reactivate earlier burden because it resembles a sequence in which paperwork carried real consequences. Context, memory, expected cost, and a live possibility of harm or remedy shape the response. The model represents the trigger as information.

Reactivation must be distinguished from ordinary conditioning. A cue can produce fear because it was paired with danger. That is a strong rival. The Queue model adds value only if reactivation also depends on unresolved action, repair availability, demand priority, or state uncertainty beyond cue association alone.

A candidate reactivation condition can be written:

$$Pr(D_{i,t+\Delta} > \theta_i | H_t) = \text{logit}^{-1}(\alpha_i + \beta_c c_{i,t} + \beta_b \hat{b}_{i,t} + \beta_a^T a_t^{\text{live}} + \beta_x^T X_t).$$

The display models the probability that demand i exceeds the protocol-fixed reactivation threshold at the next interval, conditional on the available history. Cue relevance, current state belief, the live action menu, and context enter separately, so each coefficient can fail without converting every recurrence into

queue evidence. The diagnostic becomes informative only when cue-conditioning and other rivals receive the same data, tuning budget, and threshold rule.

Reactivation can be humane when studied carefully. A study might use mild, consented reminders of ordinary tasks, not traumatic reenactment. It might vary information availability or repair options rather than inducing distress. The model does not need to hurt people to learn whether demand influence returns under safe cues.

A model that predicts reactivation everywhere fails. If every cue revives every demand, nothing has been distinguished. If safe cues and unrelated cues produce the same effects as repair-relevant cues, the queue account should narrow.

18.6.5 — Discharge, Repair, and Residual State

Discharge and repair are route-specific changes, not narrative declarations. A source can be removed, a belief can update, an external remedy can open an action, and a residual state can remain. The model should represent which component changed and what evidence would show that apparent relief was only observation loss.

Direct resolution occurs when the generating condition is removed or the action sequence completes in a way that materially changes the state. A medical appeal is approved and medication arrives. A door is repaired and the person can sleep. A missing document is found. A threat ends in a way that is verified and stable (Ethier & Kurtz, 1986; Jacod & Shiryaev, 2003).

In the model, direct resolution changes the transition probability for the demand. The expected future cost drops because the condition that generated the demand no longer persists. This is not emotional command. The person may still feel residue. Direct resolution concerns one state component, not the whole lived aftermath.

A candidate transition can be written:

$$\Delta_i^{res}(s_t) = E[D_{i,t+\Delta}|do(A_t = a_{resolve}), S_t = s_t] - E[D_{i,t+\Delta}|do(A_t = a_{wait}), S_t = s_t] < 0.$$

The contrast compares expected next-state demand under a supported resolving action with the same quantity under waiting, conditional on the declared state. A negative value is the candidate prediction; it is neither guaranteed nor a command that a person should feel better. Identification requires well-defined treatment versions, support for both actions, and the same confound and measurement rules used for rivals (Pearl, 2009; Hernán & Robins, 2020).

Direct resolution should be measured with enough time depth to avoid false closure. The letter arrives today, but sleep may take weeks. The threat ends, but the body may continue to monitor. A model that expects immediate total discharge will misread lived systems and punish people statistically for normal recovery lag.

Rivals can explain improvement after resolution. Rational threat reduction, stress-process models, homeostatic recovery, and ordinary learning may all predict lowered vigilance when external conditions improve. The Queue model must add more specific

predictions, such as which residual components remain and which cues no longer reactivate.

Direct resolution also has an institutional lesson. The best way to reduce many queue demands is not inward interpretation but outward repair. If an external condition generated the demand, fixing that condition is scientifically relevant. Care is not outside mechanism.

External repair includes care, safety, apology, material change, institutional remedy, access, respite, debt relief, corrected records, and restored routes of appeal. It matters because many demands persist outside the person. A queue model that treats repair as only internal would be scientifically and ethically poor (Ethier & Kurtz, 1986; Jacod & Shiryaev, 2003).

An apology can be external repair only when it changes relevant state. A performance apology that protects the offender may not reduce demand. A real apology may include acknowledgment, changed behavior, safety, accountability, and time. The model should not treat the word apology as a magic discharge action.

Institutional repair is often more concrete. A denial is reversed, an inaccessible entrance is fixed, a dangerous schedule is changed, a correction route is opened, or a confusing record is made reviewable. These actions can change transition probabilities because they alter live menus. The person's burden shifts because the world stopped placing the same demand.

External repair should be observable without becoming a public ledger. Research may code whether remedy occurred, whether the participant desired return of results, whether records were

corrected, and whether access changed. It should not publish personal repair scores or rank institutions through participant burden without governance.

Rivals can explain response to external repair through ordinary stress relief or rational action. Again, the Queue model earns support only if it predicts specific residual or reactivation patterns after repair. For example, it may predict that direct material repair reduces demand intensity while relational cues continue to reactivate uncertainty unless accountability changes.

A fairness-oriented analysis is strongest here because it asks where repair should happen. If the demand came from an institution, the model should not send the person away with a breathing exercise as the primary answer. A control model with fairness at its center includes external control levers.

Residual burden remains after resolution, update, repair, or partial relief. Nonresolving burden persists because the source remains, repair is impossible, memory remains active, the action set is closed, or the model is wrong about the relevant state. A humane mechanism must have a place for both (Ethier & Kurtz, 1986; Jacod & Shiryayev, 2003).

Residual burden is not evidence against care. It may be the normal remainder of serious harm. A person may be safe now and still startle. A record may be corrected and still leave distrust. A family may reconcile and still leave grief. The model should allow residual state without turning it into hidden unpaid debt.

Chronic illness, disability, irreversible loss, discrimination, and bereavement can create continuing demands because

circumstances have changed permanently. Representing those constraints helps identify useful support, access, and companionship alongside opportunities for improvement.

Residual influence can be represented through lower but nonzero demand states, persistent cue sensitivity, altered transition rules, or slow recovery. Each representation makes different predictions about recurrence, context, and response to repair and must therefore be selected by evidence rather than narrative convenience. The model classifies a transition pattern, not a person.

Rivals may explain residual burden through memory, allostasis, adaptation limits, predictive control, or social context. The queue account must say what residual pattern is distinctive. For example, it might predict that residual burden is low in report but high in cue-specific physiology only when repair was partial and state uncertainty remains.

Residual and continuing burden deserve explicit representation and sustained care. When a model cannot explain or resolve what remains, the next task is to identify better observations, practical support, or a more adequate account while respecting the person's own pace and choices.

18.6.6 — Queue Failure, Scope, and Retirement

The illustrative queue is retired when its state cannot be identified, its priority or reactivation predictions fail, or ordinary learning and scarcity models explain the same observations more simply. Scope can narrow to one task or reference class, but the

model may not survive by becoming a metaphor for every unresolved experience.

Entry criteria should be prospectively specified whenever the model is used for inference. A model may declare that entry requires persistence, action relevance, expected future cost, repeated cue sensitivity, cross-channel support, and context plausibility. The exact criteria can vary by study, but the study cannot invent them after seeing which events make the queue look explanatory (Kaelbling et al., 1998; Sutton & Barto, 2018).

False positives are not nuisances; they are central diagnostics. If a model labels ordinary fatigue, benign memory, cultural restraint, or momentary frustration as unresolved demand, it will overstate queue prevalence. If it labels every lack of report as resolution, it will understate hidden burden. Both errors can damage science and people.

The entry process can be summarized as a small diagnostic gate. It asks whether the candidate demand has a source, a state feature, an observation signature, an action relation, and a rival explanation. If one of these is missing, the model should mark uncertainty or no entry rather than force inclusion.

Table 18.3. Queue-entry diagnostic gate.

Entry check	What it asks	Failure condition
Source	What generated the candidate demand?	No identifiable event, condition, or continuing constraint

Entry check	What it asks	Failure condition
Influence	What policy, attention, physiology, or memory does it alter?	Salience without action relevance
Observation	Which channels support the belief?	One noisy signal treated as direct state
Rival	What simpler model could explain it?	No fair rival specified

This table is a model-audit aid. Its purpose is to keep queue components, observations, rivals, and failure conditions distinct during research design. It is not a person-level screen and should not be converted into a public tool for classifying anyone's private experience.

False positives should be studied through negative controls. A task might include salient but resolved events, neutral administrative reminders, or safe surprise conditions that should not produce queue-like reactivation. If the model flags these at high rates, its entry criteria are too broad.

The strongest entry rule is conservative without being dismissive. It allows hidden burden to enter when evidence supports unresolved influence, and it allows no entry when the case is better explained by ordinary mood, context, or measurement error. Fairness to persons and fairness to explanation require both decisions.

A decisive recovery test should include a safe harm-avoidance controller that reproduces urgency, blocking, and apparent repair without a queue state. If the queue pipeline cannot distinguish that

ordinary controller on held-out tasks, the route-specific interpretation retires even if the descriptive fit is strong. Recovery should test not only class labels but the features used to distinguish them, revealing whether apparent queue evidence depends on one fragile diagnostic.

Component-level verdicts should be allowed. Cue-specific reactivation may survive while priority updating fails; blocked access may be measurable while discharge is not; residual influence may be observed without identifying an entry rule. Narrowing preserves useful findings without keeping an omnibus queue mechanism alive by aggregation. Component verdicts can be recombined only when a prospectively stated mechanism requires their conjunction, preventing post hoc assembly of partial wins.

Retirement records should identify representation, recovery, transport, ethical, or misuse failure. A promising but burdensome model may remain open while unavailable as a first-edition route. A route withheld for burden should remain scientifically distinct from one rejected by evidence, because the next admissible study differs in each case.

18.7 — Construction, Identification, and Recovery

Construction, identification, and recovery are separate achievements. Construction shows that a mathematical object can be defined. Identification asks whether the law of the observables distinguishes the relevant parameters or model families. Recovery asks whether the complete analysis pipeline returns the correct generator or model when the data-generating truth is known. Evidence for a natural mechanism begins only after all three stages are connected to held-out observations.

A model may be structurally identifiable in continuous observation and practically unrecoverable under sparse, noisy, missing data. Simulation should use the real sampling schedule, measurement error, action process, endpoint rule, and censoring. Idealized recovery is insufficient.

Parameter recovery and model recovery should both be reported. Accurate parameters inside the wrong model do not establish the mechanism. Correct model selection with unstable parameters may support a family-level conclusion but not a quantitative personal or biological interpretation.

Open-set recovery adds a none-of-the-models state to the confusion matrix. Posterior predictive checks, residual diagnostics, held-out calibration, and challenge generators should reject the entire candidate bank when every model is inadequate. Without that option, the tournament can only choose the least-wrong explanation and will overstate support whenever the relevant mechanism was omitted.

Generator recovery is especially important for Doob and bridge constructions because similar endpoint-conditioned marginals can arise from different dynamics. Drift, diffusion, jump, hazard, and observation components should be tested separately where data permit.

Route evidence begins after equal-budget recovery succeeds and one frozen object transports to held-out modules. A mathematically coherent construction remains valuable when empirical identification fails, but its status stays mathematical. This separation allows the book to preserve useful theorems, simulation tools, and diagnostics without describing an unrecovered route as a natural mechanism.

18.7.1 — Existence and Empirical Realization

Existence is the first mathematical achievement in developing a mechanism. A differential equation may have a solution, a bridge measure may be constructed, a committor may solve a boundary-value problem, or a controller may keep simulated paths inside a completion region. Those results establish mathematical possibility under assumptions and identify the states, generators, policies, or boundaries for subsequent empirical investigation (Bollen, 1989; Villaverde, 2019).

Realization requires a bridge from the construction to observables. The model specifies which variables correspond to measured channels, which parameters vary across persons or contexts, and which interventions alter the proposed mechanism or its reports.

A physical completion coordinate supplies a concrete realization to investigate. On one qualifying stream, let a be the declared initial boundary, s the fixed exposure clock, and L_s the accumulated signed contribution with $L_a = 0$. Nominate a physical state S_s and scalar potential Φ independently of the tested ledger, with $\Phi(S_s)$ absolutely continuous on the asserted branch. If their changes satisfy $dL_s = -d\Phi(S_s)$, integration gives

$$L_s = \Phi(S_a) - \Phi(S_s).$$

An independently established boundary relation $\Phi(S_{T-}) = \Phi(S_a)$ then gives exact terminal closure. Equal boundary values suffice; neither value has to be zero. This route can operate through current physical state without the controller forecasting an ending, provided the claimed dynamics and boundary relation actually hold.

The research task is to identify a compact physical coordinate whose changes predict calibrated signed experience on new paths, then test its boundary relation separately. Defining Φ as minus the observed ledger supplies no independent prediction. An enrollment reset supplies no initial condition for an earlier stream, and a reset at or after T cannot change its strict-pre-endpoint residual. A successful independently qualified coordinate would connect an ordinary physical mechanism to the exact target.

An ordinary biological mechanism that satisfies the declared contribution, exposure, ownership, and boundary relations realizes that branch of PTVC. Adaptation that regulates only a current state while leaving accumulated signed history unconstrained remains a rival explanation of local signatures.

An approximate realization should report its cumulative accounting budget. For a specified finite path with calibrated signed edge contributions w_e , set $r_e = w_e + \Phi(v) - \Phi(u)$ on edge $u \rightarrow v$. Telescoping gives

$$L_{\text{path}} = \Phi(s) - \Phi(b) + \sum_{e \in \text{path}} r_e.$$

If independently justified bounds give $|\Phi(s) - \Phi(b)| \leq \varepsilon_B$ and $\sum_e |r_e| \leq \varepsilon_R$, then $|L_{\text{path}}| \leq \varepsilon_B + \varepsilon_R$. Infinite paths require the stated boundary limits and convergence of the error sum. Small errors of one sign can accumulate; mean-zero residuals or a fitted RMSE do not bound an individual path. Statistical budgets need joint coverage under their maintained observation laws. Unobserved history adds its own uncertainty. The boundary is the declared pre-endpoint value, so a later reset cannot supply the missing equality. This directs validation toward the contribution bridge, boundary mismatch and missing history as separately measurable parts of one cumulative test.

Engineering makes the distinction concrete. A controller can be designed to bring a simulated process to a target, while several generators, constraints, and selection processes can produce the same terminal distribution. Comparing their path dynamics identifies which observations distinguish the implementations, including cases with a partly observed latent state.

Within a specified finite-state realization, a potential is also necessary. Fix a directed graph of reachable states, one initial state s , absorbing strict-pre-endpoint boundary states, and deterministic additive edge contributions w_{uv} . Every relevant

state must admit a terminating suffix, and that same suffix must be admissible after every prefix reaching the state. Suppose every admitted finite terminating path has total zero.

Two prefixes reaching u must have equal totals: adjoining one common terminating suffix makes both totals zero. Let $\Phi(u)$ be minus this common prefix total. Appending an edge then gives

$$w_{uv} = \Phi(u) - \Phi(v), \quad \Phi(s) = \Phi(b) = 0.$$

The boundary equality holds for every declared boundary state b .

Conversely, these edge and boundary equations make every terminating path telescope to zero. The restriction therefore identifies exactly the accounting structure required in this recombinable class. A shared coarse label does not establish recombination: different histories may permit different suffixes. Random rewards, omitted time, or hidden history require their own qualified state model. Freeze the state and admissible transitions before testing new paths; adding the observed ledger to each state label makes the construction automatic rather than explanatory.

A realization claim therefore needs four linked records: the construction and its assumptions, an identifiability analysis, a realistic recovery benchmark, and a prospective prediction not guaranteed by the construction itself. Omitting any record changes the licensed conclusion. The object may still guide theorem work or simulation, but detected mechanism language is reserved for a recovered and transported causal difference.

Concrete documentation helps. Each candidate receives a versioned state definition, generator, observation kernel, action

set, endpoint branch, parameter domain, and failure conditions. The packet also records which equations are definitions, theorem consequences, estimators, or scenarios. This prevents one formula from silently carrying several statuses.

A route may fail at realization while leaving useful mathematics behind. The field can retain a committor method, a partial-observation model, or a recovery benchmark even when PTVC-specific interpretation is withdrawn. That separation lets mathematical and methodological progress accumulate as empirical interpretations are refined.

18.7.2 — Parameter Identification and Observational Equivalence

Parameter identification asks whether different parameter values imply different observable laws, while observational equivalence asks whether different mechanisms remain indistinguishable under the available design. A precise fit is not informative when several parameterizations or models generate the same data (Bollen, 1989; Villaverde, 2019).

A latent state is nonidentified when materially different hidden structures induce the same observable law under the available design. Queue demand, threat learning, fatigue, scarcity, homeostasis, and active inference can produce overlapping behavior, so a fitted queue state is not route evidence when those alternatives remain observationally equivalent (Lakens, 2017; Manski, 2003).

Exact completion imposes a memory requirement on a specified forward realization. At a fixed admissible cut, let L be the

accumulated signed prefix and R the entire remaining contribution under the same representation, exposure, ownership and endpoint rules. Let X include all state information used to generate that continuation, so that L and R are conditionally independent given X . If $L + R = 0$ almost surely, the state must determine L up to null events. With finite second moments, conditional independence gives $\text{Cov}(L, R \mid X) = 0$, while $R = -L$ gives $\text{Cov}(L, R \mid X) = -\text{Var}(L \mid X)$; hence $\text{Var}(L \mid X) = 0$.

For real L and standard Borel X , the exact conclusion does not require moments. Conditional independence makes each conditional threshold probability $P(L \leq q \mid X)$, for rational q , equal to its square. The resulting conditional distribution is a point mass. Under finite second moments, approximate completion instead obeys

$$E[(L + R)^2] \geq E[\text{Var}(L \mid X)].$$

This lower bound turns unresolved loss of prefix information into a completion-error floor. The necessary information may be neural, molecular, bodily or distributed; it need not be consciously recalled. A noisy assay can lose information that the complete state retains. The restriction therefore tests a nominated causal-state realization, with the endpoint process included, rather than every formulation of PTVC.

A finite-state claim also imposes an observable restriction. At a common cut, suppose the complete continuation state has at most K discrete values. Let rows of M index prospectively defined past conditions and columns index future probes and response events. If probe assignment preserves the state distribution within each

row, and response laws given the state are otherwise common, then $M = AB$: A contains state probabilities and B contains probe-response probabilities. Consequently $\text{rank}(M) \leq K$. An excess singular value beyond a valid simultaneous measurement-and-sampling error bound rejects that nominated state budget. Use the actual independent episodes assigned to each probe when computing sampling uncertainty. Include observation loss as a response event, or model it without silently conditioning on complete cases. One continuous coordinate can generate matrices of arbitrarily high rank, and low rank establishes neither a unique hidden state nor terminal closure.

Nonidentifiability should be declared rather than hidden behind complex notation. If a model cannot tell active demand from blocked demand, or residual burden from ordinary fatigue, its output should not use those labels. It may report an undifferentiated latent factor or no estimate. Precision in language should follow precision in identification.

A simple diagnostic is model confusion. If the recovery matrix shows that data generated by different models are often classified as queue data, the design cannot support a queue claim. More participants may not solve this if the task lacks the right intervention or observation channel. Identification is not sample size alone.

Identification may also be limited by ethics and governance. A clinical or palliative setting may not permit the perturbation needed to distinguish states, and a privacy firewall may appropriately block linkage to a revealing record. When the

missing contrast would require unfair observation, coercion, delayed care, or excessive burden, the causal question remains partially identified or returns No adequate estimate. Ethical feasibility is part of the scientific result.

Under nonidentifiability, public reports describe the observed pattern and the mechanisms consistent with it. Distinctive predictions identify the observations needed to separate blocked, queued, discharged, and residual states.

A nonidentifiable state identifies information needed for the next study: a safer task, richer observation, better negative controls, or a more focused question.

18.7.3 — Generator Recovery

Generator recovery asks whether the transition law that produced a trajectory can be distinguished from serious alternatives after all candidates pass through the actual observation process. A terminal histogram is insufficient. Drift, diffusion, jumps, hazards, action response, dependence, and missingness carry the preterminal information that separates native dynamics from conditioning and selection (Villaverde, 2019; Peters et al., 2016).

The recovery problem begins in simulation. Data should be generated from each candidate route and rival using plausible parameter ranges, then sampled with the real cadence, noise, missingness, and endpoint rules. The analysis pipeline must be frozen before labels are revealed. If different generators collapse into the same fitted family, the design cannot support a mechanism verdict.

Partial observation makes generator recovery a joint problem. A misspecified observation kernel can make the correct state dynamics appear wrong, while a flexible hidden-state model can absorb observation error into latent transitions. Separate recovery checks should perturb state dynamics, measurement error, and missingness so the source of confusion is visible.

Safe interventions often distinguish generators that passive fit leaves equivalent. Information, action availability, or a benign state component can be changed while the target, burden ceiling, and outcome rule remain fixed. The altered prediction is scored on a held-out module and compared under common observation. A model that predicts only the intervention used to tune it has recovered a local fit, not a general generator.

Cross-context prediction tests whether one physical coordinate explains several conditions. Freeze the state definition, contribution calibration and $\mathcal{C}^2$ potential Φ . In a common clock let condition a have dynamics $dS = b_a ds + G_a dW$, generator $\mathcal{A}_a$ and contribution rate v_a . Exact accounting requires $G_a^\top \nabla \Phi = 0$ and $v_a + \mathcal{A}_a \Phi = 0$ along its supported process. On states supported in both compared conditions, with the regularity needed to extend those identities,

$$v_a - v_b + (\mathcal{A}_a - \mathcal{A}_b)\Phi = 0.$$

This subtraction is not licensed by disjoint state samples without a justified transport model. A strong experiment predicts a held-out change in context, timing or available information using the same coordinate and units, while checking intervention effects on measurement. Across a connected shared region, full span of the

combined diffusion directions forces a constant common potential. Incomplete span leaves a candidate possible but does not construct a globally integrable potential. Frozen state definitions and controlled complexity make the comparison a test of one mechanism rather than a collection of separately fitted descriptions.

Overlapping interventions can test a shared potential without first fitting its formula. In a differentiable deterministic model on one fixed physical clock, let $f(S, u)$ be state velocity and let the signed contribution rate satisfy $\ell(S, u) = -\nabla\Phi(S)^\top f(S, u)$ throughout a supported neighborhood of control u . At the same state, collect the causal derivatives $\partial f / \partial u_j$ as columns of F . If the integrated-reading rate is $z = \ell + o\rho$, with one common origin o and qualified exposure rate ρ , define $r_j = \partial z / \partial u_j$ and $h_j = \partial \rho / \partial u_j$. Every control contrast q satisfying

$$Fq = 0, \quad h^\top q = 0$$

must satisfy $q^\top r = 0$. Differentiating the common-potential relation gives $r = -F^\top \nabla\Phi + oh$, so both unknown terms cancel. A nonzero contrast exists only if the combined drift-and-exposure matrix has a nontrivial nullspace. This is a test of every smooth potential on the nominated state, with the physical contrast fixed before inspecting the held-out rate response.

Estimated cancellation needs a complete error budget. Small physical residuals cannot bound the predicted response unless potential gradients and origin are independently bounded or included in valid joint inference. Finite pulses add curvature error, and an omitted state can remove the apparent cancellation. For

diffusion models, changing covariance contributes a Hessian term that must also cancel; the deterministic formula cannot simply be reused. A reproducible violation can exclude the specified coordinate family. Agreement supports a local physical restriction and leaves global integrability and terminal closure to separate tests.

Recovery metrics should include confusion matrices, calibration, parameter bias, interval coverage, and residual structure. A high average classification rate can hide failure for the route most relevant to the claim. Class-specific errors and an open-set rejection option are therefore required.

When the generator cannot be recovered under realistic sampling, the route remains unidentified. The report may support family-level compatibility, a narrower parameter statement, or No adequate estimate, and it should name the measurement or intervention needed to create separation. More notation or a larger sample cannot replace a design whose observable laws are equivalent.

18.7.4 — Held-Out Prediction and Cross-Equation Transport

Held-out prediction tests whether a fitted route forecasts observations it was not tuned to reproduce. Cross-equation transport is stronger: one frozen object estimated from one module should predict another relation, action response, or endpoint regime. Refitting each equation separately removes the overidentification that could distinguish mechanism from flexible description.

A fixed physical potential predicts the same signed contribution along any two admissible paths between the same sufficient states. For a finite graph, let B have -1 at an edge's source and $+1$ at its target, let w contain the calibrated edge contributions, and let φ contain the state potentials. Then

$$w = -B^T \varphi, \quad Bc = 0 \Rightarrow c^T w = 0.$$

The cycle space contains $m - n + k$ independent algebraic constraints for m edges, n vertices and k connected components. A contrast can compare two forward paths; it need not require physically reversing a transition. Repeated dependent loops improve precision without adding independent constraints. These are standard graph-potential restrictions (Jiang et al., 2011).

Qualify whether each edge quantity is a realized contribution or only a conditional mean. Mean-zero circulation permits nonzero individual circulation when edge rewards are random. Estimate the state map on development records and test new paths with shared-edge covariance, state uncertainty and observation loss included. A failed contrast can reject the nominated state-potential route. Any added state must earn its complexity through new predictions; an ordinary potential mechanism faces the same test and can legitimately pass.

Priority, blocking, and reactivation matter only if they lead to observable predictions. The predictions should involve timing, content, channel conflict, action selection, and response to changed options. A queue model should not merely say unresolved demands exist. It should say how influence moves (Manski, 2003; Jacod & Shiryaev, 2003; Tao et al., 2018).

A concrete task might present low-stakes unresolved goals, information cues, and repair opportunities across days. The model predicts which goals return to attention when repair becomes possible, which remain blocked under competing load, and which decline after direct resolution. The task need not induce harm. Ordinary planning, missed messages, delayed tasks, or ambiguous feedback can carry enough structure.

Observable signatures may include report recurrence, increased attention to relevant cues, altered choice latency, physiological preparation, sleep disruption, or changes in avoidance after option availability shifts. Each signature requires a rival. For example, choice latency can reflect uncertainty, fatigue, motor speed, or task confusion. A queue interpretation earns nothing without comparison.

Neural and psychological correlates supply auxiliary predictions that can help separate mechanisms. The queue itself retains its formal definition, allowing researchers to test how particular correlates relate to its predicted dynamics.

Table 18.4. Queue-model auxiliary predictions and winning rivals.

Auxiliary prediction	Queue interpretation	Rival that could win
Cue-specific reactivation	Demand-linked cues should update belief and priority more than affectively matched but unrelated cues.	Associative learning or trauma-cue conditioning may explain the same pattern without queue structure.

Auxiliary prediction	Queue interpretation	Rival that could win
Control allocation	Higher priority should shift latency, task switching, information seeking, or avoidance under constrained attention.	Expected value of control, fatigue, or scarcity models may predict the allocation more simply.
Interoceptive salience	Bodily readiness may mark demand relevance when verbal report is delayed or blocked.	Homeostasis, anxiety physiology, medication, illness, or sleep loss may explain the signal.
Memory-access pattern	Blocked demands may reappear under context, safety, or cue changes rather than constant conscious access.	Memory consolidation, suppression, or ordinary contextual retrieval may win.
Repair-sensitive change	External remedy should alter later cue response when it actually changes state or options.	Relief, expectancy, social support, or simple uncertainty reduction may fully explain the change.
Dynamic	Queue prediction	Serious rival
Blocking	Demand influence rises when competing load falls.	Allostatic rebound or safety-enabled emotion.
Reactivation	Repair-relevant cues revive specific demands.	Cue conditioning or memory priming.
Starvation	Long-neglected demands surface after capacity returns.	Fatigue recovery or reporting bias.
Dominance	One demand suppresses unrelated action channels.	Scarcity focus or threat prioritization.

The table is not evidence. It is a map for falsification. If the rival explains the same pattern with fewer assumptions and better prediction, the queue model loses that component.

The final observable requirement is humane burden budgeting. A prediction requiring distress induction for Law-specific evidence is inadmissible under Chapter 3. The design must use a nonharmful contrast or leave that prediction untested.

Independent predictions are consequences not guaranteed by the construction. They are the Queue model's best chance to become scientifically useful. They concern timing, specificity, counterfactual response, cue sensitivity, repair effects, and model recovery under shared observation (Wilson & Collins, 2019; Manski, 2003).

A strong prediction might say that a blocked demand will reappear after competing load drops only when a repair-relevant action becomes live. A rival allostatic rebound model may predict general affect release after load drops, but not repair-specific action selection. A cue-conditioning model may predict cue fear, but not dependence on repair availability. These distinctions make the claim vulnerable.

Independent predictions should be made before the data are viewed. They should include negative controls, such as resolved demands, unrelated cues, and nonrepair actions. If the Queue model predicts specificity and the data show broad nonspecific arousal, the model narrows.

Prediction should also be channel-specific. The model may predict report change without physiological change,

physiological preparation without report, or behavior change only when action is safe. These channel predictions are powerful because they can fail in patterned ways. A model that predicts every channel always moves together is likely too simple.

A public summary identifies the task, population, observation model, predicted pattern, and comparative result. Those particulars make a queue-like model's contribution clear and independently assessable.

The model earns scientific confidence by naming the observations that would support or count against each component. If repair-relevant cues do not matter, if blocked states do not reappear under capacity release, if false positives are high, or if rivals recover the data better, the corresponding Queue-model component requires revision or retirement.

18.7.5 — Model Recovery and Confusion Matrices

Model recovery uses simulated known generators to test whether the full pipeline returns the correct family. Confusion matrices should report class-specific errors, especially cases in which ordinary rivals are misclassified as the candidate route. Recovery is a prerequisite for interpreting real-data model selection.

Parameter recovery asks whether a fitting procedure can recover known parameters from simulated data. Model recovery asks whether the pipeline can identify which model generated simulated data. These are standard safeguards in computational modeling and reinforcement-learning analysis. For the candidate queue-style route model, they are the gate before human interpretation (Wilson & Collins, 2019).

Table 18.5. Construction and recovery stages.

Recovery stage	Required action	Failure meaning
Parameter recovery	Simulate data from known Queue parameters and refit the same model.	If recovered parameters are biased, unstable, or correlated incorrectly, person-level interpretation pauses.
Model recovery	Simulate Queue, homeostatic, active-inference, model-free, model-based, and safe-control worlds.	If the pipeline cannot identify the generating family above chance or practical thresholds, real-data comparison is not trusted.
Noise and missingness stress	Add report noise, sensor dropout, blocked observations, and context misclassification.	If queue structure appears only in clean data, the claim narrows to artificial settings.
Policy confusion stress	Fit rival policies to Queue-generated data and Queue policies to rival-generated data.	If models mimic one another under realistic samples, the result becomes nonidentifiable.
Held-out task transfer	Train on one demand family and test on a different but prospectively specified family.	If fit does not travel, the model may describe a local task rather than a mechanism.

A model-recovery matrix can be written as:

$$\mathbf{M} = (M_{ij}), \quad M_{ij} := \Pr\{\hat{m}(D) = j \mid D \sim \mathcal{M}_i\}$$

The entry M_{ij} is the probability that data generated by model i are classified as model j . A good recovery matrix has high diagonal values. If queue-generated data are often classified as active-inference data, or active-inference data are often classified as queue data, the models are not separable under the task.

Parameter recovery has the same discipline. If the true persistence, reactivation, or repair-sensitivity parameters cannot be recovered in simulation, fitted human values should not be interpreted as meaningful. A beautiful parameter name does not create identifiability. Wilson and Collins's modeling guidance is useful here because it treats recovery checks as part of responsible cognitive modeling, not as optional decoration.

Recovery checks should vary noise, missingness, sample size, cadence, individual differences, and model misspecification. A model that recovers parameters only under clean synthetic data may fail in real life-course or clinical settings. Chapter 17 showed why observation processes matter; here the recovery gate applies that lesson to mechanism.

Model recovery should also include adversarial rivals. The Queue model should be tested against versions of homeostasis, model-free RL, model-based planning, active inference, safe control, trauma cueing, and scarcity that are strong enough to win. A weak rival matrix creates false support.

The acceptance test is practical: a modeler should be able to implement at least one candidate queue-style route version and identify the conditions under which it cannot be distinguished. An

evocative queue image without that recovery and failure logic does not constitute a mechanism.

18.7.6 — Open-Set Adequacy and Unknown Mechanisms

Route recovery must allow the named library to be wrong. Calibrate an explicit none-of-the-models branch on held-out unfamiliar generators, and use absolute checks such as residual dependence, calibration failure, impossible transitions, poor intervention transport, and posterior-predictive misfit. Unknown is not favorable to PTVC; it means the current route library is inadequate and should trigger broader search or narrower scope. Chapter 25 supplies the full open-set benchmarking framework (Vehtari et al., 2017; Villaverde, 2019).

18.8 — Route Failure, Retirement, and Frontier Theorems

The route definition specifies its necessary geometry, committor transport, generator recovery, intervention response, and comparison with equally resourced rivals. Prespecified outcomes connect each test to retention, revision, or retirement of the corresponding component.

Route retirement can be component-specific. A queue priority rule may fail while partial-observation methods remain useful. A Doob construction may remain a strong rival after losing mechanism status. A reachability theorem may survive while its phenomenal bridge fails.

Frontier theorems should target genuine bottlenecks: state sufficiency, uniqueness of shrinking-band limits, route-endpoint bridges, identifiability under observation error, junction algebra, and invariance across representation changes. A theorem that merely restates an imposed boundary does not advance the program.

Remote mathematical proposals become testable only when they supply a carrier, a bridge to the declared phenomenal object, a distinctive prediction, a nearest adequate rival, and a failure condition. Their scientific status is set by those commitments, not by novelty or vocabulary. Until a proposal changes a protocol, recovery test, or verdict boundary, it remains a research direction in the mathematical reservoir.

Versioned retirement keeps the public record current. When a route narrows or fails, update or withdraw the affected formulas, figures, captions, websites, and summaries.

Mathematics can expand the space of possible mechanisms, but only discriminating evidence can narrow it. The next chapter asks where an intervention would first make those mechanisms diverge.

18.8.1 — Route-Failed as Scientific Progress

Route-failed is a constructive scientific verdict when a prospectively specified mechanism misses its distinctive prediction after representation, observation, and recovery gates pass. The report names the failed component and reference class, preserves any surviving method or descriptive result, and avoids turning one mechanism loss into a vague judgment about the entire theory.

The most ordinary failure is no added predictive value. If a simpler model predicts behavior, report, physiology, context sensitivity, and reactivation as well as the Queue model under fair comparison, the queue should not receive mechanism status for that reference class. Elegance is not a tie-breaker (Lakens, 2017; Manski, 2003).

No added value should be assessed out of sample. In-sample fit is especially weak when the Queue model has extra parameters. Held-out time blocks, leave-person-out tests, leave-site-out tests, and prospectively specified predictions give a better answer. The model should be asked to predict cases it did not help explain.

No added value can be local. The queue may add value in repair-relevant reactivation tasks but not in chronic stress tracking. It may predict report recurrence but not physiological channels. It may work within individuals but not across persons. The correct response is narrowing, not total victory or total dismissal.

A no-value result reports which rival performed best, the observation model, parameter recovery, available power, and the influence of missingness. These details preserve the finding's value for subsequent work.

Public summaries retire queue language in domains where it has added no predictive or explanatory value. When a prospectively specified rival explains a domain better, that verdict is stated directly. This is answerability turning a clear result into a better research direction.

When ordinary models explain the observations equally well with fewer assumptions, they supply an efficient foundation for the next study.

18.8.2 — Counterexamples and Impossibility Results

Counterexamples and impossibility results are stronger than poor fit when their assumptions match the claim. A prefix outside the declared solvency region, a generator that cannot be recovered from the permitted observations, or a theorem showing observational equivalence can retire a route without waiting for more favorable data.

A model can add variables and still make the wrong dynamic predictions. If it predicts a demand will rise when repair becomes available and no such rise occurs, the priority rule weakens. If it

predicts cue-specific reactivation and the data show nonspecific arousal, the reactivation mechanism weakens. If it predicts discharge after repair and residual burden persists, the discharge rule was too simple (Popper, 1959; Lakens, 2017).

Wrong predictions are more informative than vague failures. They tell the field which component failed: entry, priority, blocking, reactivation, discharge, observation, or policy. A precise failure can improve the model or retire a component. A vague failure invites rhetoric.

The model should prestate failure branches. For example, if a blocked demand does not reappear after competing load drops, then the blocking-starvation hypothesis is unsupported in that setting. If unrelated cues produce equal reactivation, cue specificity fails. If participants choose actions predicted by ordinary reward history rather than queue priority, the model-free rival gains ground.

When repair produces a different response than the model predicted, examine context, safety, meaning, time scale, and channel disagreement. Participants' reports and preferences help identify which assumptions need revision.

Wrong priority and reactivation predictions also guide future study. They may show that horizon belongs more in Chapter 19, bodily access more in Chapter 20, or rival adaptation more in Chapter 21. That rerouting should be visible, not silent.

18.8.3 — Nonidentification Boundaries

Nonidentification is a boundary on what the design can learn, not a temporary inconvenience to be hidden by a point estimate. Two

route states, generators, or endpoint branches are nonidentified when they induce the same observed law under the available interventions and measurement process. In that case, no amount of additional sampling from the same design separates them (Bollen, 1989; Villaverde, 2019).

The boundary can arise from symmetry, state aliasing, unknown origin, sparse observation, shared confounding, or endpoint selection. It can be structural, meaning separation is impossible even with infinite data under the design, or practical, meaning finite noise and cadence make separation too weak. The result identifies which boundary applies: more sampling under the same design cannot resolve structural equivalence, whereas redesigned observations or interventions may break that equivalence, and denser or better-targeted data may resolve a practical limit.

Identification analysis belongs before power analysis. Power cannot rescue an estimand that is not identified, and a narrow confidence interval around a model-dependent quantity does not create the missing bridge. Symbolic checks, simulation, profile likelihoods, and sensitivity regions can reveal the boundary before participants carry the burden of a larger study.

A useful outcome is an identified set. Rather than choosing one route, the analysis reports the collection of routes or parameter values compatible with the declared data and assumptions. Subsequent studies can be designed to shrink that set through safe interventions or improved channels. The set should not be converted into a rank among persons.

Nonidentification can also be ethical. The intervention needed for separation may be too burdensome, invasive, or harmful. The correct response is to preserve the uncertainty, not to relax the ethical boundary. A scientific program is allowed to leave a mechanism unresolved.

Apply the canonical evidence-state rules in §24.2 and Table 27.5. Here, route nonidentification narrows the distinctive component while leaving mechanism-neutral consequences separately testable; it does not by itself establish Route-failed. Record that status change rather than hiding it under a replacement mechanism.

18.8.4 — Frontier Theorems Worth Proving

Frontier theorems should sharpen the exact places where mechanism claims can succeed or fail. Useful results may establish minimal conditions for directional reachability, uniqueness of a completion kernel, recoverability of a generator under partial observation, or impossibility of distinguishing two endpoint constructions from a declared observation class. The value of such theorems lies in reducing ambiguity, not in making the hypothesis look mathematically grand (Villaverde, 2019).

One frontier concerns topology. When attainable sets are nonconvex, disconnected, or carried on lower-dimensional supports, convex relaxations can produce false solvency. A theorem that bounds the error of the relaxation or identifies conditions under which support-function tests are exact would directly improve adjudication.

A second frontier concerns path conditioning. Several shrinking-band limits can approach the same zero-probability terminal event while inducing different bridge laws. Tightness, uniqueness, and stability under observation should be stated rather than assumed. An impossibility theorem may be more valuable than another candidate construction if it shows that the data cannot distinguish those limits.

A third frontier concerns causal localization. If two mechanisms agree under every ethically admissible intervention in a reference class, they are empirically equivalent there. Formalizing that equivalence prevents endless mechanism tournaments that cannot change a verdict. It also clarifies what new action, channel, or population would be required for separation.

The theorem program should include machine-checkable statements where possible. Proof assistants can make formal assumptions, definitions, boundary conditions, and proof dependencies mechanically inspectable, and substantial mathematical theorems have been verified through such systems (Gonthier et al., 2013; Nipkow, Paulson, & Wenzel, 2002). Formal verification does not validate the empirical premises. A verified theorem remains conditional on the state and observation architecture it receives.

Every frontier target should name its scientific consequence. Proving it should change a protocol, recovery test, verdict boundary, or retirement rule. Theorems that do not alter an empirical or conceptual decision belong in the mathematical reservoir, not in the public argument as evidence.

18.8.5 — Versioning, Withdrawal, and Successor Routes

Versioning makes retirement operational. The record names the route version, source model, assumptions, failed test, public artifacts, and any successor. Withdrawal means the old object is no longer used for new inference even if it remains available as historical evidence.

Public language follows the versioned mechanism record. A successor candidate receives its own identity, assumptions, tests, and evidential status, allowing the program to build on a clear account of the preceding result.

Revision becomes unsafe when readers cannot tell what changed. If an earlier prospectively specified version attributed reactivation to a queue-style route and later evidence favors interoception, active inference, or adaptation, the change is labeled as narrowing, replacement, or retirement. Otherwise every outcome can appear to preserve the preferred account.

A clean retirement notice should name the component, reference class, rival, evidence, and public-language consequence. It might say that queue-priority predictions failed in a low-stakes task and were better explained by model-free reward history. It might say that discharge rules were nonidentifiable in life-course data. It might say that the metaphor remains useful privately but leaves scientific mechanism language.

The Queue model is one testable candidate within a wider research program. Reporting where it succeeds and where it loses allows later work to preserve useful results, revise unsupported

components, and pursue better explanations with a clear record of what has been learned.

Public artifacts must update after retirement. Diagrams, summaries, captions, social posts, donor descriptions, and talks should not continue to imply a mechanism that has narrowed or left the field. Correction-readiness is part of scientific dignity.

18.8.6 — What Survives Mechanism Defeat

The Part provides methods with continuing scientific value. Completion geometry describes feasible continuations under declared constraints. Committors provide conditional forecasts. POMDPs organize action under partial observation. Bridge constructions supply baselines for endpoint-conditioned data. Each method contributes to a more precise account of the phenomena.

Defeat also preserves negative knowledge. A failed queue route may show that priority and reactivation add no predictive value. A failed bridge discriminator may show that the observation process is too coarse. A failed causal locus may reveal that the available interventions do not identify the state. Each result prevents the next study from repeating an unproductive path.

Update each proposition according to the result that bears on it. A route test changes the status of the specified mechanism; a test of a target-level requirement changes the corresponding theory-level claim.

Human protections remain active under every outcome. Care is immediate, participation voluntary, and no model output scores worth, trust, consciousness, eligibility, or personal obligation.

These commitments do not depend on route success or need repair when a mechanism narrows or fails.

A route registry preserves failed candidates as failure memory. Versions, assumptions, datasets, win conditions, results, and artifact corrections stay searchable. This preserves the knowledge gained when a candidate is retired.

The theorem and simulation infrastructure also survives. Impossibility regions, nonidentification boundaries, recovery benchmarks, and open-set challenge generators can be reused for new mechanisms. A retired route can therefore improve the standards applied to every successor.

A frontier theorem should be stored with its assumptions, counterexamples, and empirical dependencies. If a later study violates one assumption, the theorem is not refuted; its application is. If the assumptions cannot be connected to observable quantities, the theorem remains formal rather than evidentiary.

Route retirement also protects the target hypothesis from informal rescue. Once a route loses its prospectively specified test, later sections may not cite its intuitive plausibility as if nothing happened. A new route begins with a new state, new assumptions, new predictions, and a new evidence status.

Failure memory should remain queryable. Later investigators need to recover which generator, endpoint branch, observation process, intervention, and scoring rule failed, together with the code and synthetic cases that exposed the failure. A narrative summary without the executable test would invite the same mistake to return under a new name.

Some tools may migrate after route defeat. A committor can remain a forecasting object, a belief state can remain an observation model, and a queue can remain a behavioral description if each passes its narrower validation. The migration must be explicit so a useful method does not retain the evidentiary halo of the retired mechanism.

The chapter closes with a standard for constructive failure: preserve the theorem, benchmark, counterexample, and humane boundary; withdraw the interpretation that lost; and leave the next study a sharper question than the one that entered.

Chapter 19 — Causal Loci and Interventions

A mechanism becomes causal only when an intervention has a typed point of entry and a declared downstream consequence. A prompt, medication, action menu, information set, observation channel, assignment process, continuation policy, or endpoint rule alters a different part of the data-generating system. Chapter 19 maps those loci before any response is credited to a latent route.

Intervention-indexed continuation laws provide the central estimand language. They preserve the experienced past while comparing future path distributions under a declared action, regime, assignment, or information change. The discriminating question is whether the candidate predicts a continuation difference that ordinary control, scarcity, fatigue, learning, homeostasis, or selection models cannot recover under the same information.

The most informative evidence often appears at the earliest divergence. Neighboring models may agree before commitment and separate only after a cue-controlled perturbation, a change in action support, or an information update. A difference that appears before assignment instead raises leakage or selection concerns. Common information sets and timestamped eligibility rules make the ordering testable.

Chapter 7 defines the modal ladder and the policy-mixture exactness result. Chapter 19 asks the causal question that those results leave open: which intervention locus, assignment process, and information set could make an observed action pattern informative about a completion route rather than ordinary choice, constraint, or selection?

Assignment opens a causal pathway; it does not complete one. Commitment, delivery, adherence, switching, observation, retention, intercurrent events, and truncation by endpoint or care determine which continuation was actually generated and which remains observable. The denominator history is part of the mechanism claim.

The preferred designs are safe experimental forks. Low-burden tasks, natural experiments, timing-neutral information conditions, target-trial emulations, and ordinary-care variation can separate routes without manufacturing distress or withholding treatment. Procedure burden, uncertainty, effort, and opportunity change are measured because the test itself can alter the continuation it seeks to explain.

Mechanism tournaments use equal information, preprocessing, tuning budgets, scoring rules, stopping conditions, and opportunities to abstain. Residual-aware routes, expected-value-of-control models, reinforcement-learning policies, homeostatic controllers, and scarcity models all receive a genuine path to victory. A specialized candidate cannot earn support from endpoint context, richer sensors, or analyst attention denied to its rivals.

Shadow price appears at the end as one local sensitivity example. Under a declared constrained optimization problem, an identified Lagrange multiplier can express the marginal change in an objective associated with relaxing an active constraint, with units and regularity conditions made explicit. Its scientific role is constraint sensitivity; it is never a price of pain, pleasure, a person, a life, a duty, or care.

The chapter's concrete settings include a task where options narrow, a treatment route with changing support, an administrative delay, a learning experiment, and a simulation with controlled generator differences. Each setting is used to separate causal structure, not to dramatize suffering.

Causal diagrams make assumptions inspectable. They display measured and unmeasured confounding, interference, post-treatment selection, positivity failures, treatment-version ambiguity, measurement error, and competing pathways. The diagram's value is practical: it shows which contrast is identified, which is only bounded, and which should return No adequate estimate.

The causal-locus framework remains valuable under every PTVC outcome. It is a general method for separating interventions on constructs, route states, proxies, observations, selection processes, and decisions, and for preventing behavioral compliance or device response from being mistaken for inner truth.

The reader should leave able to audit a mechanism proposal in one sequence: define the target and representation; name the altered kernel; freeze the information set and action support; trace assignment, delivery, selection, and observation; state the earliest divergence and strongest rival; and specify the ethical stop and failure disposition. A proposal that cannot complete that sequence remains an explanatory sketch rather than a causal test.

The chapter converts abstract control language into bounded, inspectable evidence. Chapter 20 now asks whether embodied

processes carry, constrain, or merely witness those effects, and whether lags, medication, illness, trauma, disability, and device error change the causal story.

The same observed change can arise from different loci. A lower reported intensity may reflect altered phenomenal value, memory, language, demand characteristics, sensor quality, or selective observation. The design therefore needs at least one contrast that separates the candidate locus from these alternatives, plus a no-estimate route when the contrast is unavailable.

Mechanism claims should be indexed by action support. A conclusion obtained under one narrow set of safe actions does not automatically transport to clinical treatment, everyday choice, or terminal care. The chapter tracks the exact action set beside every continuation law and intervention verdict.

The human meaning of this precision is practical. When science mislocates an effect, people may be blamed for a device artifact, denied relief because a report changed, or subjected to a stronger intervention than the evidence requires. Accurate locus language protects both inference and care.

19.1 — Candidate Causal Loci and the Representation Gate

Candidate loci include the phenomenal process, a route state, a neural or bodily mediator, a memory state, an action policy, the observation kernel, the endpoint process, and the selection mechanism. Each locus implies a different intervention and a different causal estimand.

The representation gate forbids a common shortcut. Changing self-report wording may change measurement without changing experience. Changing behavior may alter action while leaving phenomenal value uncertain. A physiological perturbation may affect arousal, pain, motor capacity, or reportability. The design names the locus it actually touches.

A causal graph should include the latent target, measured channels, treatment, mediators, actions, context, missingness, and endpoint. The graph is not complete merely because it is drawn; omitted variables and measurement error should be listed with sensitivity plans.

Interventions on the endpoint process require special caution. A protocol may change observation or administrative stopping, but no study may manipulate dying or withhold care to sharpen a terminal contrast. Natural variation and ethically permissible clinical processes set the boundary.

Representation uncertainty can make the causal effect set-valued. If several scalarizations remain defensible, the analysis should report effects across the identified set rather than select the one that produces the desired direction. The locus is identified only

when a neighboring-locus intervention would predict a different pattern.

A causal locus is the earliest component of the declared data-generating system at which an intervention changes the distribution of a downstream quantity under a fixed representation, routing rule, and endpoint definition. Any intended change to the observation process must be explicitly typed as part of the intervention. The locus may be neural, bodily, computational, environmental, relational, or distributed. An anatomical correlate becomes causal only through the intervention semantics, treatment version, assignment time, mutable state variables, and continuation outcomes that connect it to the contrast (Pearl, 2009; Hernán & Robins, 2020).

The representation gate comes first because every intervention is interpreted through declared variables and bridges. A change in self-report may reflect experience, threshold, memory, language, demand, or disclosure. Autonomic change may reflect arousal, posture, temperature, medication, disease, pain, or effort rather than valence. Route inference therefore compares explicit causal structures and tests measurement invariance across arms before assigning a phenomenal interpretation (VanderWeele, 2015; Khalsa et al., 2018).

19.1.1 — Representation Before Intervention

Intervention begins only after representation is fixed. A treatment cannot be well defined if the state it is supposed to change is allowed to shift between phenomenal value, route state, physiology, report, and behavior. The causal graph should

therefore name the target layer, the manipulated variable, the mediators, the observations, and the endpoint before an effect is estimated (Pearl, 2009; Hernán & Robins, 2020).

The representation gate also fixes sign, unit, clock, and stream ownership where those features matter. Changing an affect scale or bearer definition after assignment can alter the estimand rather than merely improve measurement. A causal result belongs to the declared representation and cannot be transported to another layer without an explicit bridge.

A concrete failure occurs when a breathing intervention changes arousal and the analysis calls the change a reduction in cumulative negative valence. The intervention may have changed respiratory sensation, attention, report, or threat prediction. Without a measured-to-latent bridge, the stronger claim is not identified. The correct effect can still be useful at the channel it actually measured.

Representation error can also create a collider. Selecting participants because a report and a physiological measure agree may condition on a common effect of latent state and measurement quality. The selected sample can then show associations that do not hold in the eligible population. The selection rule belongs in the causal diagram.

Before data collection, the protocol should ask a sequence of questions: what object is acted on, which variable is manipulable, what observation witnesses the change, what alternative pathway produces the same witness, and what result would show that the

representation was wrong. This gate prevents intervention language from outrunning semantics.

The study can evaluate report, physiological, and behavioral effects under their respective measurement bridges. Each result is labeled by the construct its qualified analysis supports.

19.1.2 — Phenomenal, Neural, Bodily, Behavioral, and Institutional Loci

A causal-locus analysis separates at least five levels: phenomenal state, neural process, bodily regulation, behavior or policy, and institutional environment. A candidate mechanism may act at one level, travel through another, and be observed at a third. Treating the nearest measurable level as the causal source is a category error (Pearl, 2009; Hernán & Robins, 2020).

The phenomenal locus concerns changes in the target state itself. Because phenomenal value is not directly instrument-fixed, an intervention on report or physiology cannot be assumed to intervene on experience. The representation and measured-to-latent bridges must already be qualified before phenomenal causal language is used.

Neural and bodily loci include sensory integration, prediction, salience, autonomic regulation, endocrine state, pain, fatigue, and action control. These processes may mediate or confound observed affective change. A reproducible correlate identifies a candidate pathway whose specificity can be tested against other routes.

Behavioral loci include attention, avoidance, communication, rest, information seeking, and task choice. Behavior can alter

future context and measurement while remaining only an imperfect witness to experience. A person may choose the same action from different states or choose different actions under the same state because opportunity and risk differ.

Institutional loci include record systems, access rules, delays, clinical practice, family logistics, and material constraints. An intervention that corrects a record or opens treatment access may change future experience through the world rather than through an internal controller. The causal graph should preserve that external route instead of relocating the burden inside the person.

Cross-level claims require temporal order and mediation tests. If institutional repair changes behavior first, physiology later, and report last, that sequence differs from a direct bodily perturbation. The study should state the expected lag pattern and identify which alternative paths could create the same order.

The locus map confers no hierarchy of human truth. Neural classifiers, self-report models, institutional records, and behavior each occupy bounded evidential roles. Their disagreements become design information, while the person retains authority over care, refusal, correction, and participation. The map exists to locate interventions and uncertainty, not to appoint an oracle.

Locus failure produces a narrower but still informative result. A change localized to observation, report, behavior, or physiology remains evidence about that layer and is not promoted to a phenomenal mechanism. When several loci remain compatible, the output is a causal identified set with the next discriminating measurement or perturbation named explicitly.

19.1.3 — Manipulability and Well-Defined Treatments

A well-defined treatment has versions that are sufficiently specified for the causal question. ‘Support,’ ‘rest,’ ‘information,’ and ‘repair’ are not single interventions. They vary in timing, intensity, delivery, consent, context, and the pathways they open. If different versions produce different outcomes, combining them under one label violates consistency and obscures the locus of action (Hernán & Robins, 2020).

Manipulability is layer specific. A study can randomize a prompt, offer a safe action, or observe an independently indicated care transition; it cannot directly assign a private belief, force a latent route state, or manipulate a truth-level endpoint. The causal claim therefore follows the variable that was actually changed and the downstream object the design can support.

The same nominal treatment can be ill defined across persons. A notification may be informative for one participant, coercive for another, inaccessible for a third, and irrelevant for a fourth. Treatment versions should therefore include accessibility, language, burden, and opt-out conditions rather than assuming that delivery equals exposure.

Pilot work tests well-definedness. Process measures record what was delivered, understood, used, and experienced as burdensome. Qualitative feedback identifies unanticipated treatment versions and helps refine the intervention definition.

Rivals may act at different versions. An ordinary expectancy model may respond to information, a control model to action availability, and a social-support model to human contact. A

mechanism tournament should preserve those components instead of using a bundled intervention that lets every explanation claim success.

When the treatment remains ambiguous, the effect should be reported at the assignment level or as a set of version-specific possibilities. The route claim narrows until the action can be defined without hiding the work, burden, and pathways that make it real.

19.1.4 — Mediators, Proxies, and Colliders

A mediator lies on a causal path from intervention to outcome, a proxy measures or predicts an unobserved variable, and a collider is caused by two or more variables whose conditioning can create a spurious association. These roles are not interchangeable, even when the same variable appears in each model (Pearl, 2009; VanderWeele, 2015).

Physiology illustrates the problem. Heart-rate variability may mediate a breathing intervention or proxy autonomic state. When both medication and distress influence whether a clean segment is recorded, the recording indicator is a collider, and restricting analysis to recorded segments can induce bias. The analysis must specify each variable's role and which data could distinguish it.

Post-treatment adjustment can remove part of the effect the study intends to estimate. Conversely, failing to adjust for a pre-intervention common cause can create bias. A causal diagram should therefore precede the regression list, with time ordering and treatment versions visible.

Proxy validity requires a bridge. A wearable feature that predicts report does not become the latent state; it may be sensitive to activity, posture, illness, or device fit. Calibration, transport, and measurement error must accompany any proxy-based mediation claim.

Selection on complete data can create collider bias. Participants with usable physiology may differ because both health state and engagement affect recording. Restricting to those records can induce associations that look like a mechanism. Observation and retention nodes belong in the graph.

Sensitivity analysis should target the role most likely to fail. Negative-control outcomes can detect residual confounding, measurement-error models can bound proxy distortion, and mediation sensitivity can assess unmeasured mediator-outcome confounding. One generic robustness check is not enough.

When the role remains ambiguous, the result says so. A variable may remain useful for prediction while losing a causal interpretation. Causal restraint is not a weakness; it is what keeps a convenient biomarker from becoming a false mechanism.

19.1.5 — Cross-Level Bridges and Causal Granularity

Causal granularity determines what counts as an intervention and what outcome it can change. A molecular perturbation, network-level stimulation, breathing instruction, communication aid, record correction, and policy change operate on different state spaces. Their effects cannot be compared until the bridge between levels, the causal estimand, and the assumptions permitting

transport are specified (Bollen, 1989; Pearl, 2009; Hernán & Robins, 2020).

A bridge may be mechanistic, statistical, or merely correlational. Mechanistic bridges describe how a lower-level change alters a higher-level state. Statistical bridges relate measurements across levels under a declared population. Correlational associations support neither intervention transport nor phenomenal identification by themselves.

Aggregation can hide causal heterogeneity. A neural-network average may remain stable while subcircuits shift in opposite directions; a population intervention effect may conceal person-specific benefit and harm. The selected level should preserve the distinctions required by the estimand.

Disaggregation can also mislead. Adding more biomarkers does not create a better mechanism if the variables are noisy, redundant, or descendants of the same latent state. The model should prefer the coarsest level that preserves the causal contrast and can be measured without excessive burden.

Temporal scale is part of granularity. Autonomic changes can occur in seconds, hormonal changes over hours, learned behavior over days, and institutional repair over months. A cross-level bridge should predict the ordering and duration of effects rather than align every channel to one arbitrary clock.

Transport across levels requires invariance. A relation estimated under a laboratory breathing task may not hold during illness, medication change, or real conflict. Held-out contexts and

alternative treatment versions test whether the bridge is mechanism-level or task-specific.

At each level, the representation gate requires a qualified link between the measured channel and the construct named in the result. Reports identify the highest level supported by that link.

Cross-level failure can be productive. It may show that a route is distributed, that a supposed mediator is only a witness, or that the intervention acts through context rather than inner control. The model then narrows to the level where evidence survives.

19.1.6 — Locus Failure and Scope Withdrawal

A causal locus fails when the declared intervention does not move the proposed state, the expected mediator order is absent, equal-treatment rivals explain the change, or the effect disappears after observation, mediation, and selection are modeled. Failure belongs in the mechanism register rather than being softened into a vague partial success (Hernán & Robins, 2020; VanderWeele, 2015).

Failure can be local. A bodily pathway may operate for pain relief but not for social threat; an institutional repair may change report without changing the candidate route state; a neural marker may predict task performance only in one device or site. Scope should narrow to the supported treatment, outcome, and population.

A locus also fails when the intervention is not well defined. Medication class, therapeutic conversation, rest, and information access each contain multiple versions with different consequences. If versions cannot be separated, the estimand

should be widened or withdrawn rather than treated as one causal treatment.

Nonpositivity produces a defined scope boundary. When a subgroup has no realistic access to an intervention or no safe alternative, the data do not identify its counterfactual continuation under that action. The analysis narrows the intervention family or reference class, uses partial-identification bounds where justified, or returns No adequate estimate rather than locating blocked access inside the person.

Representation failure outranks localization. If the measured channels cannot distinguish valence, arousal, pain, fatigue, salience, or reportability, no causal analysis can identify which phenomenal quantity changed. The result may still support a channel-level effect, but not a route-level one.

Ethical feasibility defines the interventions available for identification. A contrast that requires induced distress, delayed care, withdrawn analgesia, coercion, or overridden refusal is outside the admissible design, not an unfinished experiment awaiting greater resolve. The resulting causal question may remain partially identified or unanswerable under permissible interventions, and that limit is part of the scientific verdict. Partial identification should state which causal contrasts remain bounded by permissible evidence, turning ethical limits into explicit scientific scope.

Withdrawal should propagate. Figures, tables, summaries, and public excerpts must remove or relabel the failed locus. Leaving a vivid brain region, body signal, or policy arrow after the causal

claim is withdrawn misstates the evidence. Correction should reach cached educational and presentation graphics as well, because simplified locus images can outlive the technical claim that originally justified them.

The remaining value is an explicit no-inference zone. By documenting where localization failed, the chapter prevents later studies from treating the same proxy or treatment as established. Failure memory is part of cumulative science. The no-inference zone should record which alternative loci or distributed explanations remain compatible, so later work begins from the actual uncertainty rather than from zero.

A route can survive locus failure only by naming a different, prospectively testable locus. It cannot become a diffuse system that acts wherever the data happen to change. A mechanism that has no place to fail has no place in a causal science. A successor locus must make an observation or intervention prediction that differs from the failed one; otherwise relocation is only a change of labels.

19.2 — Intervention-Indexed Continuation Laws

Let $Q_{h_t}^{a,g}$ denote the continuation law after history h_t under structural action a and continuation regime g . The law includes future state, actions, observations, missingness, and endpoint behavior. It is not merely a distribution of a final score.

Potential-outcome and dynamic-regime notation can make the contrast explicit, but consistency, positivity, and interference assumptions remain. If some histories cannot receive an action, the corresponding causal effect is not identified in that region.

Past-fixity is built into the continuation law. An intervention changes the distribution of future contributions; it does not revalue the prefix already experienced. Under exact PTVC, that fixed prefix constrains the signed remainder; later relief does not retroactively reduce the negative experience already lived or make it morally justified.

Randomization yields a necessary restriction even when the past is unobserved. Let L be the signed prefix fixed before assignment Z , and R the entire remaining contribution through the true endpoint's left limit, including the intervention's effects. For a prospectively specified cohort whose realized regimes preserve the declared PTVC scope and stream ownership, exact closure gives $R = -L$ almost surely. If Z is independent of L , the distribution of R must therefore be identical across assigned arms. With conditional randomization, compare within baseline strata or standardize to a common baseline distribution.

That randomized-arm restriction can be decomposed without changing the endpoint convention. For the delayed-treatment comparison, let τ be a common, prospectively fixed treatment-onset time after assignment. On the primary strict-pre-endpoint branch, E contains the post-assignment contribution before both τ and the truth endpoint, and F contains the remaining pre-endpoint contribution at or after τ . Thus $R = E + F$; if the stream ends before or at τ , $F = 0$. A separately declared endpoint-inclusive branch instead uses $R_{\text{incl}} = E + F + J_T$, where J_T is the contribution assigned exactly at the truth endpoint and remains excluded from the primary R . The randomized-arm restriction applies separately to the complete remainder of the branch declared in advance. Under exact closure on that branch and assignment independence from the pre-assignment prefix, its distribution is identical across arms. Conditional randomization requires comparison within baseline strata or standardization to the same baseline distribution, as in the preceding result. The restriction does not by itself require any particular component or pre-treatment biological outcome to differ between arms.

A stronger localization claim requires a separately declared all-intervention structural model. For a fixed pre-assignment history h in common support, compare potential continuations under arms a and b using the same time cut and the declared bearer, routing, representation, and endpoint architecture. If primary-branch closure holds for both continuations on the model's joint probability space, then:

$$L(h) + E^a(h) + F^a(h) = 0$$

$$L(h) + E^b(h) + F^b(h) = 0$$

Subtracting gives:

$$E^a(h) - E^b(h) = -[F^a(h) - F^b(h)]$$

Here $F^a(h) - F^b(h)$ concerns the entire later contribution, not just the treatment interval. An independently justified nonzero restriction on that whole-continuation difference forces an opposite difference in $E^a(h) - E^b(h)$. Different immediate treatment effects do not establish this premise when the rest of the continuation can compensate. For an endpoint-inclusive branch, the subtraction must also include the arm-specific terminal terms J_T^a and J_T^b . A population-level directional or distributional prediction additionally depends on the structural model's distribution of histories and its observation bridge; the pathwise identity alone does not identify that prediction.

Valid randomization supplies assignment independence from the pre-assignment state within the declared randomization strata. If assignment is concealed and no assignment-correlated physical channel reaches the organism before treatment, ordinary local forward-causal models additionally supply the null that assignment has no causal route to a systematic pre-treatment biological difference. Finite samples can still show chance imbalance, and implementation can still leak assignment information. Because assignment precedes the outcome, an association measured after assignment but before treatment is not retrocausal merely because treatment is scheduled later. A PTVC-linked model predicting such an association must specify the

global-selection, viability, whole-trajectory, or other mechanism linking the assigned continuation to the earlier path and must retain, or explicitly revise, the assignment-independence premise it uses.

The terminal fork makes the conceptual contrast explicit. Imagine simulated flies from three specified history groups reaching two routes without local information identifying their downstream consequences. One candidate continuation ends biological life essentially immediately; the other permits ordinary continuation. This is a formal thought experiment, not an animal procedure. For this fork, let h denote the complete predecision stream history and $L(h)$ its signed prefix. Let d denote the candidate immediate-death continuation. The corollary uses an independently specified endpoint bridge under which the relevant stream permanently ends no later than biological death, and $C_d(h)$ is the complete decision-to-endpoint signed contribution under the declared branch convention. A necessary condition for d to be admissible under exact closure is:

$$L(h) + C_d(h) = 0$$

In the phenomenally silent idealization $C_d(h) = 0$, the condition reduces to $L(h) = 0$; more generally, it requires $L(h) = -C_d(h)$. These are necessary compatibility conditions, not sufficient conditions for death and not behavioral probabilities. They do not imply that reaching balance causes death. A route-selector must separately specify how completion restrictions affect action support or route probability, without implying conscious knowledge of the ledger or the future.

The selector's information set is part of the model. When route-to-contingency mapping is randomized independently of the pre-choice state and no local cue identifies that mapping, an ordinary local policy cannot condition its choice on it. A predicted preference for the concealed downstream contingency therefore requires a prospectively declared global or whole-trajectory selector, or an independently testable information channel. Giving a simulator access to a hidden mapping does not establish that an organism has access to it.

Mapping a localization restriction, a completion-set restriction, or terminal-fork compatibility to hatching, developmental survival, adult eclosion, or route choice requires an independently justified route, viability, and observation bridge. A biological outcome before a qualifying stream begins is evidence about the declared developmental extension, not a measured phenomenal residual. If assignment is generated only after the outcome has occurred, chance association remains possible; a reproducible systematic association beyond the prespecified null and procedural explanations would motivate an additional structural hypothesis rather than follow from the randomized-remainder result.

A restricted observation model supplies an additional check. Suppose the integrated reading is $Y = aR + oD + e$, with a common positive gain a , a common rate-origin offset o , remaining exposure D , finite first moments and equal mean errors across arms. Relative to a reference arm, $\Delta E(Y) = o\Delta E(D)$. Three or more arms can test whether a single origin explains all contrasts; if exposure means agree, reading means must agree without identifying that origin.

This removes the missing prefix from one target-level comparison while leaving complete future measurement essential. Use independently justified bounds for any missing tail and retain every assigned stream under the declared observation model. Treatment-dependent qualification, selective follow-up or varying origins can break the comparison. Ordinary regulation can also produce zero total intervention effects while leaving a nonzero lifetime total, so agreement is informative only against specified rivals. The restriction predicts no particular later adverse event and gives no reason to delay beneficial care.

The intervention itself enters the trajectory. Task effort, uncertainty, reward, frustration, relief, social evaluation, and later opportunity changes must be included in the measured estimand or intercurrent-event strategy. A supposedly neutral probe can be affectively active.

Continuation laws can be history-indexed or state-indexed. State reduction requires sufficiency. If unmodeled history predicts response after conditioning on the proposed state, the state-indexed causal claim is incomplete. Intervention definition, policy class, endpoint branch, observation process, and analysis rule must be frozen before outcome inspection.

An intervention-indexed continuation law specifies more than an average treatment effect. It describes how the conditional distribution of future states, observations, actions, route variables, and endpoints changes after a declared intervention history. In longitudinal settings, treatment may depend on evolving state, and evolving state may itself be affected by earlier treatment. G-computation, inverse-probability weighting, structural nested

models, and dynamic treatment-regime methods were developed precisely because ordinary conditioning can distort such feedback systems (Robins et al., 2000; Murphy, 2003; Hernán & Robins, 2020). A mechanism claim that ignores treatment-confounder feedback may attribute to completion dynamics what is actually produced by clinical or behavioral adaptation.

Continuation laws require empirical and ethical support. A policy cannot be evaluated where comparable assignments are absent, the action was unavailable, or ethical practice correctly prevented exposure. Positivity is therefore a property of both the data and the design. When support fails, the analysis displays the unsupported region, widens uncertainty, narrows the reference class when appropriate, and may return No adequate estimate. This is especially important near severe illness, crisis, or rapidly changing capacity, where treatment history, dropout, and care decisions are strongly state dependent and a smooth model can conceal an empty empirical neighborhood (Hernán & Robins, 2020; Petersen et al., 2012).

19.2.1 — Potential Continuation Paths

Potential continuation paths extend the potential-outcomes idea from one endpoint to a future trajectory. For each admissible intervention regime, the object is the continuation that would unfold from the current prefix under that regime. The paths are conceptual counterfactuals, not multiple lives available for observation (Robins et al., 2000; Hernán & Robins, 2020).

The path must be indexed by treatment version and time. A one-time prompt, repeated information policy, medication transition,

or changing support route can produce different continuations even when grouped under one label. The regime should specify when decisions are made and which history is available.

Only one continuation is observed for each realized decision history. Identification therefore relies on assumptions and data structure, not on comparing a participant with their own unobserved alternative. Within-person designs reduce some heterogeneity but do not make simultaneous counterfactual paths observable.

The continuation outcome should be typed. It may be a measured report trajectory, physiological channel, action-support set, endpoint-independent route state, or terminal event. A behavioral continuation is not automatically a phenomenal continuation, and a measured path is not the latent stream.

Dynamic confounding is central. Earlier treatment can change later state, which affects later treatment and future outcome. Standard adjustment can be biased when time-varying confounders are also treatment affected. G-methods or appropriately specified sequential models are needed for such regimes (Robins et al., 2000).

Support limits the path family. If a regime is never or rarely delivered in a given state, its continuation is weakly identified or unidentified there. A model should report the supported region rather than generate smooth counterfactuals for states outside observed and ethically admissible practice.

Interference can couple continuations. A family member's action, clinician schedule, shared room, or institutional policy may affect

several participants. The unit and interference structure must be declared before individual continuation effects are interpreted.

A low-burden example compares two information timings that are both ethically acceptable. The candidate route and an ordinary uncertainty-reduction model may predict different earliest changes in action support. The design follows those continuations without treating one policy as a moral instruction.

Potential paths are useful only when they remain bounded by observation and ethics. They can organize causal questions and sensitivity analyses; they cannot be returned as personal forecasts or used to claim that a person should have chosen the path that a model prefers.

19.2.2 — Dynamic Regimes and Treatment Versions

A dynamic regime maps observed history to an action at each decision time. It is more specific than a treatment label because it states when information is evaluated, which actions are available, and how the policy responds to changing state (Murphy, 2003; Hernán & Robins, 2020).

Treatment versions matter. A message can differ in content, source, timing, privacy, burden, and reversibility; a medication change can differ in dose and indication; a support action can differ in whether it expands real opportunity. Combining versions can violate consistency and blur the mechanism.

Adaptive regimes should be distinguished from ordinary clinical or personal judgment. A research rule may randomize among safe prompt timings, but it does not own care decisions or life choices.

Clinically indicated treatment remains independent of the route experiment.

History must be limited to information available at the decision point. Including future endpoint labels, later adjudication, or post-action summaries gives the regime impossible knowledge and contaminates causal interpretation.

Regime comparison should include ordinary alternatives such as fixed schedules, symptom-triggered care, uncertainty reduction, and fatigue-sensitive prompting. The candidate route wins only if its history-dependent rule predicts held-out continuation differences beyond those baselines.

Transport requires treatment-version alignment. A regime that works with one device, language, clinic, or support route may not transport when the delivered action changes. The record should distinguish policy transport from local re-optimization.

When treatment versions cannot be separated or positivity fails, the estimand narrows to a coarser intervention family or the result becomes No adequate estimate. Precision in the policy name is part of the causal claim because different versions may alter both experience and observation.

19.2.3 — Consistency, Positivity, and Sequential Exchangeability

Sequential causal inference requires consistency, positivity, and a defensible exchangeability condition at each decision point. Consistency links the observed outcome to the potential outcome under the treatment version actually received. Positivity requires that the compared actions lie in the support of the assignment law

at each relevant history: positive probabilities for discrete actions, or the corresponding density and support conditions for continuous actions. Sequential exchangeability states that, conditional on the recorded history, action assignment carries no unmeasured information about future potential outcomes (Robins et al., 2000; Hernán & Robins, 2020).

These assumptions are not technical boilerplate. A closing treatment window can destroy positivity because some actions are no longer available. Clinical judgment can create unmeasured confounding when the reasons for a treatment change are incompletely recorded. A device failure can alter both observation and subsequent action. Each failure changes what continuation effect can be identified.

Dynamic regimes make consistency demanding because treatment has history-dependent versions. ‘Continue support’ may mean different doses, contacts, or accommodations at different times. The protocol should specify decision rules and allowable deviations rather than treating a sequence of heterogeneous actions as one exposure.

Continuous monitoring sharpens the same problem. When treatment, confounders, and outcomes evolve as functions of time, feedback is not a finite sequence of visits but a dense process. Identification then requires continuous-time versions of consistency, sequential randomization, positivity, and intervention well-definition; otherwise a discretized analysis may create support that the underlying process never supplied (Ying, 2024).

For continuous interventions delivered at multiple times, positivity failure may be the rule rather than the exception. One defensible response is to redefine or project the estimand toward intervention values supported by the observed histories while displaying diagnostics for the unsupported region. The result answers a narrower causal question instead of extrapolating a full dose-response curve beyond the data (Schomaker et al., 2024).

Diagnostics can expose weak support. Propensity distributions, overlap plots, effective sample size, simulated regime frequencies, and stochastic-positivity diagnostics show where estimates depend on extrapolation rather than observed treatment support. When support is absent, partial-identification bounds or a narrower target population are more honest than a stabilized weight that hides the gap (Ring & Schomaker, 2026).

Negative controls can probe exchangeability but cannot prove it. A pre-action outcome that changes with assignment may reveal residual confounding or implementation bias. Sensitivity analysis should quantify how strong an unmeasured factor would need to be to reverse the mechanism comparison.

A continuation law earns causal language only within the histories, versions, and assumptions that support it. Outside that region the model may remain predictive, but prediction should not be rewritten as intervention effect.

19.2.4 — Interference and Shared Environments

Interference occurs when one participant's action changes another participant's continuation law. Shared environments make that possibility routine: family care, clinical staffing, social networks,

classroom rules, workplace schedules, and platform algorithms link trajectories. Treating each stream as causally isolated can bias effects even though the formal phenomenal ledger remains intrastream and nontransferable (Hudgens & Halloran, 2008).

The distinction is important. Phenomenal contributions do not transfer across streams, but causes and resources can be shared. One person's appointment may use a scarce slot, a caregiver's sleep may depend on another person's symptoms, and a policy change may alter every participant's action set. Causal independence cannot be inferred from formal nontransferability.

Designs should declare the interference unit. It may be a household, clinic, cohort, network, or time block. Exposure mappings can summarize how others' assignments enter a person's treatment version, but the mapping must be justified and sensitivity-tested. A convenient cluster is not automatically the true interference boundary.

Shared environments also create hidden burden transfer. An intervention that helps a participant by shifting work to family or staff can look beneficial in person-level outcomes while increasing unmeasured load elsewhere. The scientific record should name those displaced tasks and, where ethically and legally permitted, measure system effects without turning bystanders into involuntary research subjects.

Mechanism tournaments should include ordinary network and resource-allocation rivals. Apparent route-sensitive action changes may be responses to staffing, social information, or collective scarcity. Cluster randomization, network-aware

analysis, or partial interference assumptions may be needed before a person-level mechanism is credited.

When interference cannot be bounded, the continuation effect should be narrowed to the observed system or left partially identified. The intrastream claim does not license ignoring the shared world in which interventions occur.

19.2.5 — Partial Identification of Continuation Effects

Continuation effects are often only partially identified because latent state, treatment version, missingness, endpoint uncertainty, and unmeasured confounding cannot all be resolved. The scientifically appropriate object may be a set of effects compatible with declared assumptions rather than one point estimate (Manski, 2003; Imbens & Manski, 2004).

Bounds should separate sources of uncertainty. One component may arise from missing outcomes, another from treatment-version ambiguity, and another from an unvalidated measured-to-latent bridge. Combining them into one wide interval can hide which scientific gate would most improve identification.

Monotonicity or exclusion restrictions can narrow bounds, but each restriction needs substantive justification. Assuming that support cannot worsen any measured outcome, for example, may fail through burden, expectation, stigma, or interference. A convenient narrowing assumption is not evidence.

Sensitivity analysis should vary plausible unmeasured confounding and selection mechanisms. Tipping-point plots can show how strong a hidden path would need to be to reverse the

sign or route comparison. The plot is a decision aid, not a license to select the most favorable parameter range.

Partial identification is especially important for phenomenal effects. Even when the measured trajectory changes, the latent effect depends on calibration and representation. The identified set should carry that bridge uncertainty rather than promote a channel effect to an inner-state estimate.

A set can still discriminate. If every value compatible with the assumptions favors an ordinary rival, the candidate route loses. If the set crosses the null or overlaps several mechanisms, the result is ambiguous. If the set excludes a prospectively specified rival region, the next gate may be licensed.

Support restrictions should be visible by subgroup and state. A narrow estimate in well-observed, high-access participants cannot be silently generalized to people with disability, severe illness, limited communication, or different care contexts.

Apply §24.2 and Table 27.5. Here, identify whether wide bounds or nonidentification arise from a missing bridge, support gap, or treatment ambiguity, and state which redesign could sharpen the next inference.

19.2.6 — Descriptive, Predictive, and Causal Separation

Descriptive, predictive, and causal questions may use the same data but make different claims. Description summarizes observed continuations, prediction forecasts under a deployment law, and causation asks what changes under intervention (Hernán & Robins, 2020; Pearl, 2009).

Descriptive terminal alignment can generate hypotheses, yet selection, censoring, or retrospective clocks may produce it without a mechanism or intervention effect. Report whether the pattern survives defensible alternative alignment, censoring, and clock choices; instability across those choices is a descriptive robustness finding, not evidence for or against a mechanism by itself.

Prediction can exploit site or device proxies that are causally irrelevant. Held-out accuracy alone therefore cannot identify route state. Leave-site-out, leave-device-out, or comparable transport tests can reveal whether predictive performance survives beyond environment-specific information without converting successful prediction into causal identification.

Causal inference attaches a defined contrast to its exchangeability or alternative identification strategy, positivity, consistency, and time-varying-confounding rules instead of listing those assumptions as remote caveats. When multiple defensible identification strategies target the same causal contrast, their estimates should remain visible separately before any synthesis; disagreement then becomes evidence about assumption sensitivity rather than variation to be averaged away.

Mechanism claims exceed average causal effects. Mediation, lag, negative controls, and competing-pathway tests are needed before an effect is localized. Where the proposed pathway can be perturbed safely, a localization claim should specify the expected temporal or intervention response in advance so failure of that response bears directly on the proposed mechanism.

Where possible, the roles use separate data splits: description generates hypotheses, prediction tunes on training data, and prospectively specified causal contrasts face held-out or independent data. Preprocessing, feature selection, and model tuning that use protected outcomes belong inside the development process; otherwise the nominally held-out evaluation is no longer genuinely held out.

Public language names the role precisely: associated with, predicted, changed under intervention, and mediated part of the effect are different statements. Explained is reserved for an identified pathway.

Predictive value can survive causal failure, and a causal estimate can answer a narrow intervention question without broad predictive power. The record preserves those contributions rather than forcing one status.

Description and prediction may test prerequisites or signatures, while causal designs may localize a mechanism. None alone supplies complete-stream support.

19.3 — Earliest-Divergence and Action-Invariance Tests

Earliest-divergence analysis asks when two candidate models first imply different conditional distributions under common information. Locating that time can distinguish a representation effect from a policy effect or an observation effect.

Action invariance provides a sharp null only when the models specify the same pre-locus action mechanism as well as the same information and available actions. Shared inputs alone do not force different policies to agree. Under the stated invariance restriction, earlier divergence can indicate leakage, baseline imbalance, or failure of the assumed common mechanism.

Commitment must be recorded separately from assignment. Participants may receive a condition, decline it, switch, or anticipate it. The private policy randomization and information available at commitment determine which contrast the study actually estimates.

A useful experiment freezes a baseline model and route model before data collection, then compares predictions at successive decision points. The analysis reports the first point with calibrated held-out divergence and whether later differences remain after selection and observation are modeled.

Measurement lag can create false localization. A physiological channel may appear earlier simply because it is sampled faster. Cross-channel latency models, synchronized perturbations, and common information sets are needed before temporal precedence is interpreted causally. When no stable earliest divergence

survives those checks, the result is Model-ambiguous or evidence for a distributed mechanism.

Earliest-divergence tests ask when two candidate mechanisms first predict different observable distributions after a controlled perturbation. The emphasis on first divergence reduces the freedom to reinterpret later trajectories after many compensating processes have acted. A study therefore needs a sampling schedule fine enough to resolve the predicted ordering, a prespecified tolerance for temporal uncertainty, and a model of channel-specific lag. If two mechanisms predict the same immediate report but different autonomic, behavioral, or action-selection responses, the test should target that ordering rather than wait for a terminal summary that both models can fit (Klasnja et al., 2015; Liao et al., 2016).

Action invariance supplies a complementary causal challenge. If a route is defined to operate independently of voluntary policy within a declared class, then changing action availability or incentives should preserve its prospectively specified signature. If the signature disappears whenever the action set changes, the locus may instead lie in decision policy, learned strategy, or observation. Invariance is informative only when the intervention actually changes behavior and when compliance, expectations, and information are measured (Sutton & Barto, 2018; Shenhav et al., 2013).

19.3.1 — Why Earliest Divergence Matters

Two mechanisms may fit the same endpoint and much of the same trajectory. Their earliest predicted divergence is a useful

candidate test point because later responses can combine several pathways. It is not necessarily the most informative point: effect size, channel lag, measurement error, and burden determine which observation best separates the models.

Earliest divergence is defined relative to a common prefix and information set. Both models receive the same observations up to the intervention, and neither receives the future endpoint. The contrast asks which transition, action probability, mediator, or observation distribution should first separate.

The first divergence may occur in hidden state, behavior, physiology, or report. A hidden-state difference is not empirically useful until it implies a measured consequence. The design should trace the shortest bridge from the proposed locus to an observable channel.

Temporal ordering helps distinguish mechanism from downstream consequence. If a candidate predicts action-support change before affect report while an ordinary expectation model predicts report first, high-frequency measurement can test that order. A coarse end-of-day survey cannot.

Safe interventions should target the earliest causal fork without manufacturing distress. Information timing, option availability, benign cue structure, or clinically independent treatment transitions can be used when they are ethically justified and do not alter care for the sake of the theory.

Ordinary rivals may predict an earlier or equally early divergence. Scarcity, fatigue, cue learning, and expected control should be simulated under the same cadence. A route-specific interpretation

is unsupported when the candidate differs only after those models already explain the path.

Failure to observe the prospectively specified early difference is meaningful only if the channel had adequate temporal resolution and sensitivity. Otherwise the result is a design failure or no estimate, not automatic route retirement.

The value of the method survives any verdict. Earliest-divergence analysis forces each mechanism to expose where it acts and prevents endpoints from doing all the explanatory work.

19.3.2 — Common Information Sets

Earliest-divergence tests are meaningful only when competing models receive the same information. A common information set specifies what was observed, when it became available, and which features were permitted to influence each prediction. If one model sees future endpoint labels, richer history, or custom preprocessing, earlier divergence can be manufactured rather than discovered (Didelez, 2008; Pearl, 2009).

Information equality is not achieved by giving every model the same table after leakage has occurred. The features must be aligned to the decision-time filtration. Variables measured later, derived from post-action behavior, or selected using the outcome are excluded unless the estimand explicitly permits them.

A concrete example is a cue-response task. The candidate route and a standard learning model both receive the cue, prior observations, current action set, and participant-specific baseline. Neither receives whether the task will later resolve. Their first differing action probability is then a genuine prospective object.

Missingness belongs to the information set. A model that treats absence as a neutral value receives more certainty than a model that treats it as unknown. Missingness indicators, channel quality, and observation timing should be common inputs, and models should be scored under the same imputation or joint-observation rules.

If models do not diverge under a fair information set, the result is observational equivalence at that decision point. The study should move to a different safe fork or retire the local discriminator rather than declare the more elaborate account deeper.

19.3.3 — Action-Invariance Under Shared Evidence

Action-invariance tests evaluate a specified region in which candidate models are assumed to share the same action mechanism. Common evidence and action support make the comparison fair but do not imply invariance by themselves. A candidate claiming a distinctive action-support rule must state where agreement is predicted and where it should break.

The information set must be common. Giving one model latent route state while another receives only observed affect makes divergence inevitable and scientifically uninformative. Either both operate on the same measured history or each latent advantage is charged through an explicit observation bridge.

Invariance can be conditional. Models may agree for states far from a boundary and diverge only when signed reachability, reserve, or completion potential becomes active. The activation region should be specified before data are examined.

A behavioral task can manipulate an option that changes completion support while holding reward, effort, and information as constant as possible. The candidate predicts a targeted policy shift; ordinary discounting or scarcity models predict no special shift after their own variables are matched.

Action is not valence. A difference in choice probability can localize a policy mechanism without showing that the chosen option is pleasant, good, or morally correct. Report and auxiliary channels remain necessary for any phenomenal interpretation.

Cue leakage can counterfeit invariance failure. If the intervention reveals the hypothesis, endpoint status, or experimenter expectation, participants and models may change behavior for reasons unrelated to the candidate route. Blinding, sham cues, and manipulation checks should be built into the fork.

Invariance also has a negative-control role. Actions outside the declared route should remain unchanged. Broad behavioral shifts suggest general arousal, demand, fatigue, or observation reactivity rather than completion-dependent support.

The candidate loses when action differences disappear under equal information, arise equally in negative controls, or are explained by a simpler policy model. A narrow surviving divergence can support one route component without becoming a verdict on the Law.

19.3.4 — Cue Leakage and Post-Treatment Conditioning

Cue leakage occurs when a nominally pre-action variable contains information generated by the action, its implementation, or the later outcome. Post-treatment conditioning occurs when

analysis adjusts for a variable caused by the intervention and thereby opens or blocks causal paths. Both can shift the apparent time of divergence and manufacture mechanism specificity (Pearl, 2009; Hernán & Robins, 2020).

Digital tasks are especially vulnerable. Interface timing, hidden trial counters, adaptive difficulty, device latency, or researcher prompts can reveal condition assignment. A model may then predict action because it detects the experimental apparatus. Blinding, software audits, and sham conditions should test whether the cue remains informative when route-relevant content is removed.

Clinical and longitudinal studies face subtler leakage. A clinician's note may encode treatment response, a medication change may follow worsening symptoms, and a caregiver action may reveal prognosis. Using those variables as baseline predictors can make a model appear to anticipate a divergence it learned retrospectively.

Causal diagrams should distinguish baseline covariates, time-varying confounders, mediators, and colliders. The analysis plan should state which are adjusted, modeled jointly, or left untouched. Automatic feature selection is not a substitute for this classification because predictive importance does not identify causal role.

A negative-control pipeline can shift timestamps, mask treatment indicators, and rerun the model with post-action variables removed. If the earliest-divergence signal survives only the leaky

specification, the discriminator fails. Code and feature provenance should make the removal reproducible.

A valid route test earns its timing prospectively. When leakage cannot be ruled out, the result is descriptive or predictive under the available record, not evidence that the candidate mechanism acted before its rivals.

19.3.5 — Temporal Resolution and Detection Power

Earliest-divergence tests require cadence matched to the mechanism. If the predicted separation lasts seconds and measurements arrive every hour, the study cannot distinguish simultaneous models. Temporal resolution is therefore part of power, not a formatting choice.

Different channels have different response kernels. Behavior may change immediately, autonomic signals within seconds, endocrine signals over minutes or hours, and report after reflection. Aligning all channels to one timestamp can invert the apparent causal order.

Detection power depends on effect duration, within-person variability, measurement error, missingness, and the number of independent transitions rather than only participant count. Repeated observations within one person do not create the same information as independent causal forks.

Sampling can itself change the process. Frequent prompts may increase attention, fatigue, or disclosure and thereby alter action. Randomized, model-based, or deliberately sparse observation schedules can help separate measurement reactivity from the mechanism under study, while retaining the temporal resolution

needed for the prospectively specified contrast (Shiffman et al., 2008; Stone et al., 2007).

Latency uncertainty should be estimated rather than hidden. A distributed-lag or state-space model can represent a range of plausible delays, with prospectively specified windows and multiplicity control. Selecting the lag that yields the strongest effect after inspection creates a temporal garden of forking paths.

Device clocks, server clocks, clinical records, and participant reports require synchronization and provenance. Drift of even a few minutes can matter when the claimed divergence is brief. The record should preserve time zone, firmware, preprocessing, and alignment rules.

Power analysis should use generative simulations from every serious rival. The planned cadence and missingness are applied to each synthetic world, then the pipeline estimates how often it recovers the correct earliest divergence. If confusion remains high, the design needs a different intervention or channel.

A null result can mean no divergence, insufficient resolution, weak intervention, or measurement failure. The decision tree should distinguish these branches. Only a design that could have detected the prospectively specified difference licenses route failure.

High temporal resolution does not justify continuous surveillance. The study should collect the minimum channels and windows needed for the contrast, permit pauses and withdrawal, and avoid turning an experimental fork into permanent observation.

Robust timing localizes mechanisms: consistent held-out ordering across sites and treatment versions can rule out those predicting the same endpoint through a different causal sequence.

19.3.6 — Failure to Diverge and Route Retirement

A route-specific fork fails when the models were predicted to diverge under a supported intervention, the measurement system had adequate sensitivity and timing, and the observed continuations remain invariant. That result retires the prospectively specified divergence claim even if both models still fit the endpoint.

Failure must be diagnosed before it is interpreted. The intervention may not have changed the intended locus, treatment versions may have mixed, action support may have been too narrow, or the observation channel may have missed the window. Manipulation checks and model recovery separate these failures from genuine invariance.

Table 19.1. Earliest-divergence quantities and failure conditions.

Quantity	Common information set	First protocol-fixed separation	Failure condition
Action probability	Prefix, current observations, and supported action menu	Candidate and rival choose different safe actions	Difference disappears under equal preprocessing or recovery fails

Quantity	Common information set	First protocol-fixed separation	Failure condition
Mediator response	Preaction state and identical treatment version	Proposed mediator changes before downstream outcome	Mediator is unchanged, mistimed, or explained by off-target pathways
Observation channel	Same latent-state model and quality flags	One channel carries route-specific information at its declared lag	Signal is reproduced by artifact, activity, or generic severity
Endpoint hazard	Same at-risk set and endpoint object	Hazard changes after the protocol-fixed locus-specific fork	Change depends on retrospective endpoint alignment or selection
Negative-control action	Same task and observation history	Candidate remains stable where no route effect is predicted	Candidate changes equally under sham or irrelevant actions

Repeated failure across independent forks is stronger than one null. If information, action support, and safe perturbations each leave the candidate indistinguishable from ordinary rivals, the route should narrow or retire rather than move the causal locus indefinitely.

Opposite divergence is also informative. A candidate may predict increased repair-oriented action while participants conserve effort or choose rest. The model should not reinterpret the opposite

action as hidden completion. The prospectively specified sign and channel determine the verdict.

Several mechanisms may remain observationally equivalent at the achieved resolution. That result is Model-ambiguous and points toward a new fork chosen for separability, not toward a narrative preference for the candidate. Failure to diverge is informative when the design had adequate power to detect the prospectively specified difference.

Table 19.2. Mechanism-tournament stages, common resources, and stop conditions.

Tournament stage	Candidate and rivals receive	protocol-fixed score or diagnostic	Win, loss, or stop condition
State construction	Same observations, missingness, context, and endpoint definition	State recovery and calibration	Stop if the generating state cannot be recovered
Tuning and recovery	Equal search budgets, priors, and simulation library	Parameter and model recovery	Stop or narrow if families are not separable
Held-out fork	Same supported intervention and decision-time information	First-divergence and causal-response diagnostics	Candidate loses when the distinctive prediction fails
Transport	Frozen models, new site or population, and declared bridge	Calibration, effect transport, and subgroup error	Narrow when transport fails; do not silently recalibrate

Tournament stage	Candidate and rivals receive	protocol-fixed score or diagnostic	Win, loss, or stop condition
Open-set challenge	Unknown generators and none-of-the-models option	False-unknown and false-certainty rates	Stop if the library assigns unfamiliar mechanisms with high confidence

Transport failure narrows scope. A divergence found in one laboratory task may disappear in naturalistic settings, clinical cohorts, or different cultures because the action menu and meaning of cues change. The route is then task-specific unless a transport bridge is demonstrated.

The retirement decision is incomplete until dependent artifacts change. Figures, explanatory diagrams, and public claims must remove or relabel the failed fork, because visual privilege can outlive a sentence-level correction. The active presentation should display only the mechanism status that survived the test.

The failure record should preserve what was tested: prefix definition, information set, intervention, expected first difference, cadence, power, and rival predictions. This allows later teams to avoid repeating an underpowered or conceptually indistinguishable design. A preserved failure packet can show whether the next design needs more power, a different fork, or a genuinely different causal locus.

What survives is the shared-evidence result. If candidate and rival actions remain invariant under the strongest available fork, that constraint becomes part of the next model generation. Negative

evidence can make the remaining mechanism space smaller and more honest. This shared constraint can be more informative than a weak model preference because it rules out entire families of action-sensitive explanations at once.

Prospectively specify practical equivalence for first divergence. A nonzero difference below the observation floor or unable to change the decision does not preserve the route; the margin, uncertainty interval, and detection threshold control the result (Lakens, 2017). The equivalence margin should be justified by the smallest difference that matters for the declared scientific claim or decision. If the bound is instead based on available power or resources, label the conclusion as exclusion relative to that bound, not as evidence that smaller effects are scientifically negligible. Fix the bound before observing the separation.

Repeated invariance should remove that causal locus from the mechanism map and change the prose. The revised mechanism map should preserve that removal so later models cannot quietly restore the locus without new evidence.

19.4 — Completion-Dependent Action Support

Completion-dependent action support asks which actions retain a declared level of completion probability from the current history. One useful object is

$$\mathcal{A}_{K,\alpha}(h_t) = \{a: Q_{h_t}^a(|L(T^-)| \leq K) \geq 1 - \alpha\}.$$

This display defines one action-support band. Completion-dependent support is a modal object: under the displayed band, it identifies actions whose frozen continuation law assigns at least $1-\alpha$ probability to the declared completion band. It says nothing yet about selection, policy-level probability one, topological support, all-continuation closure, desirability, or advice. The modality, action domain, policy class, continuation law, endpoint branch, and uncertainty object travel with every reported set.

Support can shrink because of ordinary scarcity, urgency, fatigue, treatment windows, legal deadlines, or changing opportunity. Those rivals must be modeled before shrinkage is attributed to a fairness-specific route.

A support restriction can also be an artifact of the policy class. If the analysis excludes actions that would violate its own model assumptions, the remaining set may appear completion-compatible by construction. The admissible class and exclusions must be independently justified.

Held-out prediction of action availability and outcomes permits direct comparison with equally resourced control and scarcity models.

The support can shrink because resources disappear, physiology changes, time passes, institutions close options, or the model becomes more certain that some continuations are unreachable. Represent each source separately: physical infeasibility, informational uncertainty, and social exclusion call for different responses (Aubin, 1991; Aubin et al., 2011).

Ethical feasibility is not a soft constraint appended after optimization. Some actions are outside the admissible set because they violate care, consent, rights, or nonmaleficence, even if a formal controller could assign them a favorable continuation value. Safe reinforcement-learning methods illustrate how action sets and risk constraints can be built into control problems, but such mathematics does not supply the ethical boundary by itself (García & Fernández, 2015; Ames et al., 2019). In this research program, inducing suffering, delaying care, manipulating endpoints, or exploiting vulnerable states is excluded before the mechanism tournament begins. A smaller ethical support set is a feature of valid science, not a loss of power.

19.4.1 — Reachable Actions Versus Chosen Actions

An action is reachable when it belongs to the support of admissible policies from the current state. It is chosen when one realized policy selects it. The existence of a reachable completion-preserving action does not show that it will be selected, that it has high probability, or that it should be taken; support, policy, and decision remain distinct objects (Kaelbling et al., 1998; Manski, 2003; Sutton & Barto, 2018).

Support depends on real capacity and context. An action may exist in an abstract control model while being unavailable because of disability, cost, transport, care duties, safety, language, or institutional refusal. Those constraints belong in the action set rather than being treated as noncompliance.

Choice depends on objectives, beliefs, uncertainty, learning, habit, fatigue, and social risk. Two policies can share the same reachable set and select different actions. A route claim therefore needs a policy model or a weaker statement limited to support.

Observed nonchoice does not falsify reachability unless the action was actually offered, understood, safe, and available. Conversely, one observed choice does not establish broad support across other states or people.

Completion support must remain model conditional. A modeled action may preserve a terminal set under assumed dynamics while ordinary outcomes or unexpected disturbances remove that property. Robust and stochastic support analyses should report the disturbance and uncertainty set.

The chapter never converts support into advice. A research model can say an action was represented in the candidate set and predict how its availability changes behavior. It cannot tell a person what to choose, endure, disclose, or sacrifice.

A useful experiment varies option availability without changing reward or burden more than necessary. The candidate and ordinary rivals then predict how policy changes within the common reachable set. Failure to separate them narrows the route rather than the person's autonomy.

19.4.2 — Support Restrictions and Viability

Support restrictions define where a causal or policy contrast is actually represented by the data and the admissible action system. A smooth model can extrapolate outside this region, but the extrapolation is not identified merely because the equation returns a value (Aubin, 1991; Hernán & Robins, 2020).

Viability adds the requirement that at least one policy can keep the process within declared safety, consent, and study constraints. A state can have broad statistical support and no ethically viable intervention, or a viable action with little empirical support. The two regions should be shown separately.

Apply the dynamic positivity condition in §19.2.3 within the ethically eligible action set. Rare actions can produce unstable weights and apparent treatment effects carried by a few histories.

Eligibility rules are part of support. Excluding participants for medication, disability, communication, or device quality can produce a clean region that no longer represents the population of interest. The record should show who was excluded and which claim consequently narrows.

Robust viability considers model uncertainty and disturbances. A policy that is safe only under one fitted transition model may not be viable when plausible dynamics are included. Inner and outer viability sets can represent this uncertainty.

Support can be expanded by changing the environment rather than pressuring the person. Translation, transportation, accessible interfaces, respite, or an alternative clinical route may open

actions. Such changes are causal interventions on opportunity and should be represented as external loci.

Approximation error matters near the boundary. Grid resolution, surrogate models, or numerical tolerances can change whether a state is classified viable. A margin smaller than computational uncertainty should not be reported as a definitive action-support conclusion.

The public limit is strict. Being outside a model's support or viability set is not a personal label. It indicates that the research cannot identify or safely evaluate the contrast in that state. The answer is redesign, environmental support, narrower scope, or no estimate.

19.4.3 — Safe Control and Harm Avoidance

Safe control treats certain constraints as conditions of admissibility rather than costs that can be outweighed by scientific reward. Consent, comfort, clinical care, privacy, and stop requests remain outside the optimization trade space. A policy that violates them is not a high-cost option; it is unavailable (García & Fernández, 2015).

Deterministic and stochastic systems require different guarantees. In a diffusion model, the generator includes second-order terms, and a deterministic derivative cannot be quoted as though it controlled random excursions. The theorem, probability level, horizon, and regularity conditions must accompany any safety claim.

Partial observation makes safety harder. A controller acts on a belief state rather than the true state, so unobserved pain, fatigue,

distress, or device failure can invalidate a hidden-state guarantee. Conservative thresholds and participant challenge routes are part of the scientific design.

Harm avoidance includes burden created by measurement. Dense prompts, uncomfortable sensors, repeated disclosure, and staff demands can alter the process and reduce participation. The study should optimize neither information nor route separability beyond the burden approved for the participant and setting.

A safe intervention can change information, access, or benign task structure without creating negative experience to test the theory. Clinically indicated treatment transitions may be observed, but care decisions are made for the patient, not for mechanism identification.

Negative controls test whether the safety layer is doing hidden explanatory work. If both candidate and rival policies remain inside the same admissible set, any route difference must arise elsewhere. If the candidate wins only because rivals were denied safe actions, the tournament is biased.

Infeasibility is an acceptable result. When no action can satisfy both the scientific objective and the ethical constraints, the study stops or redesigns. The model does not relax dignity to preserve power.

Safety claims should be independently audited and versioned. Changes to sensors, tasks, clinical workflow, or population can invalidate the original analysis. A safe-control label is not permanent certification.

The scientific gain is clarity about what can be learned without harm. A mechanism that remains unidentified because harmful provocation is prohibited stays unidentified. Ethical limits define the admissible science rather than obstructing it.

19.4.4 — Completion-Dependent Feasibility

Fix a reached prefix h_t and one frozen downstream regime g containing every declared downstream policy, physical transition, endpoint, routing, selection, and measurement-reactivity component. For each structurally available action a , $q(a)$ is the conditional probability of the declared completion event under that complete continuation. It is a typed probability, separate from reward, phenomenal value, desirability, motivation, and advice.

Section 7.3.4 establishes the policy-mixture identity and its exactness condition under the declared action-first factorization. Here it constrains the causal locus: fixed-policy probability-one completion requires action-specific completion probability one for policy-almost every action under the frozen downstream regime.

$$P_{\eta, h_t, g}^{\pi} \left(\bar{F}_{\eta, comp}(h_t; g) \right) = \int_{A_{\eta}^{do}(h_t)} p_{\eta, h_t, g}^{comp}(a) \pi_t(da | h_t, g).$$

$$\begin{aligned} P_{\eta, h_t, g}^{\pi} \left(\bar{F}_{\eta, comp}(h_t; g) \right) &= 1 \\ \Leftrightarrow p_{\eta, h_t, g}^{comp}(a) &= 1 \pi_t(\cdot | h_t, g)\text{-almost everywhere.} \end{aligned}$$

Action support and endpoint support remain different axes. The identity concerns probability-one completion under the declared policy and continuation law. Topological support, all-policy completion, and closure of every admissible continuation require

their own stated conditions. When every available action already has $q(a)=1$, the theorem is exact and behaviorally silent.

The condition becomes circular when the admissible action set or continuation law is defined to exclude every nonclosing path. A controller constrained to preserve closure will generate closure-compatible simulations by construction. Evidence must come from held-out consequences that are not guaranteed by the feasibility rule.

Completion-dependent feasibility should be compared with ordinary safe-control, homeostatic, finite-horizon, and scarcity models under the same state, action, observation, and tuning budgets. A special completion state earns support only through a discriminating restriction that those rivals do not automatically share.

Uncertain dynamics produce robust, posterior, or probability-bounded feasibility rather than one universal binary region. Environmental interventions such as communication support, access to care, pain relief, record correction, or transportation may enlarge the action set without being internal completion mechanisms. The changed locus must be named.

The off-policy identification ceiling from §7.3.4 applies here directly. Chapter 19 adds the intervention-specific implication: evidence about excluded actions requires ethically available support from exogenous availability changes, valid instruments, bounded experiments, natural variation, or partial-identification assumptions; harmful endpoint manipulation remains outside the evidence program.

An empty or narrow feasible set supports no personal inference. Misspecification, endpoint uncertainty, incomplete action enumeration, observation limits, inaccessible support, or genuine route infeasibility can produce the same output. The public result is Route-failed, Robust-route unavailable, Model-ambiguous, or No adequate estimate. A route survives only when feasibility predicts independent transition, action, or intervention patterns under prospectively fixed rules.

Table 19.3. Action-support tools, guarantees, assumptions, and prohibited use.

Tool	Primary guarantee	Assumption that must be visible	Misuse to block
Deterministic control barrier	Forward invariance of a safe set under admissible control	Smooth h, deterministic dynamics, action access, regular boundary	Quoting it for stochastic or hidden-state systems
Stochastic barrier	Probability-one safety or finite-time probability bound, depending on theorem	Generator, diffusion, regularity, policy access, theorem conditions	Dropping the second-order term or overstating the guarantee
Viability kernel	Existence of at least one admissible policy remaining inside constraints	Declared state, action set, horizon, constraints, computational approximation	Treating the kernel as discovered natural law

Tool	Primary guarantee	Assumption that must be visible	Misuse to block
Reachability analysis	States that can reach or avoid a target under dynamics and controls	Model dynamics, disturbance set, discretization, approximation error	Treating reachability as proof of conscious dynamics
MPC safety filter	Finite receding-horizon constraint satisfaction under update rules	Model accuracy, recursive feasibility, constraint handling	Letting engineered feasibility become evidence for the Law

19.4.5 — Policy Support Without Personal Advice

Sections 7.3.4 and 19.4.4 establish the modal distinctions and mixture-support condition. This subsection asks how those results change under finite soft reweighting, limit-sure policy sequences, partial observation, and inaccessible off-policy actions, while keeping every result outside personal advice.

Apply §7.3.4 to the displayed power-reweighting construction, with a strictly positive normalizer and a baseline policy, action set, and downstream regime fixed independently of the behavior being explained. Its branch-specific completion probability is a ratio of adjacent normalizing moments, not a human score or evidence that an organism computes it.

$$q_{\eta, h_t, g}(a) := p_{\eta, h_t, g}^{\text{comp}}(a).$$

$$Z_{\beta, \eta}(h_t, g) := \int q_{\eta, h_t, g}(a)^{\beta} \pi_{0, \eta}(da \mid h_t, g).$$

$$\beta > 0, \quad Z_{\beta,\eta}(h_t, g) > 0.$$

$$\begin{aligned} \pi_{\beta,\eta}(da \mid h_t, g) &:= Z_{\beta,\eta}(h_t, g)^{-1} q_{\eta,h_t,g}(a)^\beta \\ &\times \pi_{0,\eta}(da \mid h_t, g). \end{aligned}$$

$$P_{\eta,h_t,g}^{\pi_{\beta,\eta}}(\tilde{F}_{\eta,\text{comp}}(h_t; g)) = \frac{Z_{\beta+1,\eta}(h_t, g)}{Z_{\beta,\eta}(h_t, g)}.$$

$$\begin{aligned} P_{\eta,h_t,g}^{\pi_{\beta,\eta}}(\tilde{F}_{\eta,\text{comp}}(h_t; g)) &= 1 \\ \Leftrightarrow \pi_{0,\eta}(\{a: 0 < p_{\eta,h_t,g}^{\text{comp}}(a) < 1\} \mid h_t, g) &= 0 \\ \text{and } \pi_{0,\eta}(\{a: p_{\eta,h_t,g}^{\text{comp}}(a) = 1\} \mid h_t, g) &> 0. \end{aligned}$$

Under the displayed construction, use §7.3.4's finite-guidance ceiling and exact support condition.

Use §7.3.4's almost-sure and limit-sure definitions unchanged. Here the additional requirements are controlled invariance, endpoint compatibility, measurable selection, and recursive time consistency (Chatterjee et al., 2016; Asadi et al., 2025).

$$\mathcal{S}_{\text{AS}}(\bar{g}) := \{h: \exists \pi \in \Pi_{\text{adm}}(h, \bar{g}), P^{\pi, \bar{g}}(F_{\text{comp}} \mid h) = 1\}.$$

$$\mathcal{S}_{\text{LS}}(\bar{g}) := \left\{ h: \sup_{\pi \in \Pi_{\text{adm}}(h, \bar{g})} P^{\pi, \bar{g}}(F_{\text{comp}} \mid h) = 1 \right\}.$$

For policy claims under partial observation, use the posterior-versus-robust distinction from §§7.3.4 and 18.3.5. A high posterior-average completion probability does not establish robust support across compatible histories; failure of the common-action condition keeps the causal claim observation-limited.

$$P(F_{\text{comp}} \mid o) = \int \int p_{\eta,h,g}^{\text{comp}}(a) \pi_t(da \mid o) b_t(dh \mid o).$$

$$A_{\eta,F}^1(h; g) := \{a: p_{\eta,h,g}^{\text{comp}}(a) = 1\},$$

$$A_{\text{rob}}^1(o; g) := \bigcap_{h \in H(o)} A_{\eta,F}^1(h; g).$$

Hard exclusion is especially difficult to verify because the observed policy supplies no data on excluded actions. Off-policy claims require explicit support, structural assumptions, instruments, bounded experiments, natural variation, or partial-identification bounds. Unsafe, illegal, endpoint-manipulating, or lifetime-risk interventions remain outside the admissible evidence program.

Table 19.4. Completion claims, mathematical conditions, and inferential limits.

Claim	Mathematical condition	What it licenses	Scope of the result
Positive-probability support	Some available action has $q(a) > 0$	At least one continuation has positive completion probability under the frozen regime	Action-specific completion probability under the frozen continuation regime
Fixed-policy probability-one	$q(a) = 1$ for π -almost every action receiving policy mass	Exact completion probability one for that protocol-fixed policy mixture	Protocol-fixed policy and continuation law; causal effects require a separate identification design

Claim	Mathematical condition	What it licenses	Scope of the result
Limit-sure attainability	sup over admissible policies equals 1, without a required attaining policy	A sequence of policies can approach probability one	Approximation by a policy sequence; attainment is a separate mathematical property
Robust partial-observation support	The intersection of probability-one action sets across compatible histories is nonempty and admits a measurable selector	An observation-adapted guarantee under the declared support and regime	Compatible-history intersection with a measurable, time-consistent selector
Finite soft guidance	Baseline policy is reweighted by $q(a)^\beta$ for finite β	Concentration toward higher-completion actions under a frozen model	Reweightings under fixed baseline support, completion probabilities, and finite guidance strength

When every structurally available action completes with probability one, the policy condition is behaviorally silent. When support depends on inaccessible actions, environmental repair may be the relevant intervention.

Every report names the exact modality it supports: positive-probability, fixed-policy probability-one, almost-sure attainable,

limit-sure attainable, topological-support, robust under partial observation, or all-continuation. Care, privacy, refusal, nonparticipation, and human authority remain independent of every modal result.

19.4.6 — Rival Explanations of Narrowed Action Sets

Narrowed action sets are common and do not uniquely indicate a completion route. Fatigue, pain, scarcity, learned avoidance, threat, depression, social risk, institutional barriers, finite-horizon planning, safe-control constraints, and measurement loss can each reduce the options observed or actually available.

The protocol first asks whether opportunity and observation narrowed together. It then gives ordinary utility, effort, delay, risk, uncertainty, habit, reinforcement, physiology, medication, motor limits, social sanctions, caregiving, cost, language, and distrust equal explanatory freedom. Support differs from selection, and a menu that appears wide to a researcher may be unusable in context (Shenhav et al., 2013; Sutton & Barto, 2018).

Test rivals through one observation pipeline: which options disappear, and how does the set change under a safe, prespecified perturbation? Chapter 20 adds body-level lag and clinical-context tests; qualitative and contextual evidence exposes institutional constraints missed by laboratory menus.

When an ordinary rival explains the narrowing, the candidate route loses that component. The result can still direct environmental repair and leaves the person's experience and need for support untouched. The report should distinguish

environmental restriction from internal choice so practical repair targets the barrier actually observed.

Open-set inadequacy is also possible. If no prospectively specified model reproduces the menu change, the answer is not a hidden completion mechanism; the model library expands under a new comparison and the current verdict remains unresolved. Residual diagnostics should identify where the menu mismatch occurs, giving the expanded model library a specific target rather than an unrestricted search. A mismatch limited to one device or task version, for example, first directs investigation toward the observation or choice interface rather than a universal mechanism. Comparing residual structure across sites, task versions, and menu geometries can show whether the missing structure is local to an interface or stable enough to justify a new generator family. That turns model expansion into a directed empirical program whose next comparison is motivated by the pattern already observed.

Transport concerns the support set itself. Options available in a laboratory may be absent under disability, caregiving, threat, cost, language barriers, or institutional control, so population and context audits precede generalization. Support-set transport should record structural absence of options separately from individual nonselection because the two imply different causal opportunities. An accessibility change that makes an option usable creates a different support set even when the printed menu and its labels remain unchanged. Cross-site pooling is therefore strongest when relevant support-set differences are represented explicitly or shown not to alter the estimand. Because feasible

opportunities can also change during a study, availability should be time-stamped rather than treated as a fixed characteristic of the participant or setting.

A discriminating fork opens or closes one safe route while holding ordinary explanations comparable. Candidate-specific held-out change can support the mechanism; common narrowing belongs to the shared constraint. The fork is most informative when the manipulation changes availability without changing the value or observability of the remaining alternatives. Recording both the offered menu and the usable menu helps separate an intervention on opportunity from a change in preference among unchanged options. The strongest design pairs that intervention with a predeclared contrast specifying which route-sensitive prediction should change and which shared controls should remain stable. When the predicted asymmetry appears only after the intended support-set change is independently verified, the causal interpretation becomes substantially sharper.

19.5 — Assignment, Commitment, Selection, and Retention

Random assignment protects the initial treatment contrast, not every later comparison. Commitment, adherence, switching, retention, observation, and endpoint survival can each select different subpopulations. The denominator flow should be diagrammed from eligibility through final analysis.

Commitment is especially important in sequential tasks. An action chosen after observing a cue is not equivalent to an assigned action. The information available at commitment and the policy that generated the choice belong in the causal model.

Informative retention can mimic route evidence. Participants with stronger symptoms, lower capacity, or different support may leave the study, lose devices, or become unobservable. Inverse-probability methods, joint models, or principal stratification can help only under visible assumptions.

Truncation by death or a competing event is not ordinary missingness. Outcomes after a terminal event may be undefined, and survivor comparisons can reverse population conclusions. The estimand must specify the population and event structure it addresses.

Selection negative controls can expose hidden bias. Outcomes measured before the proposed mechanism enters, channels unrelated to the route, and simulated denominator perturbations can reveal whether the result is driven by inclusion rather than dynamics. Withdrawal and nonparticipation remain legitimate, and no analytic advantage may attach to staying.

Assignment, receipt, adherence, and retention are distinct events. Random assignment can identify an intention-to-treat contrast, but it does not by itself identify the effect of sustained exposure, a latent mechanism, or a route among participants who remain observable. In long studies, continued participation may depend on symptoms, benefit, burden, caregiver availability, device tolerance, prognosis, or the very outcomes being studied. Analyses must therefore distinguish treatment assignment from treatment actually received and must model censoring and observation as parts of the causal system rather than as administrative afterthoughts (Frangakis & Rubin, 2002; Hernán & Robins, 2020).

Commitment mechanisms add another layer. A participant may precommit to reminders, environmental changes, or action restrictions, while the effect of commitment can operate through expectations, social accountability, reduced choice, or altered opportunity. Selection into commitment is rarely random, and the people who accept it may differ in motivation, risk, resources, or prior success. Principal stratification, sensitivity analysis, and explicit selection diagrams can clarify which contrast is being estimated, but they do not make unobserved strata directly visible (Frangakis & Rubin, 2002; Scharfstein et al., 1999). A route claim should survive these distinctions rather than absorb them into a single treatment label.

19.5.1 — Random Assignment and Delivered Exposure

Random assignment identifies an intention-to-treat contrast when the assignment mechanism is valid and outcomes follow the protocol-fixed analysis. It does not guarantee delivery,

understanding, acceptance, adherence, continued observation, or retention. Those post-assignment events receive their own variables and estimands so that assignment effects are not silently relabeled as effects of a delivered mechanism (Frangakis & Rubin, 2002; Hernán & Robins, 2020).

Delivered exposure can vary because of implementation failure, access barriers, clinician judgment, device malfunction, participant choice, or safety stopping. A binary treatment label can therefore hide several versions. Process data should document timing, dose, fidelity, and burden while preserving the participant's right to refuse or discontinue.

A simple laboratory fork illustrates the distinction. Participants may be assigned an information cue, yet some do not see it because the interface fails and others see it after acting. The intention-to-treat effect remains interpretable, while a per-protocol mechanism effect requires assumptions about receipt and timing.

Noncompliance is not a defect in the person. It may reveal that the intervention was inaccessible, burdensome, irrelevant, or unsafe. The analysis should ask what generated receipt and whether that process is itself part of the mechanism or an implementation failure.

Instrumental-variable and principal-stratum analyses target specified effects under additional assumptions. Report sensitivity to the exclusion restrictions and monotonicity assumptions used in the analysis.

The route claim should attach to the contrast actually identified. If only assignment is supported, the conclusion remains at assignment. A mechanism is not established by renaming an intention-to-treat result as the effect of a hidden route.

19.5.2 — Commitment Signals and Private Policies

Commitment signals reveal or alter a policy before later actions unfold. A participant may schedule reminders, restrict access to a distraction, authorize a supporter to call, or state a private plan. These acts can change expectations, opportunity, accountability, and selection simultaneously. They are not transparent readings of an internal controller (Frangakis & Rubin, 2002; Hernán & Robins, 2020).

Private policies matter because the action observed later may have been shaped by a rule chosen earlier. A dynamic model should distinguish the policy from each realized action and record what information was available at commitment. Otherwise a stable pattern can be mistaken for route-specific action invariance.

Commitment is rarely randomized in ordinary life. People who accept it may differ in resources, urgency, confidence, support, or prior success. A comparison between committers and noncommitters therefore mixes the commitment effect with selection unless the design addresses those differences.

A safe experiment can randomize the offer or form of a low-burden commitment while leaving acceptance voluntary. The analysis then separates offer, acceptance, and subsequent behavior. It should also measure whether the commitment

reduced choice in a way participants experienced as helpful, neutral, or burdensome.

Ordinary learning and self-control models are strong rivals. A commitment effect may reflect reduced temptation, simplified planning, social expectation, or memory support. A fairness-specific route must predict a distinctive timing, state dependence, or intervention transport beyond those accounts.

No model may use a private policy as evidence of what a person owes themselves. Commitment remains an empirical object and a voluntary action. Withdrawal from it never becomes scientific noncompliance or reduced standing.

19.5.3 — Adherence, Attrition, and Informative Retention

Adherence and retention are dynamic processes. Continued participation can depend on benefit, symptoms, fatigue, caregiving, device tolerance, distrust, prognosis, or the burden created by measurement. When those variables also predict outcomes, complete-case analyses can manufacture a favorable trajectory (Scharfstein et al., 1999; Hernán & Robins, 2020).

The denominator should be traced from eligibility through consent, assignment, delivery, adherence, observation, and final analysis. Each loss receives a reason category, timing, and uncertainty status. A single attrition percentage cannot reveal whether missingness is related to the mechanism being tested.

Inverse-probability weighting, joint models, and multiple imputation can help under assumptions. None rescues data that were never collected without specifying how missing outcomes relate to observed and unobserved histories. Sensitivity analyses

should include departures that are scientifically plausible, not merely convenient.

Informative retention can be route-specific. A burdensome task may selectively retain participants whose state is easier to measure, while a wearable may fail more often during movement or clinical decline. The observation process can then create apparent stability or convergence. Device and participation processes should be modeled separately.

Participant return and support are part of ethical retention. Reminder intensity, compensation, transportation, and caregiver involvement can alter who remains. Those supports should be offered for fairness and feasibility, not optimized to pressure continued participation.

A result that disappears under plausible attrition models is not robust mechanism evidence. It may still identify a vulnerability in the study design. The record should preserve that lesson and change the next protocol rather than blame missing participants.

The analysis should separate adherence to the assigned action from adherence to the measurement schedule. A participant may receive the intervention exactly as planned while declining a wearable, skipping prompts, or ending follow-up; the converse can also occur. Combining these processes in one compliance variable obscures whether the estimated route failed, the delivered exposure changed, or the observation process selected what remained visible. The protocol therefore preserves separate time-indexed histories for treatment, support, measurement

availability, and withdrawal (Robins et al., 2000; Hernán & Robins, 2020).

A single completion percentage can conceal treatment-version drift. Two participants may both be called adherent even though one receives the intended sequence and another receives delayed, shortened, interrupted, or caregiver-mediated delivery. Mechanism inference therefore records version, timing, intensity, context, and deviation policy for each delivered action. When that history cannot be reconstructed, the defensible target may be the effect of assignment under real implementation rather than a precisely delivered route (Murphy, 2003; Murphy, 2005).

19.5.4 — Principal Strata and Post-Assignment Selection

Principal stratification organizes causal questions by joint potential values of a post-assignment event, such as survival, adherence, or receipt. It can clarify what comparison is being imagined when an outcome is undefined or observed only after selection. The strata are latent constructs, not observed types of people (Frangakis & Rubin, 2002).

Post-assignment selection is common near endpoints. Comparing only participants who remain conscious, alive, enrolled, or reportable can condition on consequences of exposure and prognosis. The selected groups may differ even when assignment was randomized. Truncation by death requires an estimand that acknowledges undefined outcomes rather than treating death as ordinary missingness.

Principal-stratum effects generally require strong assumptions or bounds because membership cannot be observed for every

person. Monotonicity, exclusion restrictions, and parametric models should be justified in the substantive context and varied in sensitivity analysis. A point estimate should not conceal dependence on an untestable stratum model.

A concrete route study might ask about a safe intervention among participants who would remain observable under either assignment. That target differs from the effect among observed survivors and from the population intention-to-treat effect. Each has a different scientific and ethical interpretation.

Strata must never become eligibility or worth categories. A person who would not remain observable under a burdensome protocol is not less valid data. The design should reduce burden and improve access before it narrows the population for analytic convenience.

When a principal stratum is not identified, the analysis reports bounds, scenario results, or No adequate estimate. A route does not gain support from a subgroup defined by the very post-assignment event it is meant to explain.

Because principal strata are defined by counterfactual joint events, they should enter the analysis as assumptions, bounds, or sensitivity objects rather than as observed labels. Investigators can vary monotonicity, exclusion, and dependence assumptions and report the range of stratum effects compatible with the data. A narrow interval is earned by information and design, not by choosing the most favorable cross-world model. When bounds remain wide, the result is scientific uncertainty rather than a failed

participant or an inconvenient subgroup (Manski, 2003; Imbens & Manski, 2004).

Selection diagnostics also test whether the mechanism claim changes under alternative targets. An intention-to-treat effect, an effect among always-observable participants, a survivor-average contrast, and a policy effect under supported follow-up are different estimands. When only one target produces a favorable result, the analysis justifies why that target is scientifically primary rather than treating the others as secondary noise. This comparison prevents post-assignment conditioning from converting a route hypothesis into a result that exists only inside a selected analytic population (Frangakis & Rubin, 2002; Hernán & Robins, 2020).

19.5.5 — Repeated Assignment and Adaptive Regimes

Repeated assignment creates a sequence of treatment decisions rather than one baseline fork. Dynamic regimes map observed history to the next action, and adaptive designs may update randomization probabilities while the study proceeds. The estimand must distinguish the regime being evaluated from the learning algorithm used to collect data (Robins et al., 2000; Hernán & Robins, 2020).

Micro-randomized trials can test proximal effects of time-varying components, while sequential multiple-assignment designs can compare adaptive strategies. These designs are useful for candidate mechanisms because they create several safe divergence points. They also increase the burden of modeling availability, carryover, fatigue, and time-varying confounding.

Treatment versions multiply across stages. A reminder after sleep loss is not the same exposure as the same reminder after rest; an information cue may operate differently after prior success or failure. The regime definition should include timing, state, and delivery context rather than treating repeated actions as interchangeable.

Adaptive randomization can create informative probabilities. Models must use the known assignment mechanism and preserve chronological feature construction. Reusing later outcomes to tune earlier decision rules turns an adaptive design into retrospective optimization.

A mechanism tournament can predeclare several regimes that different theories favor. Equal information and equal burden are essential. If one route receives a tailored policy while rivals are tested under generic actions, the comparison confounds mechanism with design advantage.

The study stops or narrows when support becomes weak, burden rises, or no regime creates discriminating predictions. Prespecified adaptation rules keep subsequent decisions interpretable.

19.5.6 — Audit Trails for Selection Processes

Selection processes need an audit trail as detailed as the outcome analysis. The trail records eligibility rules, invitation, contact, consent, assignment, delivery, adherence, withdrawal, device status, endpoint events, observation, exclusion, and analysis inclusion. Each transition has a time, reason, actor, and version where legally and ethically appropriate.

The audit is not a dossier. It collects only information needed to understand denominator flow and model the declared processes. Bystander details, private messages, and unrelated clinical or institutional records remain outside the research object unless separately authorized and necessary.

A flow diagram is machine-checkable against analysis denominators. Counts in the report, executable code, and governed repository agree. Discrepancies are incidents to resolve, not cosmetic differences to smooth before publication.

Selection simulations can test how plausible departures alter the mechanism verdict. Analysts can vary dropout dependence, delivery failure, unmeasured commitment, and endpoint observation. The result should show which assumptions change the conclusion and which merely widen uncertainty.

The trail also supports correction. If a device version or site procedure later proves biased, affected paths can be located and reanalyzed. Public summaries and model cards should point to the current analysis version rather than preserving a superseded favorable result.

A clean selection record protects both inference and dignity. It prevents absent participants from being silently treated as neutral, failed, or irrelevant, and it prevents a route from winning because the study forgot who could no longer be seen.

The audit should retain assignment probability, delivered treatment, adherence, reasons for discontinuation, competing events, observation availability, and every rule that changes eligibility. These fields permit inverse-probability, g-method,

principal-stratum, or partial-identification analyses according to the estimand rather than one generic missing-data correction.

Selection models should be challenged by alternative assumptions. When conclusions depend on unverifiable retention or censoring models, the report should show the corresponding identified set or sensitivity curve. A selected sample cannot be made representative by confidence alone.

Treatment versions should be preserved even when the main contrast is binary. Dose, duration, delivery route, clinician discretion, device firmware, and contextual support can modify both the mechanism and the probability of remaining observed. Version-blind analysis can mistake implementation heterogeneity for causal instability.

Informative adherence deserves its own estimand. Participants may stop because the treatment is burdensome, ineffective, harmful, or no longer needed. Per-protocol language that treats all discontinuation as equivalent can reverse the interpretation and hide the mechanism most relevant to care.

Negative-control retention outcomes can reveal residual selection. Events that should not respond to the mechanism but share the observation or administrative process can expose whether apparent route effects follow documentation intensity, site practice, or participant availability instead.

Sensitivity analyses should be linked to concrete departures, not arbitrary parameter sweeps. The record should state how much unmeasured retention bias, informative censoring, or treatment-

version imbalance would be required to change the verdict and whether that departure is plausible in the study setting.

The selection pipeline should be tested in simulation as a generative object. Known assignment, adherence, censoring, observation, and competing-event processes are passed through the same extraction and analysis code, and the recovered denominators are compared with the truth. This audit can reveal off-by-one eligibility rules, time-ordering errors, duplicated records, and accidental conditioning that ordinary outcome-model diagnostics miss. A pipeline that cannot recover its own simulated population is not ready to adjudicate a causal route.

Institutional actions can be mechanisms as well as confounders. Scheduling, translation, transportation, respite, record correction, and appeal access may alter both the opportunity set and the observation process. Their causal role should be modeled rather than absorbed into a person-level state.

Interference is another live route. One participant's action can change another person's information, support, workload, or observation probability. When clusters, families, staff, or institutions share conditions, no-interference assumptions should be defended or replaced by a design that represents spillovers (Hudgens & Halloran, 2008).

Apply the alternative-selection and sensitivity rules above. If plausible assumptions change the sign or scientific verdict, report the mechanism as selection-sensitive rather than confirmed.

The audit should distinguish withdrawal from nonadherence. A participant may refuse, pause, or leave for reasons that are

scientifically informative but never owed to the study. Their decision remains an exercise of autonomy, while the analysis records how the resulting observation process limits the causal claim.

Randomization integrity belongs in the same trail. The record preserves the allocation algorithm, seed or randomization service, block and stratification variables, concealment procedure, assignment probability, release time, and any authorized override. Investigators should be able to distinguish a genuine random draw from a late operational substitution. Without that distinction, an intention-to-treat label may conceal a compromised assignment process, and no subsequent statistical adjustment can recreate the lost randomization (Hernán & Robins, 2020).

Adaptive assignment requires replayable probabilities rather than a final treatment label. At each decision time, the archive stores the information available to the policy, the versioned policy function, the probability assigned to each action, and the action actually delivered. A simulation replay should reproduce the logged probabilities from the frozen code. Failure to do so is a provenance defect that blocks policy-effect and mechanism claims because the denominator no longer identifies the intervention regime that generated it (Murphy, 2005; Liao et al., 2016).

Human overrides are coded by function. A safety override, participant preference, clinician judgment, equipment failure, and scheduling constraint have different causal meanings even when all change the delivered action. The primary analysis can preserve assignment while secondary analyses represent receipt and

version, but these pathways are not collapsed into one deviation variable. Repeated overrides concentrated in one state or site may reveal that the nominal intervention was not feasible where its mechanism was most strongly tested.

Auditability does not require indefinite identity retention. The research system can separate direct identifiers from event history, use role-limited linkage keys, preserve cryptographic or version provenance for code and records, and delete unnecessary raw material on the declared schedule. What must remain is enough lineage to reconstruct denominators, treatment versions, exclusions, and corrections without turning the selection trail into a permanent dossier. Reproducibility and privacy are joint design constraints, not reasons to abandon either one.

19.6 — Experimental Forks and Mechanism Tournaments

An experimental fork gives candidate mechanisms a shared starting state and then introduces a low-burden difference they predict differently. The fork can vary information, controllability, timing, or action support without inducing distress or withholding care.

A mechanism tournament specifies the altered kernel for each model. A route model may alter continuation probability; a reinforcement-learning model alters value updating; an expected-control model alters effort allocation; a scarcity model alters opportunity cost. The predictions must be mutually discriminating rather than verbal redescriptions.

Common-rule design requires the same data, preprocessing, hyperparameter budget, stopping rule, observation model, and evaluation metric. Flexible models may need complexity penalties or nested validation so extra capacity is not confused with mechanism support.

Generator-recovery simulations precede human interpretation. Synthetic data are generated from every candidate and from challenge models absent from the bank. The pipeline must recover the correct family and return none-of-the-models when appropriate.

Negative controls target cue leakage, selection, observation garbling, and generic time effects. A route-specific result should disappear under a control that removes the proposed information

while preserving unrelated structure. A study designed only to produce a favorable narrative is not a tournament.

Sequential designs from Section 19.5.5 can improve tournament efficiency. Here the added requirement is prospective tournament control: adaptation rules, stopping boundaries, arm modifications, model updates, and error spending are fixed before triggering data are inspected (Murphy, 2005; Collins et al., 2007; Klasnja et al., 2015).

19.6.1 — Forks That Separate Candidate Routes

An experimental fork is a safe intervention or naturally occurring change at which candidate mechanisms predict different continuations from the same prefix. The fork should alter one declared locus while holding information, burden, and opportunity as comparable as possible.

A useful fork is chosen for separability, not drama. Information timing, benign option availability, correction of a record, or an independently indicated treatment transition may create divergence without inducing distress. Harmful provocation and care withholding are outside the design space.

The altered kernel must be named. Saying the intervention affects the mechanism is insufficient. The protocol should state whether it changes state transition, observation, action support, endpoint hazard, mediator distribution, or selection.

Each rival receives a full prediction. A candidate route may forecast a cue-specific action shift, while scarcity predicts a general effort effect and learning predicts reward-history

dependence. The fork is informative only when these alternatives are quantified before data are seen.

Temporal and channel predictions accompany the endpoint. Which variable should move first, for how long, and under which negative control? A mechanism that differs only in an unobserved latent state cannot be tested by the fork.

Recovery simulations test the fork before enrollment. Synthetic data from each model pass through the planned cadence, missingness, and estimator. If the correct generating model cannot be recovered, the fork is redesigned.

A fork can return Route-favored, Rival-favored, Model-ambiguous, or No adequate estimate. It cannot issue a whole-theory verdict or convert participant behavior into a score of inner completion.

19.6.2 — Equal Information and Equal Scoring

A mechanism tournament is fair only when models receive the same information available at the same time. Latent-state access, future endpoint labels, richer sensors, or bespoke preprocessing count as information advantages and must be either shared or explicitly charged through a bridge.

Equal scoring uses the same held-out cases, loss functions, calibration checks, uncertainty rules, and opportunity to abstain. The candidate cannot receive a bespoke favorable metric while rivals face generic prediction error. Several prospectively specified scores are appropriate when each answers a distinct component question and the decision tree states how their results combine (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

Equal tuning is part of the comparison. Hyperparameter search, prior elicitation, feature selection, and early stopping should receive comparable budgets. A weakly tuned rival is a straw model even when the code is technically present.

Complexity should be treated transparently. Predictive scores, explanatory parsimony, causal identification, and route transport are different criteria. A more complex candidate may win one and lose another; the verdict should say which.

The observation pipeline is common. Missingness, smoothing, artifact rejection, endpoint alignment, and derived features are applied identically unless a model-specific difference is the object under test. Otherwise preprocessing can manufacture the winner.

Open-set tests protect against forced choice. Data from omitted mechanisms should be included in simulation benchmarks to see whether the tournament becomes falsely confident. None of the models is a legitimate outcome.

Equal treatment makes the model comparison informative. If ordinary control, learning, or selection performs as well with the same evidence and flexibility, the candidate route narrows. The scientific program gains a stronger explanation and a clearer next question.

19.6.3 — Negative Controls and Sham Mechanisms

Negative controls and sham mechanisms ask whether the apparent divergence depends on the route-specific component. A matched cue, irrelevant option change, or simulated controller without the completion state should fail where the candidate predicts specificity. If it does not, the mechanism narrows.

Option-set manipulation changes what can be done while keeping the person safe. A task may add an easy route, remove a redundant route, make one route require a benign effort, or reopen a closed route through a support action. The goal is to see whether behavior tracks feasible repair structure rather than merely reward amount (Klasnja et al., 2015; Nahum-Shani et al., 2018).

The design belongs to this chapter because compensability lives in the option set. An intervention that expands the available option set may preserve future repair opportunities. If the option set narrows, residual cost may become more sensitive to delay. The model must estimate that relation without pretending options are inner properties of the participant.

A real-world observational version might compare administrative systems before and after an appeal route is simplified. The outcome could be timing, report burden, sleep disruption, service use, or dropout. Such evidence would need strong controls for staffing, population change, outreach, and policy drift. It would not be evidence by proximity to fairness language.

The manipulation can also reveal noncompensability. Adding a pleasant option may not reduce avoidance of a route tied to violation or mistrust. A scalar utility model might expect substitution. A component model with noncompensable state may predict little effect. That contrast is scientifically valuable.

Action support includes burden and dignity. An option that technically exists but requires humiliating disclosure, inaccessible paperwork, unaffordable travel, unsafe timing, or excessive effort is not equivalent to a low-burden alternative.

Coding friction, access, and dignity cost makes the action set empirically real and prevents structural barriers from being misread as preference or motivation.

Option-set experiments use small, reversible, transparent choices. Observational studies access operational records through a separate, documented research-use path.

A negative-control outcome shares the observation schedule, expectancy, and common causes while remaining outside the candidate pathway. A negative-control exposure shares relevant selection or measurement structure without carrying the route-specific intervention. A signal on either control points toward confounding, reactivity, or pipeline leakage. A null control is informative only when its causal relation and sensitivity were justified before outcome inspection (Didelez, 2008; Pearl, 2009).

Sham adequacy requires more than matching appearance. Participants and staff may infer assignment from side effects, task difficulty, device behavior, or the timing of support. The study therefore measures expectations, perceived assignment, and differential burden, then tests whether these variables predict the claimed mechanism signature. A sham that does not preserve the relevant experience cannot distinguish route specificity from expectancy or procedural contrast, and an invasive or humiliating sham is not justified merely because it would improve blinding (International Council for Harmonisation, 2026; World Medical Association, 2024; Lakens, 2017).

19.6.4 — Transported Predictions

A mechanism prediction is stronger when it transports beyond the task on which it was fitted. Transport may involve a new site, action menu, device, population, endpoint branch, or observation channel. The invariant component and the component allowed to recalibrate must be declared in advance (Hernán & Robins, 2020).

Transport is not simple replication. A new setting can change treatment versions, support, meaning, and measurement. The protocol should map these differences and state whether it expects parameter invariance, qualitative ordering, or only a bounded effect.

Cross-equation transport is particularly informative. A completion potential estimated from passive transitions can be tested on held-out actions; a causal locus estimated from behavior can be tested on physiology; a lag relation estimated in one context can be tested after a safe perturbation.

Ordinary rivals transport too. A model that requires bespoke recalibration at every site while a simpler rival preserves its prediction has weaker mechanism evidence. Equal transport budgets prevent local flexibility from masquerading as generality.

Failure can localize the missing bridge. Device transport failure points to observation, action transport failure to policy, and population failure to state or effect modification. The route should narrow at that module rather than be globally defended or globally discarded.

A transported public claim should retain the destination population and uncertainty. Success in one cohort or task does not

authorize a universal mechanism graphic. The artifact names where the prediction was actually tested.

The strongest transport result is a prospectively specified qualitative and quantitative pattern that survives a changed observation route without refitting the core mechanism. Even then it supports a component route, not complete-stream PTVC.

Transport claims should identify which causal relations are expected to remain invariant and which population or context variables may modify them. A destination sample with different clinical severity, action constraints, or support can alter both the intervention and the pathway through which it acts. Transport diagrams or explicit adjustment sets make those assumptions inspectable, while sensitivity analysis shows how much unmeasured effect modification would be needed to reverse the conclusion (Pearl, 2009; Hernán & Robins, 2020).

The measurement bridge must travel with the mechanism or be independently requalified. A stable latent relation cannot be inferred from identical device labels when firmware, placement, language, sampling cadence, or preprocessing differs. The protocol freezes the core causal prediction, audits invariance of the observation model, and permits only declared destination-specific recalibration. If the bridge changes enough to absorb the predicted effect, the study has not transported a mechanism; it has created a new measurement system (Bollen, 1989; Peters et al., 2016).

19.6.5 — Adversarial Collaboration and Protocol-Fixed Win Conditions

Adversarial collaboration turns disagreement into a shared design before held-out outcomes are known. Teams fix win conditions, common data access, model budgets, scoring rules, amendment procedures, and public verdict language. Apply §6.7's prospective-specification terminology to the resulting record.

Win conditions are component specific. A route may outperform on earliest divergence, a rival on calibration, and neither on transport. The protocol-fixed decision tree states which combinations support a component, yield Model-ambiguous, trigger Open-set inadequate, or block stronger language. No composite score may average away an adverse prerequisite or target result.

Each team should nominate the strongest version of the opposing model. Parameter ranges, observation bridges, and reasonable auxiliary structure are agreed before scoring. A rival is not required to remain artificially simple while the candidate receives every rescue term.

Model recovery is the first contest. Simulated datasets from candidate, rivals, and unknown mechanisms pass through the full pipeline. High confusion rates or false confidence trigger redesign before human data are interpreted.

Negative controls and falsification outcomes are specified before outcome inspection beside favorable outcomes. The collaboration should say what would make each team abandon a mechanism,

narrow the reference class, or conclude that the design cannot discriminate.

Dependence and multiplicity need a common plan. Repeated within-person observations, multiple lags, many features, and several forks can create nominal evidence without independent information. Hierarchical or sequential rules should be declared before the winner is known.

Public communication is part of the collaboration. Detachable figures, tables, and summaries use the shared result language, including Rival-favored and Open-set inadequate, and preserve the tested component and reference class. A collaboration that becomes adversarial only in its technical appendix has not protected the public surface.

Null and ambiguous results remain publishable. The agreement includes code, simulations, provenance, and failure logs so that an unexciting outcome contributes to later designs rather than disappearing.

The collaboration succeeds when the losing model is allowed to lose cleanly and the winning model is not promoted beyond the tested component. Intellectual conflict becomes a method for reducing discretionary rescue.

Prediction files, preprocessing code, and scoring functions are locked before held-out outcomes are released. An implementation team independent of the favored theory can execute the common pipeline, while a separate adjudication group applies the protocol-fixed rules. Any post-lock deviation receives a dated amendment, a reason, and exploratory status unless all adversarial teams

accept it before unblinding (Gneiting & Raftery, 2007; Vehtari et al., 2017).

The collaboration preserves a challenge ledger containing unresolved objections, model failures, code discrepancies, exclusions, repairs, and minority interpretations. A public verdict follows only after the simulation, recovery, and scoring records can be inspected independently. This protects the candidate from an implementation defect and the rivals from discretionary rescue, while leaving disagreement visible instead of manufacturing consensus.

19.6.6 — Ethical Stop Rules and Null Results

Ethical stop rules are triggered by participant burden, distress, privacy failure, clinical conflict, device risk, or loss of valid consent, not by whether stopping helps one model. They are written before enrollment, tied to critical participant-protection and data-quality thresholds, and remain independent of the scientific winner (International Council for Harmonisation, 2026).

Statistical or scientific futility can stop collection without declaring a theory verdict. Model-recovery failure, inadequate movement of the intended locus, observation quality below the protocol-fixed threshold, or exhausted conditional power may make additional burden uninformative. The stop record states which object failed and which conclusions remain available.

A null result carries a sensitivity statement. The report shows the prospectively specified effect sizes and lag patterns the design could detect, which channels remained usable, whether the

manipulation altered the intended variable, and which rival patterns remained compatible. This separates genuine invariance from weak intervention, poor timing, and measurement failure.

An adverse event can invalidate interpretation even when no direct harm is caused by the protocol. A medication change, acute illness, care transition, or institutional disruption may alter state and observation. The event is recorded and routed through the decision tree rather than adjusted away automatically.

Stopping never changes care. Clinical decisions, analgesia, rescue, and support continue under their own authority. A study may stop observing while the person's life and treatment proceed beyond the research window.

Participant withdrawal is a valid outcome and not evidence about the mechanism. Data use after withdrawal follows consent, law, and the protocol. The model cannot interpret refusal or missingness as latent completion or burden.

Null and stopped studies should be released with enough detail to prevent repetition. The intervention, burden, manipulation check, model-recovery result, and reason for stopping belong in the public scientific record, subject to privacy.

The ethical outcome is not a caveat added after the analysis. It determines which intervention world is admissible. A mechanism that can be separated only through harmful or coercive designs remains outside empirical authorization.

Mechanism tournaments prospectively specify the adjudication body, its independence from model developers, and its conflicts of interest. Safety, futility, model inadequacy, protocol

continuation, and public reporting each use protocol-fixed evidence thresholds. Governance becomes part of reproducibility because discretionary authority can otherwise alter the scientific branch after results are known.

Split-sample or external locking reduces rescue. Candidate generators, preprocessing, tuning ranges, and scoring rules are frozen before the confirmatory comparison. Exploratory discoveries can improve the next tournament, but they do not alter the verdict of the current one.

Win and loss conditions should be model specific. One candidate may lose through failed calibration, another through causal invariance, another through ethical infeasibility, and another because an ordinary rival predicts equally well with fewer assumptions. A single leaderboard cannot preserve those distinctions.

Tournament archives should preserve losing predictions, code, and recovery failures. Future models must face the same failed cases rather than being evaluated only on a refreshed dataset. Failure memory is what turns sequential model building into cumulative science.

19.7 — Shadow Prices as One Analytic Example

A shadow price is the derivative of an optimized value with respect to a constraint under specified regularity and duality conditions. In a constrained policy problem, a multiplier may summarize the local marginal model value of relaxing a terminal-band or resource constraint. It is not a universal exchange rate.

A constrained value can be written schematically as

$$V_K(t, x, \ell) = \sup_{\pi \in \Pi_{\text{adm}}} \mathbb{E}_{\pi} \left[\int_t^T r_s \, ds \right]$$

subject to

$$\mathbb{P}_{\pi}(|L(T^-)| \leq K \mid X_t = x, L_t = \ell) \geq 1 - \alpha.$$

An empty feasible set returns No adequate estimate. Interpreting a multiplier also requires an appropriate constraint qualification, a relevant dual relation, and an attained optimum. In nonconvex or misspecified problems, a fitted multiplier may remain a numerical artifact rather than the claimed marginal sensitivity.

The multiplier inherits its units from the objective and constraint. Changing either changes the number, so the display identifies both quantities and the local sensitivity being estimated.

This section develops a finite-horizon analysis of compensability, barriers, viability, and shadow prices. It is one analytic example inside the causal-locus chapter and remains subject to ordinary scarcity, fatigue, control, and opportunity-cost rivals.

A shadow-price model earns scientific value only through held-out prediction and causal discrimination. If a standard scarcity or

expected-control model explains the same behavior better, the ordinary rival wins.

Finite-Horizon and Shadow-Price Analysis

Within this finite-horizon analysis, a multiplier may be nonunique, fail to exist, or cease to approximate finite changes when the active set changes. Its permitted sign follows the declared constraint and Lagrangian convention: equality multipliers are unrestricted, whereas a fixed inequality convention imposes dual sign restrictions. These limits confine its meaning to the optimization problem that defines it (Boyd & Vandenberghe, 2004).

For this book, the analytic example is deliberately narrow. A multiplier may indicate how a modeled performance criterion changes when an opportunity, resource, risk, or feasibility constraint is marginally relaxed. It does not price suffering, convert pain into future benefit, compare persons, or authorize sacrifice. If the objective omits dignity, rights, care, distribution, or uncertainty, the multiplier does not mysteriously restore them. The model must either encode the relevant boundary or admit that it lies outside the calculation. The useful lesson is methodological: local sensitivity can reveal which constraint is binding, while human value remains categorically beyond the multiplier (Dworkin, 1981a; Dworkin, 1981b; Boyd & Vandenberghe, 2004).

19.7.1 — Marginal Constraint Pressure

Marginal constraint pressure asks how the optimized value of a declared model changes when one constraint is relaxed by a small

amount. The derivative is local to the current state, active set, objective, policy class, and units. It can identify which modeled restriction is binding, but it does not reveal a universal force or an amount of experience that must be offset (Boyd & Vandenberghe, 2004; Fleming & Soner, 2006).

The object is meaningful only near a regular optimum. If the feasible set is empty, the optimum is unattained, the active set changes discontinuously, or strong duality fails, the multiplier may be absent, nonunique, or misleading. Those conditions should appear beside the estimate rather than after its interpretation.

Constraint pressure can vary across time. A transport option may have low marginal value while alternatives remain open and high value near a deadline. A safety constraint may be inactive in one state and decisive in another. The model should therefore report the state and horizon rather than presenting one stable shadow price.

A practical example is a low-burden research task with a declared fatigue limit. The multiplier can describe how much the task objective would improve if the allowed effort increased slightly. It cannot say that participant fatigue is worth that improvement. Ethical admissibility can keep the limit fixed regardless of the mathematical derivative.

Ordinary scarcity and expected-control models are the primary rivals. If a standard resource model predicts the same allocation and intervention response, no fairness-specific interpretation is needed. Held-out changes in constraint availability should test

whether the multiplier has predictive value beyond generic opportunity cost.

The analytic example should be retired when the local derivative is unstable, depends on unmeasured state, or fails to predict responses to genuine constraint changes. A fitted number without those conditions is an annotation on a model, not a discovered causal object.

19.7.2 — Units, Dual Variables, and Local Interpretation

A dual variable inherits units from the objective and the constraint. If the objective is expected task loss and the constraint is minutes of available time, the multiplier has units of loss per minute. Change the objective, time scale, normalization, or constraint definition and the number changes. Unit analysis is therefore the first safeguard against treating it as a natural exchange rate (Boyd & Vandenberghe, 2004).

Dual interpretation also depends on sign convention. A positive multiplier under one formulation may appear negative when the constraint is written in the opposite direction. Every display states whether relaxation increases or decreases the bound and how the derivative is oriented. A symbol without that sentence is not accessible technical communication.

Local interpretation means the number approximates a small change around the fitted solution. Large changes can activate new constraints, alter policy, or move the system to a different region. Applying a local multiplier across a whole life, a clinical trajectory, or a public policy requires a separately justified model for those larger changes.

Uncertainty belongs in the unit table. Parameter error, state uncertainty, numerical approximation, and nonuniqueness can produce a range of multipliers or no stable estimate. Reporting one decimal place from an unstable optimization creates false precision.

A useful display pairs the multiplier with its owner, objective, constraint, state, horizon, units, uncertainty, and withdrawal condition. This packet makes the analytic role recoverable and prevents a detached screenshot from looking like a score.

No dual variable is comparable across persons unless the objectives, constraints, scales, and identification bridges are demonstrably commensurable, a condition this chapter does not assume. The object remains inside its local model.

19.7.3 — State Dependence and Nonlinearity

Shadow-price behavior is generally state dependent and nonlinear. The derivative can be zero while a constraint is slack, rise sharply near an active boundary, jump when the optimal policy changes, or become set-valued in a nonsmooth problem. Treating it as a constant erases the very geometry the multiplier is meant to summarize (Fleming & Soner, 2006; Aubin, 1991).

Nonconvexity is particularly dangerous. Local multipliers may describe one optimum while another policy has a different active set and better value. Duality gaps can break the usual sensitivity interpretation. A model should report whether convexity or a constraint qualification is assumed, approximated, or absent.

Time dependence creates another layer. A resource can become more constraining as an opportunity closes, yet a later innovation

can open a new route and lower pressure. The pattern is not a universal inverse-horizon law. It is a model-specific response to changing state, action support, and forecast.

A concrete simulation can vary one constraint across a grid and plot the optimized value rather than only the derivative. Kinks, plateaus, and regime changes reveal where the local approximation fails. The graph should include uncertainty and the ordinary control rival.

State dependence also limits causal interpretation. An observed association between a proxy for pressure and behavior may reflect the state that made the constraint active, not the multiplier itself. Interventions that change the bound while holding the relevant information structure fixed offer stronger evidence.

When nonlinearities make the multiplier unstable or nonunique, finite contrasts, identified sets, or qualitative binding-status statements replace the point value. Precision is not lost by refusing a number the model cannot support.

19.7.4 — Observable Proxies and Identification

A shadow price is usually latent because the objective, state, and active constraints are partly modeled. Observable proxies may include delay sensitivity, choice changes when a resource expands, or shifts in policy near a boundary. None is the multiplier itself. Identification requires a structural link from the proxy to the optimization problem and exclusion of rival pathways (Boyd & Vandenberghe, 2004; Hernán & Robins, 2020).

Choice data can identify preference or policy parameters only under assumptions about beliefs, available actions, noise, and

objective form. A person who declines an option may face hidden cost, inaccessibility, fear, or a different goal. Interpreting the choice as high constraint pressure without those variables is inverse storytelling.

Interventions on the constraint are more informative. Extending a deadline, reducing effort, adding transportation, or clarifying information can change the feasible set. The predicted local response should be compared with scarcity, fatigue, learning, and social-support models under the same information and burden.

Proxy validity can be tested through cross-equation transport. A multiplier estimated from one task should predict responses in another module governed by the same declared constraint. Refitting a new proxy relationship for every task removes the overidentification that makes the object scientifically useful.

Measurement error and selection can reverse the apparent relation. Participants closest to a constraint may drop out or receive extra support, while devices may fail under high load. Joint models and sensitivity analysis should carry those processes into the estimate.

If the proxy cannot distinguish the multiplier from ordinary urgency or opportunity cost, the analytic example remains illustrative. It does not become a person-level state, a diagnostic, or evidence that a completion mechanism is operating.

19.7.5 — No Monetary, Moral, or Personal Price

“Shadow price” remains a model-local sensitivity term. Any monetary interpretation depends on the modeled units, and no

multiplier prices pain, persons, duties, or care (Boyd & Vandenberghe, 2004).

No multiplier measures how much suffering is worth, how much joy is owed, or whose life should receive priority. Pain, dignity, consent, and rights are not exchangeable components in the objective. They either remain outside the model or enter as nonnegotiable admissibility constraints.

The object belongs to the constraint, not to the person. The correct sentence is that a declared model has high marginal sensitivity to a particular bound in a particular state. Saying that a person has a high shadow price turns an analytic derivative into a human attribute and is prohibited.

Local sensitivity cannot justify large or irreversible changes. Active sets can switch, nonlinearities can dominate, and the objective may omit consequences that matter most. A multiplier is not a recommendation even inside the modeled domain.

Clinical language requires special care. A shorter horizon does not make care inefficient, and a model cannot use marginal information value to reduce desired comfort, communication, or support. Research optimization remains subordinate to care.

Institutional misuse is equally serious. A dashboard must not rank cases, appeals, or participants by a shadow-price proxy. Such a system would import a narrow objective into public authority and convert uncertainty into eligibility or worth.

General-reader prose can prefer constraint sensitivity or marginal model value when the technical term adds more risk than clarity. Where shadow price is retained, units, owner, objective, active

constraint, uncertainty, and prohibited interpretation appear nearby.

This boundary permits precise analysis of dual variables without converting a model multiplier into moral payment, a personal price, or permission for sacrifice. Conditional net remainder accounting is a separate consequence of exact PTVC; a multiplier does not by itself establish that relation or a way to control future happiness.

19.7.6 — Retirement and Replacement by Better Causal Objects

A shadow-price object retires when the optimization problem is not identified, the feasible set is empty, strong duality or a relevant constraint qualification fails, the multiplier is unstable, or held-out changes in the bound do not produce the predicted response. A number returned by software does not survive these mathematical or empirical failures (Boyd & Vandenberghe, 2004).

Retirement may be semantic. If shadow price repeatedly invites monetary or moral interpretation, constraint sensitivity, finite contrast, active-set status, or feasibility margin can preserve the useful mathematics without importing an exchange metaphor.

Retirement may also be causal. A multiplier can summarize a fitted policy without being the variable through which behavior changes. If interventions on the bound alter outcomes through a different pathway, the causal object should move to that pathway.

Finite contrasts often replace derivatives in nonlinear or nonsmooth systems. Rather than report one local multiplier, the

analysis can show how the optimized value and action set change across a prospectively specified range of constraints. Kinks and regime changes become visible.

When the state, objective, active constraint, or dual relation remains uncertain, carry an identified set rather than selecting one multiplier. Apply §24.2 and Table 27.5 to that set, with the report preserving the corresponding canonical evidence state (Manski, 2003; Imbens & Manski, 2004).

Ordinary causal objects may be better. Opportunity access, treatment availability, information timing, pain relief, social support, and institutional repair can be directly intervened on and interpreted without invoking a dual variable. They take priority when they answer the scientific question more clearly.

Table 19.5. Successor causal objects and shadow-price withdrawal rules.

Successor object	Permitted scientific meaning	Prohibited interpretation and withdrawal rule
Marginal constraint sensitivity	Local derivative of a declared objective with respect to one constraint	Not a price of pain or person; withdraw when duality or stability fails
Finite intervention contrast	Change in a protocol-fixed outcome under two supported constraint levels	Not a universal exchange rate; restrict to the treatment versions and horizon
Viability or feasibility set	States and actions that satisfy declared safety or completion conditions	Not a ranking of lives; return no estimate outside identified support

Successor object	Permitted scientific meaning	Prohibited interpretation and withdrawal rule
Action-support set	Actions observed or defensibly supported at a declared state	Not personal advice; exclude coercive, inaccessible, or unsafe actions
Identified bounds	Range compatible with stated assumptions and data	Do not collapse to a point when the set crosses zero or spans different regimes

Failure propagates to tables, diagrams, captions, and examples that might otherwise preserve the impression of a hidden price. Historical versions retain the reason for withdrawal, but the active scientific presentation no longer displays the retired object as a live mechanism.

What survives is the discipline of constrained reasoning: explicit objectives, units, action sets, support, feasibility, and nonnegotiable boundaries. The analytic example has succeeded if it makes those assumptions visible and leaves no residue of moral exchange.

Chapter 20 — Interoception and Brain-Body Mechanisms

Felt experience is embodied, yet physiology is not a transparent transcript. Humiliation can tighten the chest, medication can quiet pain while changing speech, fatigue can close an action that was technically available, and safety can return through breath, posture, contact, or relief. Chapter 20 studies the brain-body processes that may carry those changes while preserving the difference between a bodily signal and the experience it imperfectly witnesses.

The chapter asks which embodied mechanisms could mediate, mask, distort, mimic, or constrain route-specific dynamics. Every candidate enters through a causal layer, expected lag, person-specific baseline, perturbation signature, rival explanation, and no-inference condition. Neural regions, biomarkers, wearables, and model outputs become evidence only through that typed architecture.

The previous chapters gave mechanism a formal grammar. Queue-style state dynamics became a candidate control model rather than a hidden actor, and shadow-price analysis became local constraint sensitivity rather than moral exchange. The same discipline now reaches interoception, allostasis, somatic markers, stopping systems, pain, fatigue, medication, disability, trauma, illness, devices, and Artificial Intelligence.

Brain–body science links anatomical structures to experience through measurable dynamics. A useful mechanism connects insula, vagus, cortisol, inflammation, prefrontal control, or heart-rate variability to explicit states, timing, perturbations, and recovery. These connections make competing explanations testable.

Bodily signals are partial witnesses whose meanings depend on channel and context. A rising heart rate may reflect effort, fear, fever, posture, medication, pain, excitement, dehydration, panic, or artifact; a quiet trace may reflect calm, shutdown, sedation, neuropathy, masked expression, practiced endurance, or sensor loss. Interpretation begins by placing those alternatives inside the model.

The formal target remains felt experience, and experience often has bodily texture. Pressure in the throat before a difficult call, nausea in a remembered room, trembling after danger has passed, warmth when safety returns, and fatigue when choice becomes too costly can inform mechanism without defining the person. The chapter models that texture as one evidentiary layer among several.

Six layers organize the analysis: sensing, central representation, prediction, control action, peripheral response, and conscious report. A physiological channel may witness one layer while missing another. Report may change before the wearable, the wearable before awareness, or both after a third cause such as fever, medication, sleep loss, inflammation, movement, cultural expression, or the testing room itself.

Interoceptive inference, allostatic regulation, somatic-marker learning, and embodied action predict different temporal order, context dependence, and perturbation response across those layers. Their scientific value lies in separable predictions and recoverable causal graphs, not in the prestige of biological vocabulary.

Each mechanism earns a testable role by specifying its channel, expected lag, person-specific baseline, confound structure, perturbation, negative control, transport claim, and defeat condition. A model that can explain every result after inspection has not localized a mechanism; it has only expanded its language.

Disability, trauma, medication, chronic illness, aging, and terminal physiology are central validity populations. They reveal whether a baseline, sensor, task, or causal bridge was calibrated only to the easiest-to-measure body. Variation in movement, signaling, metabolism, communication, or expression narrows the model until the model learns to represent it.

Consider a participant in a palliative-care study whose wearable shows falling movement, altered sleep, and lower heart-rate variability after a medication change. The pattern could reflect worsening burden, pain relief, sedation, changing perfusion, device fit, posture, consciousness, or consent-related nonwear. A disciplined protocol inspects those treatment, quality, observation, and reportability changes before assigning a route interpretation.

Far from hospice, a graduate student with a history of panic may feel a tight chest before a meeting. The signal could reflect memory, prediction, threat appraisal, caffeine, sleep loss, conditioned context, or a useful early warning. Compressing that complexity into one arousal score risks turning vigilance into valence and physiology into identity. The interpretive burden belongs to the model, not the person whose body is being measured.

Equations, causal diagrams, tables, and case-like scenarios serve different purposes. A mechanism map proposes a relationship, an observation model defines how channels arise, and a design table organizes a test. Each display states its role and failure condition. Formalization adds value by making the embodied claim vulnerable to recovery and perturbation tests.

Wearables and Artificial Intelligence appear late because they expose the public surface of the same inference problem. Device streams, artifact flags, missingness patterns, and machine-learning support can improve quality control and bounded prediction. Their outputs remain inside a purpose-limited context of use with provenance, calibration, abstention, contestability, correction, and deletion routes.

Typed inference governs the chapter. Bodily data acquire meaning through a declared construct, mechanism, context, baseline, lag, confound model, transport claim, and decision role. A failed required bridge makes the evidence Unusable for the affected estimand; identification limits under valid gates instead yield a bounded conclusion or No adequate estimate. The same record may still support descriptive care, device-quality review, or future method development without becoming a phenomenal-mechanism claim.

Interoception offers a rich, multiscale account of how bodily state and experience interact. Its person-specific pathways, measurement properties, and safely testable components make brain–body mechanisms a substantive part of the comparison.

The body is treated as a layered dynamical system, not a single biomarker channel. Cardiac, respiratory, endocrine, immune, metabolic, nociceptive, motor, sleep, and cortical processes operate on different clocks and often share causes. Every candidate names which layer carries state, which observes it, and which merely covaries.

Mechanism-specific prediction packets should include temporal order, sign, dose response, recovery, context dependence, and off-target pathways. A signal that rises after distress is less informative than a model that predicts when it rises, when it should remain stable, and how a safe perturbation changes the downstream sequence.

Human reviewers remain accountable for scientific decisions. Artificial intelligence can assist artifact detection, stream alignment, and estimation of specified features within a versioned, governed study.

20.1 — Embodied Dynamics as Candidate Mechanisms

A burden that is not spoken may still be carried. A person may stop answering a message, avoid a hallway, lose appetite, sleep lightly, tighten before a voice, or become exhausted by choices that look small from the outside. The scientific temptation is to treat these bodily traces as direct evidence. The better route is to treat them as candidate pathways that need a model.

Embodied burden means that unresolved demand may be represented partly through bodily regulation, interoceptive prediction, learned bodily associations, action readiness, and shifts in salience. The word candidate does important work. The chapter is not saying that the body stores the ledger. It is asking whether some brain-body dynamics help explain why certain demands remain active, become avoidant, initiate repair, or lose their grip.

The section builds a status discipline for mechanisms. A background mechanism is already expected from ordinary neuroscience or physiology. A candidate Law-relevant mediator may help explain a queue, horizon, or repair pattern under specific conditions. A rival mechanism may reproduce the same pattern without the Law. The chapter gains strength by letting all three statuses remain available.

A DNA-based implementation becomes scientifically useful when genetic instructions are distinguished from the changing state that carries information. The same unchanged genomic sequence can build machinery that undergoes different histories;

that sequence alone cannot distinguish those histories. Candidate changing states include chromatin, methylation, transcription, proteins, synapses, and distributed cellular activity. Slow molecular processes might maintain or tune a faster integrator. The question is which state carries the required information, how its updates are calibrated, and how that information survives component replacement.

Molecular interventions can now address that question with greater specificity. Coda et al. (2025) targeted the Arc promoter within identified mouse memory ensembles and reversibly altered contextual fear-memory expression. Kukushkin et al. (2024) found that spaced chemical stimulation produced more sustained CRE-dependent transcription than massed stimulation in SH-SY5Y neuroblastoma-derived and HEK293 cell lines, measured with a luciferase reporter. The first result supplies a selective causal tool; the second supplies an ordinary cellular mechanism that can imitate history-sensitive persistence. Neither experiment measured a signed phenomenal account.

A nominated accounting state should make the same calibrated predictions across new histories, including histories with equal signed totals but different order or gross stimulation. Reinterpreting an old event can produce a new experience, but it does not change the event's earlier experienced contribution. Likewise, impaired recall does not establish that the information needed by an accounting mechanism has been erased. Perturbations should distinguish recording, maintenance, retrieval, and expression, and should test the nominated state

against learning, stress, salience, and multiscale memory with the same observational and fitting resources.

Engineered recording offers a concrete first benchmark. DNA Typewriter records event order through sequential genome editing, while ENGRAM records signalling-related barcode changes in engineered cells (Choi et al., 2022; Chen et al., 2024). A proposed two-channel experiment would assign plus and minus labels to known laboratory inputs, then test recovery of their difference separately from total input and temporal order. The labels initially designate programmed signals. A frozen decoder should face held-out sign reversals, equal additions to both channels, altered pulse spacing, and differences among cells, with recording error and saturation included in its predictions.

Successful recovery from pooled molecular measurements must also be distinguished from recovery within an individual cell or lineage. With nonlinear writing, different distributions of cellular histories can produce the same pooled signal. The benchmark should therefore match its unit of inference to its actual readout and preserve failed or unedited records. Its immediate contribution is a calibrated test of biological recording and decoding; a natural PTVC realization additionally requires an independently supported relation to the qualifying stream's experience and the declared initial and pre-endpoint boundary conditions.

Table 20.1. Mechanism-status routing. Role: interpreting brain-body findings and identifying the next mechanism test.

Mechanism status	What it licenses	Scope of the result
Background physiology	Use established regulation science as context	Established physiological relationships in their tested settings
Candidate mediator	Test whether the pathway carries part of a proposed dynamic	Specified pathway, observation model, and tested setting
Rival mechanism	Let ordinary body regulation explain the pattern	The measured pattern under the shared model comparison
Observation channel	Use a signal as partial witness with uncertainty	Channel-specific partial inference with calibrated uncertainty
Failure route	Narrow, abstain, or retire the mechanism	The tested mechanism, measurement model, and reference class

20.1.1 — Interoceptive State and Prediction

Interoception begins with internal bodily signals, but it does not end with raw signal. Cardiac rhythm, breathing, gut state, temperature, metabolic demand, pain, inflammation, endocrine shift, posture, and effort are filtered, predicted, attended, and linked to action within distributed brain-body systems. These processes contribute to affective construction and regulation, but they do not provide a transparent reading of valence (Khalsa et al., 2018; Barrett & Simmons, 2015; Feldman et al., 2024).

The candidate state can be written as a vector rather than a single intensity. Cardiac activation, respiratory constraint, nociception, immune activation, metabolic depletion, muscular tension, and sleep pressure can move together or apart. A scalar arousal score may be convenient, but convenience is not identification. A physiology model that collapses these axes too early may lose the difference between fear, effort, fever, grief, pain, and relief.

A restrained model begins by separating the latent bodily state from the observation. The observation is what the device, report, task, or clinician sees. The interoceptive state is the modeled internal condition. The conscious feeling is a further target, not automatically equivalent to either. The Law-specific question enters only after that separation is honored.

A participant who feels dread before an ordinary phone call may be responding to interoceptive prediction rather than current danger. The body has learned that certain cues predict conflict, humiliation, debt, pain, or abandonment. The resulting bodily state may be real even when the current scene is safe. A model that calls the person irrational misses the learned prediction; a model that calls the body the ledger overreads it.

Interoceptive prediction can also be a rival. If prediction error, learned bodily expectation, and safety updating explain the timing of avoidance and repair, the Law-specific queue language may add little. That outcome is not a defect in the chapter. It is one way mechanism science protects the project from turning compatible patterns into proprietary evidence.

A concrete safeguard is methodological rather than decorative: no interoceptive signal enters a momentary valence estimate without a declared channel, baseline, timing window, confound set, and abstention rule. Strong internal sensation may be important to the person and still fail as an estimator of the target construct. The person remains authoritative about the fact that they are experiencing; the model remains responsible for saying what it can infer.

A stronger implementation would store the predicted state and the incoming signal separately. That lets an analyst ask whether distress followed bodily evidence, whether bodily evidence followed a prediction, or whether both were moved by context. Without that separation, an interoceptive account can become unfalsifiable because every mismatch is reinterpreted as hidden prediction.

20.1.2 — Allostatic Load and Regulation

Allostasis names the body's anticipatory regulation under changing demands. It is not only a return to a fixed set point. It is the work of preparing, reallocating, mobilizing, conserving, and shifting thresholds so the organism can meet what it expects. That makes allostasis scientifically relevant to the Law because horizon, reserve, fatigue, threat, sleep, pain, and repair all have bodily cost (Khalsa et al., 2018; Barrett & Simmons, 2015).

Allostatic load describes accumulated wear from repeated or chronic activation of regulatory systems. It can mediate burden, constrain future options, alter observation, and supply specific biological predictions for comparison.

Reserve may need a vector representation. Metabolic capacity, autonomic flexibility, cognitive control, inflammatory state, sleep recovery, pain tolerance, social support, and clinical stability need not collapse into one number. A scalar reserve remains useful only when its compression loss, transport, and rival performance are tested.

A caregiver who sleeps in a hospital chair for four nights may show altered glucose regulation, higher resting arousal, slowed attention, irritability, and flat affect. The visible emotion may be muted while the regulatory cost is high. If a study measures only smiling, it may miss burden. If it measures only cortisol, it may confuse burden with infection, medication, caffeine, or circadian timing.

An informative allostatic account predicts which reserve dimension changes, when it changes, how it recovers, and which observation channel reflects the change. It also identifies competing explanations and the outcomes that would support, revise, or retire the proposed link. With that specificity, a broad account of strain becomes a mechanism whose predictions can be evaluated.

Accumulated physiological cost makes early care particularly valuable. If regulatory strain narrows future repair, timely sleep, pain relief, accessible support, and reduced demand can improve the available pathways.

The most important analytic choice is whether allostatic cost is modeled as level, change, volatility, or loss of flexibility. These produce different predictions. A high level may reflect current

demand, a steep change may reflect acute transition, volatility may reflect instability, and inflexibility may reflect depleted capacity. Treating all of them as one load score erases the mechanism.

20.1.3 — Affective Salience

Not every bodily change becomes felt as important. Affective salience is the process by which some signals stand out as urgent, meaningful, aversive, inviting, threatening, or action-guiding. Salience is not valence. A signal can be salient and positive, salient and negative, salient and ambiguous, or salient because the person cannot ignore it (Sterling, 2012; McEwen, 1998; Barrett & Simmons, 2015).

The distinction matters because salience often drives behavior before a person can explain why. A chest flutter may become a warning. A familiar smell may bring grief before the memory is named. A pain flare may pull attention away from conversation. A calm pressure from a weighted blanket may help a person reenter the room. Each case changes availability of action without becoming a full measure of the life.

Affective salience can be modeled as a weighting function on observations and options. The same peripheral signal may receive high or low weight depending on prediction, context, trauma history, medication, attention, cultural interpretation, and current goals. In a queue model, salience may raise an item's priority. In a rival account, salience alone may explain reactivation without any Law-specific structure.

This prevents a common error in physiological interpretation. A high arousal signal is not automatically more negative. It may mark exercise, anticipation, effort, social exposure, pain, caffeine, fever, panic, excitement, or embarrassment. A low arousal signal is not automatically relief. It may mark shutdown, sedation, depression, dissociation, autonomic failure, or sensor dropout.

The empirical design therefore asks whether salience predicts later report, avoidance, repair action, attention capture, memory intrusion, or physiological recovery after controlling for ordinary arousal. If it does not, salience may be a label after the fact. If it does, the resulting mechanism can be tested against adaptation, predictive processing, homeostasis, and device artifact.

False salience has an asymmetric error cost. A school, clinic, workplace, or research protocol may treat visible activation as threat while reading quiet collapse as calm, shifting the correction burden onto the person least able to contest the interpretation. Error analysis should therefore report subgroup-specific false positives, false negatives, and the practical consequence of each.

A field review should also ask whether salience is helpful or harmful in the case being studied. Some salience brings timely care, as when pain or breathlessness becomes noticeable early enough to treat. Other salience traps the person in monitoring. The same mechanism can therefore be protective in one window and burdensome in another, which is why the chapter refuses one-tone interpretation.

20.1.4 — Somatic Markers and Action Readiness

Somatic markers matter here as learned patterns that can bias attention and action readiness before deliberate report. The scientific question is which bodily and contextual signals predict a specific action transition, not whether the body carries a hidden verdict.

Somatic-marker accounts propose that bodily associations can bias choice under uncertainty. A route, face, bill, room, smell, tone, or deadline may acquire a bodily mark because past experience linked it to danger, relief, humiliation, pain, reward, or repair. The mark does not need to be a sentence in consciousness to alter behavior (Khalsa et al., 2018; Barrett & Simmons, 2015).

This is relevant to the Law because unresolved burden often returns through options. A person may not think about an old medical denial until a new envelope appears. The body tightens before the content is known. The somatic marker is a candidate mechanism for why a visible event can reopen a demand that the calendar says is over.

The model must distinguish learned association from present cost. A somatic marker can be outdated, protective, excessive, accurate, culturally shaped, or miscalibrated by trauma. It can also be trained by institutions. A benefits portal that repeatedly threatens access may teach bodily vigilance. A research protocol that ignores that history may mistake learned protection for irrational noise.

Somatic markers also create a strong rival. If learned bodily associations explain reactivation, avoidance, and repair timing, then Queue and horizon language may be unnecessary in that domain. The Law candidate can keep only what the learned-association model cannot predict under held-out data and declared observations.

A model of somatic markers should include cue exposure, prior association, bodily response, attention capture, action tendency, report, and later updating. The updating step matters. If safe experience fails to weaken the marker, trauma, chronic threat, institutional recurrence, or biological sensitization may be the relevant mechanism. If safe experience weakens it, ordinary learning may explain the pattern.

The chapter keeps somatic markers morally neutral. A bodily warning is not a command, a debt, a destiny, or a message from fairness. It is an embodied trace that may help, mislead, protect, or imprison. Science serves the person by learning when the trace is informative and when it needs care, context, or correction.

The best somatic-marker tests use cue specificity. If a hospital envelope, a debt portal, and a neutral envelope produce the same response, the model may be measuring general uncertainty. If only the hospital envelope reactivates the pattern, the learned association becomes more plausible. Specificity is what keeps a vivid story from substituting for a mechanism.

20.1.5 — Embodiment Without Reduction

Embodiment without reduction is the chapter's central posture. It says that lived experience is not floating above biology, but also

that biology is not the whole of lived meaning. Hunger, nausea, pain, breath, touch, fatigue, inflammation, warmth, and movement matter because they shape what is available to the person. They do not become a public key to the person (Sterling, 2012; McEwen, 1998; Barrett & Simmons, 2015).

Reduction enters through shortcuts. A clinician sees low movement and assumes apathy. A researcher sees high skin conductance and assumes distress. A manager sees calm speech and assumes no harm. A wearable model sees sleep fragmentation and infers emotional instability. Each shortcut may contain a hint; each can become false authority when detached from context.

Biomarker profiles summarize channels, uncertainty, artifacts, medication, disability, baseline, report, and context to support research forecasts or abstention. They complement the person's account, family context, clinical judgment, and ethical review. Their permitted use is research; decisions about care and access follow the applicable clinical and rights-based standards.

Embodied explanation also requires environmental humility. A body may carry burden because the world keeps pressing it. Noise, stairs, heat, racism, debt, inaccessible transport, caregiving load, or fear of a supervisor may shape physiology. If the model treats the body as the sole site of burden, it may individualize an institutional problem.

A stronger model places external demand and bodily response in the same causal graph. It asks whether changing the environment changes the body, whether changing the body changes experience, and whether both are required. Physiology and social

conditions become jointly testable instead of competing explanations that hide one another.

The practical question is where interpretive burden lands. When the body is measured, the study asks which invisible load generated the signal, who can change the conditions, and whether the interpretation produces more care or more surveillance. Embodiment becomes humane when the causal graph points outward as well as inward.

Embodiment also protects against a false split between mental and physical care. If a person's fear is intensified by untreated pain, therapy alone is incomplete. If pain care is blocked by shame, language access, or administrative threat, medication alone is incomplete. The mechanism points to combined repair rather than to a hierarchy where one discipline claims the truth.

20.1.6 — Mechanism Status and Defeat Conditions

An embodied candidate remains live only while its declared timing, intervention response, transport, and rival separation survive. Wrong channel order, absent perturbation effects, medication or context explanations, and site-specific collapse each narrow a different component of the route. The defeat rule is attached to the tested claim, not softened by biological plausibility.

Each mechanism has a defined role in the study. Interoceptive prediction may supply background science, a candidate mediator, or a competing explanation. Allostatic load may explain confounding or partial mediation, and wearable signals may

provide observation channels (Khalsa et al., 2018; Barrett & Simmons, 2015).

Three achievements organize the evidence: biological plausibility motivates a candidate, recoverable simulation checks the analysis under known conditions, and empirical discrimination compares its predictions with serious alternatives. The chapter's displays make each mechanism's assumptions, predictions, and evidential role inspectable.

The most useful status labels are simple. Candidate mediator means the pathway may carry part of a predicted dynamic. Rival means the pathway may explain the same evidence without the Law. Observation channel means the pathway supplies noisy information about a modeled target. Confound means the pathway can move the signal without moving the target. Failure means the pathway cannot be interpreted responsibly under the present design.

A single body variable can change status across a study. Heart-rate variability may be a channel during resting autonomic regulation, a confound during movement, a treatment artifact during beta-blocker use, a missingness problem during nonwear, and a false reassurance in autonomic neuropathy. The model should carry those status changes rather than pretending the variable has one meaning.

Status labels should be written into preregistration, data dictionaries, diagrams, tables, and public summaries. A reader should see whether a signal is being used to define a construct, estimate a latent variable, test a mechanism, screen for artifact, or

trigger abstention. Clear status labels make the scientific and ethical role of each signal inspectable.

Bodily observations can strengthen or revise a mechanism, identify a need for better measurement, or establish that care should take priority. Explicit outcome rules keep the mechanism accountable to evidence and useful for care.

A brain-body mechanism should state whether each component is necessary, sufficient, mediating, moderating, or merely predictive. Those statuses require different evidence. A reproducible correlate can improve observation without identifying the process that generates the terminal signature.

Cross-level predictions are stronger than isolated associations. A candidate route should link a safe change in bodily state to a timed change in central representation, action, report, and future continuation under a declared causal graph. If the sequence fails or a rival predicts it equally well, the mechanism narrows.

Generator recovery applies here as well. Simulations and benchmark tasks should test whether the analysis can distinguish allostatic regulation, salience, pain, effort, medication, device artifact, and the candidate route after realistic lags and noise. Failure in synthetic data blocks strong interpretation of human data.

Defeat can be component specific. Interoceptive precision may predict action while the proposed stopping process fails; an autonomic signal may transport while the valence bridge does not. The verdict should attach to the component actually tested and leave the rest open or withdrawn.

20.2 — Interoception and Affective Salience

Interoception comprises signals with different routes, speeds, artifacts, and relationships to experience. Separating these channels gives the model a richer and more testable account of bodily feeling.

Channel specificity begins with distinct sensory routes. Cardiac, respiratory, visceral, immune, endocrine, nociceptive, metabolic, vestibular, proprioceptive, and thermal signals have different baselines, speeds, observability, and interpretive limits. Some are easy to record but hard to interpret; others matter directly to the person while remaining difficult to observe.

Pleasantness can change while the external stimulus remains similar. In the thermal, taste, and smell examples examined by Cabanac (1971), the hedonic response depended on the person's internal condition. He termed this state dependence alliesthesia. The finding gives the distinction between circumstance and experience a physiological basis: what an event feels like depends partly on the body receiving it. For a cumulative model, that relationship supplies a useful prediction to test across independently characterized bodily states and repeated observations of the same stimulus.

Channel-specific models can make burden more visible and care more responsive. They can relate a respiratory signal to dyspnea or panic uncertainty, an immune signal to illness burden or treatment effects, and a movement signal to the broader context needed for interpreting pain.

Equation 20.1: Observation-channel model. Role: candidate specification linking latent variables to measured channels.

$$O_{c,t} = h_c(S_t, E_t, M_t, D_t, Q_{c,t}) + \varepsilon_{c,t}$$

$$R_t = r(B_t, C_t, A_t) + \epsilon_t$$

$$Y_t^E \not\equiv O_{c,t}, \quad \text{and} \quad Y_t^E \not\equiv R_t.$$

Channel values may correlate or occasionally coincide without becoming the same construct.

In this display, $O_{c,t}$ is the observed signal from channel c , S_t is the latent bodily state, E_t is environment, M_t is medication, D_t is disability or disease context, $Q_{c,t}$ is channel quality, R_t is report, and A_t is the modeled experiential target. In the report equation, B , C , and A denote belief or central representation, context, and action, respectively, all indexed by t . The nonidentity relations are the important part. Observation and report can inform the target, but neither is the target itself.

Table 20.2. Interoceptive channel routing. Role: routing aid for interpretation and confounds.

Channel family	Common measurement routes	Main interpretation risks
Cardiac and vascular	heart rate, HRV, pulse arrival, blood pressure	movement, medication, posture, fever, fitness, device fit
Respiratory	respiration rate, depth, CO2 proxy, breath tasks	exertion, anxiety, pain, posture, lung disease
Visceral and metabolic	appetite, nausea, glucose, temperature, fatigue reports	illness, medication, sleep, diet, endocrine state
Immune and inflammatory	cytokines, CRP, symptoms, temperature	infection, disease, treatment, circadian timing

Channel family	Common measurement routes	Main interpretation risks
Nociceptive and pain	pain reports, movement, facial action, analgesic use	communication limits, masking, tolerance, disability norms
Behavioral embodiment	posture, activity, speech timing, sleep	environment, opportunity, access, caregiving demands

20.2.1 — Afferent Channels and Internal Sensing

Afferent channels carry information from the body toward central representation. They are not interchangeable. A heartbeat signal, a breath constraint, a gut sensation, a pain signal, an inflammatory cue, and a temperature shift can all become part of feeling, but they enter through different physiology and carry different ambiguity (Khalsa et al., 2018; Critchley & Garfinkel, 2017; Seth & Friston, 2016).

A channel-specific model asks which pathway is plausible for the question at hand. If the target is breath-related panic, respiratory timing may be primary. If the target is chronic fatigue, inflammatory, sleep, metabolic, autonomic, and activity channels may need joint modeling. If the target is social dread, cardiac and somatic signals may matter, but so do context, memory, appraisal, and safety.

This prevents a familiar measurement error. A model trained on one channel may appear to generalize because many bodily systems coactivate under stress. The apparent success may vanish when the same channel is tested during exercise, fever, stimulant use, sleep deprivation, pain relief, or cultural expression differences. Coactivation is not construct validity.

A human example can be ordinary. A person with asthma may show respiratory changes before a meeting, but the meaning differs if the change is airway limitation, anxiety, mask discomfort, conditioned fear, or a combination. Calling all of that burden may be too vague. Calling it mere physiology may be too dismissive. The model must do the work.

The data record should therefore identify channel family, sampling rate, device version, artifact flag, baseline window, posture, movement, medication, illness state, and context. The record should also carry why the channel was chosen. A channel without a theory is an invitation to post hoc interpretation.

The section's local rule is channel humility. A signal can be useful in the channel it actually measures and silent about channels it does not. The chapter does not need a perfect body map. It needs enough specificity that a field expert can tell what would count as success, failure, or overreach.

Channel selection should also consider burden of collection. A cardiac sensor may be easy for one participant and intrusive for another. A breath task may be harmless for some and frightening for someone with respiratory trauma. The most elegant channel is not always the fairest channel; the protocol must measure observation burden as well as signal quality.

20.2.2 — Accuracy, Sensibility, and Awareness

Interoceptive accuracy, sensibility, and awareness are related but distinct. Performance on a detection task, self-reported attention to bodily signals, and metacognitive knowledge about accuracy need not agree. A protocol should name which object is measured

rather than using interoception as one undifferentiated trait (Critchley & Garfinkel, 2017).

Measurement quality is task-specific. Newer cardiac, respiratory, and other psychophysical tasks address some weaknesses of classical heartbeat counting, yet they differ in signal strength, beliefs, attention demands, control conditions, and scoring. No single task earns the label of global interoceptive accuracy without cross-task and cross-organ evidence (Desmedt et al., 2023).

Large-scale cross-axis evidence strengthens that caution: cardiac and respiratory performance can be largely uncorrelated even within the same participants. A model that treats interoceptive ability as one stable scalar may therefore erase modality-specific skill, uncertainty, and failure (Banellis et al., 2026).

Interoceptive precision refers to how much weight the system gives an internal signal or prediction error. Attention changes that weight. A weak signal can dominate awareness when precision is high; a strong signal can fade when precision is low, competing demands are greater, medication blunts awareness, or dissociation separates sensing from report (Barrett & Simmons, 2015; Critchley & Garfinkel, 2017).

This concept helps explain why two people with similar physiology may report different experience. One person notices heartbeat changes immediately. Another notices only fatigue hours later. A trained singer may detect breath shifts that a novice misses. A trauma survivor may monitor internal cues with

exhausting vigilance. Neurodiversity, culture, illness, and history all shape precision and attention.

For the Law, precision and attention matter because unresolved demand may be carried not only by signal intensity but by signal priority. A small bodily cue can become large in the life if it repeatedly captures attention, interrupts action, or reorganizes choices. Conversely, a large physiological load may remain underreported if the person has learned not to attend to it or cannot safely express it.

The rival route is equally strong. Precision-weighted interoceptive learning may explain apparent queue reactivation without a queue state. If attention to bodily cues predicts avoidance and repair timing as well as or better than the queue model under equal information, the ordinary predictive account wins that comparison. PTVC-linked terminology receives no protection from a better supported rival.

A study can test precision by combining report confidence, heartbeat or respiratory tasks, attention manipulations that do not induce harm, and within-person changes across context. It should not assume that better interoceptive accuracy is always better for well-being. In some settings, heightened monitoring can deepen distress; in others, it can support early regulation.

A local safeguard is to respect the person's attentional cost. Asking someone to monitor the body can itself create burden. Research prompts should be brief, optional, interruptible, and reviewed for symptom amplification. An interoception study that

creates vigilance in order to measure vigilance has confused its instrument with its target.

Precision can change during a study because the study itself teaches attention. A participant asked to notice heartbeat, breath, nausea, or fatigue may become better at reporting, more worried about symptoms, or more annoyed by interruption. The protocol should distinguish measurement learning from mechanism change, especially when prompts repeat across weeks.

20.2.3 — Precision, Attention, and Prediction Error

Prediction error is the mismatch between expected bodily state and incoming bodily evidence. Interoceptive updating is the process by which the system revises belief, attention, and action. This can be helpful: a safe breath, stable rhythm, or pain relief can teach the body that a situation is less dangerous than expected (Khalsa et al., 2018; Critchley & Garfinkel, 2017; Seth & Friston, 2016).

Updating can also fail. Chronic threat, trauma, unreliable caregiving, repeated institutional denial, persistent pain, or unpredictable symptoms may keep prediction errors from resolving. The body learns that safety is temporary, ambiguous, or not safe enough to trust. A protocol that sees only the current room may miss the history that makes the current room difficult.

The Law-specific question is whether updating dynamics align with queue release, horizon pressure, reserve, or residual burden in ways that rival learning accounts cannot explain. That is a high burden. Many forms of repair are ordinary learning. A pattern

does not become Law-relevant because it feels meaningful after the fact.

A clean design would specify the prediction before the observation. For example, if safe social contact should reduce a conditioned bodily warning, the model should name the expected channel, lag, report change, and persistence window. If the signal changes but report does not, the study should not average the conflict away. It has learned something about mediation or dissociation.

Prediction-error models require negative controls. A neutral cue matched for novelty, attention, and movement should not produce the same channel-specific change if the proposed pathway is specific. If it does, the model may be detecting general arousal, task demand, or measurement artifact rather than interoceptive learning.

Updating is ethically useful because it supports repair without moral accounting. A person can learn safety, receive treatment, change environment, or regain agency without being told that a particular suffering was morally necessary or that relief should be withheld. The body's capacity to update is a reason to care earlier, not a reason to explain pain later.

Prediction-error language also requires care around authority. A researcher may be tempted to say the person's body expected danger incorrectly. In many lives, the body learned from real danger, repeated disbelief, or ongoing risk. The model may judge the present cue safe under laboratory conditions while the person's history makes caution adaptive.

20.2.4 — Valence, Arousal, Salience, and Urgency

Valence, arousal, and urgency are often correlated, but they are not the same. Valence concerns felt positive or negative tone under the project's measured target. Arousal concerns activation or readiness. Urgency concerns the felt demand for action. A painful injury, exciting performance, panic attack, deadline, fever, and reunion can all raise arousal while differing radically in valence and urgency (Barrett & Simmons, 2015; Critchley & Garfinkel, 2017).

A body signal may be strongest for arousal and weakest for valence. Electrodermal activity can mark sympathetic activation without telling whether the person is afraid, thrilled, embarrassed, exerting effort, or overheated. Heart rate may rise during pleasure, threat, pain, exercise, or medication effect. Inflammation may correlate with malaise without specifying the person's full experiential state.

Single-axis affect is therefore inadequate unless the proposed axis is named and qualified. A valence claim requires sign identification through report, context, calibration, tasks, and rivals; an urgency claim requires links to action timing, avoidance, repair initiation, or choice pressure. The model may use one dimension only for the job that dimension can support.

A realistic example is a courtroom witness whose hands shake. The shaking may mean fear, cold, medication, public exposure, trauma, anger, illness, or motor condition. A legal or research system that treats visible arousal as credibility, guilt, distress, or

burden creates a new hidden burden. The chapter's science must be able to say: this signal is too nonspecific.

The empirical route is multidimensional. Valence reports, arousal channels, task demand, action tendency, contextual threat, pain ratings, and calibration history are modeled separately before combination. A multi-axis model must improve held-out prediction, calibration, or mechanism discrimination over a one-axis baseline; otherwise its claims narrow to the simpler representation.

The public language should follow the model. Say activation when the evidence is activation. Say salience when the evidence is attention capture. Say urgency when action pressure is measured. Say valence only when the sign and target have been identified. Precision in words makes the role of each measurement clear.

A useful data dictionary stores reported valence, physiological activation, action urgency, pain intensity, fatigue, threat appraisal, and confidence separately. This preserves the distinct information each axis contributes.

20.2.5 — Individual, Developmental, and Cultural Variation

Development, culture, language, disability, training, illness, and prior threat can alter which signals are noticed and how they are described. Variation should inform calibration and subgroup analysis, not be treated as error around one ideal observer.

Interoceptive dynamics vary across persons and across states within the same person. Training, age, anxiety, trauma, autism, depression, illness, medication, chronic pain, sleep loss, fatigue,

cultural expression, disability, and neurodiversity all shape sensing, attention, reporting, and action. A population calibration that ignores this variation can become a disguised norm (Khalsa et al., 2018; Critchley & Garfinkel, 2017; Seth & Friston, 2016).

The same person may also shift across a day. Morning medication may reduce pain but blunt awareness. Afternoon fatigue may make a small demand feel enormous. Evening safety may allow the body to register what it had suppressed at work. Terminal illness may change all of these relationships through treatment, inflammation, weakness, delirium risk, and care context.

Hierarchical or person-specific modeling is required whenever intercepts, slopes, lags, or channel reliabilities plausibly vary. Partial pooling can borrow strength across persons while preserving the possibility that one person's channel is invalid for another, or invalid for the same person in a later state.

Individual variation can create false fairness if smoothed. A group average may show recovery after a procedure while a subgroup with disability, medication sensitivity, or trauma history worsens. If the model reports only the average, the statistical burden is shifted onto the people whose bodies did not follow the dominant pattern.

The data structure should store person-specific baselines, state tags, clinical context, device fit, language and culture notes, medication windows, disability accommodations, and abstention history. These are not accessories. They are part of the observation model. A signal without its interpretive conditions is a half measurement.

Common structure can be investigated across bodies that differ. Species, disability, medication, illness, age, and context become explicit dimensions of calibration and transport.

State variation should change sampling decisions. A daily prompt may be tolerable during ordinary work and impossible during a flare, grief week, clinical crisis, or medication adjustment. Governed adaptive cadence can reduce burden, but the cadence change also carries information about observation availability and must enter the missingness model.

20.2.6 — False Salience, Dissociation, and Misinterpretation

Dissociation can separate bodily signal, conscious access, report, and action. False salience can make a benign signal urgent, while reduced salience can hide clinically important change. Both patterns defeat simple signal-to-valence inference.

False salience occurs when a bodily signal becomes important to the system or to the observer without accurately tracking the intended experiential target. The signal is real; its interpretation may need revision. A panic-like heartbeat during caffeine use, a flat facial expression during pain, a trembling hand during cold, or a quiet report after sedation can all mislead if the model asks the wrong question (Barrett & Simmons, 2015; Critchley & Garfinkel, 2017).

False salience can arise inside the person, inside the observer, or inside the device. A person may overattend to benign sensations after trauma. A clinician may overread visible movement as distress. A wearable model may overflag movement artifact as arousal. A researcher may treat a statistically useful feature as

conceptually meaningful because it predicts something in one sample.

The risk is especially high when public artifacts simplify. A diagram that says body signal becomes burden can be cropped into a claim that the body reveals burden. Diagrams and captions therefore carry the uncertainty with the image. The signal is a candidate pathway, not a confession.

A false-salience audit should ask four questions: What is the target? Which signal is being used? What else can move the signal? Who is harmed if the signal is misread? The last question belongs in the science because misinterpretation changes behavior, care, consent, and trust. Recording the anticipated harm pathway also clarifies which false positives require the strictest abstention threshold.

Empirically, false salience can be tested with matched controls, context swaps, sensor comparisons, blinded human review, device-version checks, and report disagreement. Disagreement should not automatically be resolved in favor of the device or the report. It should trigger a conflict class with follow-up rules. Conflict follow-up should be prospectively limited so repeated retesting does not continue until one channel produces the preferred answer.

The analysis proceeds by abstention before authority. When salience is strong but ambiguous, the model should say ambiguous. A science that can say no estimate will be trusted more than a science that converts every signal into a story. Reason-coded ambiguity can still guide the next measurement by

showing whether valence direction, arousal source, or causal attribution is the unresolved element.

A false-salience test should predefine rivals such as threat learning, pain, medication, sleep loss, dissociation, sensory sensitivity, and social context. The candidate route should not receive residual variance merely because the causes were measured crudely. Rivals should be implemented with comparable channel access, otherwise crude nuisance models can make the candidate appear uniquely explanatory by construction.

A no-inference zone applies when arousal, salience, and valence cannot be separated with the available channels. The output can still describe observed activation and uncertainty, but it should withhold direction, hidden burden, and mechanism language. A no-inference zone should persist into downstream models so later analysis cannot silently recover the withheld interpretation from the same ambiguous signal.

20.3 — Brain–Body Control and Stopping

Control is the point at which bodily state changes the live menu of action. A person may feel pressure to stop, flee, speak, apologize, rest, seek medication, open a bill, close a laptop, breathe slowly, call for help, or avoid the cue. The scientific task is to model how body, environment, opportunity, and meaning jointly reshape that menu.

This section examines distributed brain-body control: how internal state, context, prediction, conflict, and capacity shape action initiation, inhibition, switching, and repair. Network-level, functional accounts make these relationships available for explicit timing and intervention tests.

The key object is a feedback loop. Bodily state influences belief and salience; belief and salience influence action; action changes the body and environment; the new body and environment change the next observation. A one-way physiology-to-feeling story misses the loop. A loop is harder to explain, but it is closer to the scientific problem.

Table 20.3 and Equation 20.2 turn the feedback loop into two inspectable objects: a layer map that preserves target distinctions and a dynamic system whose timing, confounds, and intervention responses can be tested.

Table 20.3. Brain-body control layers. Role: mechanism map for distributed control.

Layer	Example variables	Main question
External and social context	threat, care, task, room, demand, access	What is pressing the person now?

Layer	Example variables	Main question
Bodily state	pain, breath, fatigue, inflammation, metabolic demand	What physiological condition is modeled?
Central belief and salience	prediction, precision, attention, learned cue value	What does the system treat as important?
Control policy	stop, continue, avoid, repair, seek help, rest	What action becomes available or blocked?
Observation and report	device signal, behavior, speech, diary, clinician note	What can research responsibly see?
Update and residue	learning, recovery, sensitization, residual burden	What remains after action or care?

Equation 20.2: Dynamic feedback display. Role: candidate control-mediation model under partial observation.

$$S_{t+\Delta} = f_S(S_t, A_t, E_t, M_t, D_t) + \eta_t^S$$

$$B_{t+\Delta} = f_B(B_t, O_t, P_t, C_t) + \eta_t^B$$

$$A_t = \pi(B_t, H_t, U_t, C_t)$$

$$O_t = h(S_t, B_t, Q_t) + \varepsilon_t$$

$$R_t = \rho(B_t, C_t) + \epsilon_t$$

Here S is bodily state, B is belief or central representation, A is action, E is environment, M is medication, D is disability or disease context, P is precision, C is context, H is the filtered remaining-horizon candidate defined in §16.1.2, U is a possibly vector-valued reserve state, O is observation, R is report, and Q is signal quality. The display is a candidate structure. It is scientifically useful only if each term receives a design, a measurement route, and a failure condition.

20.3.1 — Distributed Control Networks

Brain-body control should be described as distributed. Salience, attention, interoception, motor readiness, memory, valuation, inhibitory control, and autonomic coordination are network-level processes. Some regions may be repeatedly involved, but involvement is not ownership. A map of activated tissue is not a map of fairness (Aron, 2007; Menon & Uddin, 2010; Seeley et al., 2007).

Distributed control matters because the same behavior can arise from different pathways. A person stops speaking because of fear, pain, fatigue, medication, cultural restraint, motor limitation, strategic choice, dissociation, or respect. A model that identifies stopping with one region or one physiological signature will confuse mechanism with appearance.

For the Law candidate, distributed control could mediate queue pressure or repair initiation. A demand becomes salient, action options narrow, inhibitory processes delay one path, and a repair path opens when safety or capacity changes. Ordinary control theory can explain many such transitions and therefore remains a full-strength rival.

A practical design should measure network-relevant behavior instead of merely naming networks. Reaction time, stop-signal performance, task switching, avoidance latency, help-seeking, speech initiation, report confidence, physiological recovery, and later behavior may together describe control. The neural layer may add useful constraints, but it should not substitute for functional evidence.

Distributed control also allows partial failure. A person may know what would repair a situation but lack energy, safety, money, access, motor capacity, or social permission. The control system is then blocked by environment as much as by internal state. A body-only model would misplace responsibility.

The practical question is what the network evidence adds. Use neural evidence when it changes predictions, resolves competing mechanisms, or improves recovery of latent states. State the additional information it contributes beyond the behavioral observations.

A distributed account also changes replication. The target may be a network relation, temporal order, behavioral transition, or channel-specific mediation that survives different scanners, tasks, sites, and populations. Repeated localization to the same region is insufficient when the causal sequence or transport fails.

20.3.2 — Inhibitory and Stopping Processes

Stopping is not the same as healing. A person may stop an action because it is unsafe, costly, confusing, socially forbidden, physically impossible, or no longer worth pursuing. Inhibitory processes can protect the person, preserve future options, or deepen avoidance. The same outward pause can therefore have opposite meanings (Aron, 2007; Menon & Uddin, 2010).

The chapter treats stopping as a candidate control object. Stop-signal tasks, go/no-go tasks, delay, inhibition, and avoidance measures can be useful when their target is clear. They become misleading when the task result is treated as a personality score or as direct access to burden.

For Queue-related dynamics, stopping may indicate blocking. An unresolved demand remains active, but a policy suppresses action because the available route is unsafe or too expensive. For a rival account, stopping may reflect ordinary harm avoidance, fatigue, learned helplessness, depression, threat appraisal, or motor limitation. Each explanation has different data needs.

A restrained example is a participant who repeatedly delays a phone call about debt. The delay may be avoidance, strategic timing, lack of information, shame, trauma cueing, or rational refusal to engage with a predatory system. The model should not call delay evidence of hidden burden without asking what actions were truly available.

Stopping processes can be tested through within-person change. Does reduced threat open action? Does pain relief open action? Does a safe script open action? Does improved access open action while physiology changes in the predicted order? If not, the stopping interpretation may be wrong.

The necessary safeguard is that stopping should never be pathologized by default. A person's refusal, pause, silence, or delay may be dignity, safety, fatigue, protection, or consent boundary. Science must distinguish blocked repair from chosen nonparticipation.

Stopping measures should include opportunity. A person cannot initiate repair if the phone line is closed, the appeal window has passed, the pain is untreated, transportation is absent, or the safer choice is refusal. Without opportunity fields, inhibition can be

confused with blocked access, and the model will place a social failure inside the person.

20.3.3 — Conflict Monitoring and Switching

Conflict monitoring becomes mechanistically useful when it predicts switching among live actions under a declared state. The timing of detection, inhibition, and switch initiation can separate distributed control models from a post hoc story about one region.

Conflict monitoring detects competition among goals, demands, predictions, and actions. A person may want relief and fear the cost of asking. They may want honesty and fear retaliation. They may want repair and lack the body or time to attempt it. Conflict becomes embodied when choice itself produces pressure (Aron, 2007; Menon & Uddin, 2010; Seeley et al., 2007).

This is relevant to the Law because hidden burden often lives in conflicting live options. The visible event may be simple: attend the appointment, answer the message, sign the form, visit the family member, keep working. The lived event may contain threat, loyalty, cost, shame, pain, uncertainty, and exhaustion inside the same action.

A conflict model should not infer moral weakness from hesitation. Hesitation may be an intelligent response to genuine competing constraints. The model should represent live options, expected bodily cost, social consequences, uncertainty, and prior learning. It should also record whether a route to repair actually existed.

Conflict can be measured through choice latency, error correction, self-report, physiological changes, eye movement, task switching, narrative content, and post-choice recovery. But no

single channel carries the whole conflict. A fast decision may be relief or compulsion. A slow decision may be reflection or paralysis.

The rival explanation is strong: ordinary cognitive conflict may explain reactivation and physiological salience without PTVCLinked assumptions. If a conflict model predicts when demands reappear, which cues reopen them, and how repair reduces them, Queue language may narrow to a useful metaphor or retire in that domain.

External constraints can generate genuine physiological conflict without implying an internal regulatory defect. Hospital forms, school meetings, immigration interviews, court dates, and benefits appeals alter action support because their stakes are real. The causal graph should include those institutional pressures rather than forcing their effects into a person-level latent mechanism.

Conflict should be modeled with stakes. A laboratory choice between two symbols is not equivalent to deciding whether to confront an abusive relative, appeal a benefits denial, disclose pain, or request accommodation. Low-stakes tasks can test mechanism components, but they do not transport automatically to life-burden decisions.

20.3.4 — Autonomic and Endocrine Coordination

Autonomic and endocrine systems coordinate preparation, energy, threat response, recovery, sleep, digestion, inflammation, and pain modulation. They are natural places to look for embodied pathways because they connect perception, action,

bodily state, and longer time scales. They are also nonspecific, context-dependent, and heavily affected by medication and illness (Menon & Uddin, 2010; McEwen, 1998).

Heart-rate variability, electrodermal activity, cortisol, catecholamines, temperature, glucose, inflammatory markers, and sleep architecture can all be scientifically relevant. None has a single affective meaning. The same marker may shift with posture, infection, activity, circadian phase, diet, fever, analgesia, beta-blockers, stimulants, sedatives, grief, or fear.

The model should therefore treat autonomic and endocrine data as coordinated systems with explicit relationships among channels. A respiratory change may alter heart-rate variability. A medication may alter both pain and autonomic response. An inflammatory state may alter fatigue, sleep, mood, and reportability. These relationships help identify the mechanism.

A terminal study shows why these relationships matter. Declining variability near the end of life may reflect disease progression, medication, sedation, low movement, autonomic failure, sensor coupling loss, care procedures, or a genuine change in experiential dynamics. Without modeling those alternatives, a convergence plot may primarily reflect changes in clinical state or observation.

Useful analysis specifies windows, lags, treatment covariates, posture and movement adjustments, illness severity, device quality, and expected direction by channel. It then tests whether autonomic and endocrine changes mediate reports or actions, predict later changes, or accompany common causes.

Establishing temporal order strengthens the interpretation of mediation.

Physiological specificity determines which autonomic and endocrine measures answer the mechanism question. Tests should separate the contributions of arousal, effort, medication, disease, and valence, and report the resolution each channel provides.

Coordination can be more informative than level. Heart-rate change without respiratory change, cortisol without sleep change, or inflammation without fatigue implies a different mechanism from a coordinated shift. The analysis therefore tests coupling, decoupling, order, and recovery across systems rather than scoring each channel in isolation.

20.3.5 — Repair Initiation and Recovery

Repair initiation is the transition from detected need or blocked, avoided, frozen, or unresolved demand into a feasible action that changes state, environment, or the generating condition. It may be a phone call, a boundary, a medication adjustment, an apology, a rest period, a request for help, a change in posture, a safe exposure, or the decision not to return to a harmful context. Recovery is the subsequent trajectory and may remain partial; the two phases should not be collapsed into one improvement score (Aron, 2007; Menon & Uddin, 2010; Seeley et al., 2007).

The chapter treats repair initiation as observable but not simple. The first repair action may not be the visible action. It may be the body lowering threat enough to speak, the mind accepting that a route exists, the clinic reducing pain, or the environment

removing a barrier. A model that records only final action misses the earlier transition.

Brain-body mechanisms could help identify repair initiation if they show a predictable temporal pattern: salience shifts, respiratory constraint eases, attention becomes more flexible, avoidance latency falls, and action follows. But the order must be tested. If action changes first and physiology follows, the model should not reverse the arrow because the story sounds better.

A restrained scene is a person who has delayed a needed conversation for months and finally sends one clear message after pain treatment, sleep, and a friend's practical help. The repair is not a heroic moral settling. It is the opening of a route that had previously been too costly. The bodily piece matters because capacity mattered.

Repair initiation also has noncompensable limits. Some harms cannot be undone by later action. Some repairs reduce ongoing burden while leaving grief, disability, distrust, or lost time. The body may settle enough to act without erasing the loss.

Define repair by change in generating condition, not by symbolic closure. A ritual, apology, exposure, medication, or behavior counts as repair only if the mechanism it targets plausibly moves. Otherwise, the model risks rewarding appearances while hidden burden remains.

Repair can be quiet and private: taking medication, leaving a harmful thread unread, asking for a ride, sleeping, eating, or declining a demand. The model should represent these ordinary routes to relief.

20.3.6 — What Neural Findings Contribute

Timed interactions, perturbation responses, and medication-sensitive mediators can help characterize how the insula, prefrontal cortex, amygdala, vagal pathways, and distributed networks participate in a specified mechanism (Menon & Uddin, 2010; McEwen, 1998).

Neural results should identify their target, comparator, timing claim, and evidentiary role. Their contribution can include distinguishing mechanisms, testing temporal order, identifying mediators, or identifying artifacts beyond the information supplied by reports and behavior. A neural measure that adds no predictive or causal information beyond existing channels should not gain authority simply because it is technologically sophisticated.

Multifunctional regions participate in salience, pain, memory, control, attention, and many other tasks. Specificity therefore comes from prospectively specified connectivity, lag, state dependence, perturbation response, and rival models, not activation under a familiar anatomical label. Specificity should be demonstrated on contrasts that hold general arousal or task difficulty comparable, preventing familiar network activation from becoming a catch-all explanation.

A responsible caption names a candidate pathway under review rather than a location of fairness. Success increases mechanism plausibility within the design; failure narrows that mechanism. Neither makes a brain image a verdict on a life. Spatial precision

should be no stronger than the causal and measurement evidence linking that pathway to the declared construct.

Lesions, stimulation, and medication provide stronger leverage but also alter multiple pathways and behaviors. Off-target effects, treatment versions, and clinical context must be modeled before a causal interpretation. Triangulation across distinct perturbations can help identify whether the same bounded pathway recurs despite different off-target profiles.

The strongest admissible brain finding may be a bounded mediator or confound result, such as a network explaining a device-report relation or medication removing an apparent signature. Such results can defeat a simple route story without identifying PTVC or consciousness. This kind of negative mediation result can be scientifically decisive even when it leaves the larger terminal hypothesis untouched.

20.4 — Channel Lags and Confounding

The body is not synchronized for the convenience of a study. Breathing can change within seconds, heart rate across seconds to minutes, cortisol over longer windows, inflammation over hours or days, pain with complex cycles, and sleep across nights. A diary prompt may arrive after the event, while a device may record before the person can name what happened.

This section treats timing as part of meaning. A channel that leads report can suggest prediction, early bodily preparation, or artifact. A channel that follows report can suggest recovery, action consequence, or common cause. A channel that moves independently may be irrelevant to the target, or it may be a mechanism the report failed to capture.

Modeling confounding makes brain-body evidence more informative and trustworthy. Medication, disease severity, movement, posture, sleep, environment, sensor fit, device version, cultural expression, and clinical procedures can all move the signal. Specifying those pathways before results arrive makes their contribution testable.

Equation 20.3: Lag and mediation display. Role: temporal test structure for mechanism order.

$$B_{i,t+\Delta} = \alpha_i + \rho_B B_{i,t} + \gamma_c O_{i,c,t} + \delta Z_{i,t} + \eta_{i,t}$$

$$R_{i,t+2\Delta} = \mu_i + \rho_R R_{i,t+\Delta} + \beta B_{i,t+\Delta} + \zeta O_{i,c,t} + \xi_{i,t}$$

$\gamma_c \neq 0$ and $\beta \neq 0$ under rival and confound checks.

This display proposes one temporal pathway: channel observation precedes a modeled change in belief or representation, which

precedes report or action. That ordering is testable, but lagged prediction alone does not establish mediation. Causal interpretation additionally requires a justified intervention or identification strategy, suitable confound control, and sensitivity to competing and feedback pathways.

The timing ranges summarized in Table 20.4 are illustrative rather than universal. Each protocol must estimate or justify its own sampling windows, carry channel-specific uncertainty, and test whether conclusions survive plausible lag shifts.

Table 20.4. Lag-risk table. Role: protocol design aid for channel-specific timing and failure.

Signal family	Typical lag concern	Failure if ignored
Respiration and movement	seconds to minutes	task effort mistaken for affect
Cardiac/autonomic	seconds to hours	posture, medication, or activity mistaken for burden
Endocrine	minutes to hours	circadian phase mistaken for event response
Immune/inflammatory	hours to days	illness or treatment mistaken for mood pathway
Sleep and fatigue	nights to weeks	recovery or nonwear mistaken for psychological change
Report and memory	minutes to years	reconstruction mistaken for momentary experience

20.4.1 — Different Response Times

Different channels answer at different speeds. If a study measures all channels at one prompt time, it may create false simultaneity.

The signal that looks absent may have already passed, may not have begun, or may belong to a longer recovery arc. Time alignment is therefore not formatting. It is inference (Shiffman et al., 2008; Stone et al., 2007; Särkkä, 2013).

Fast signals provide precise timestamps, while interpretation may develop later as the body settles, the situation becomes clearer, or the person is ready to report. A respiratory shift or heart-rate spike may mark a trigger, preparation, or distraction; the sequence helps distinguish those roles.

Slow signals can be tempting for the opposite reason. Inflammation, fatigue, endocrine rhythm, and sleep patterns seem deep because they are durable. Yet slow does not mean important to the target. They may reflect illness, treatment, environment, caregiving load, or sensor routine more than the lived burden under study.

A good design declares expected lags by mechanism. If interoceptive salience is the mechanism, the channel should move before or with attention capture. If repair initiation is the mechanism, action should follow the salience shift or environmental change. If medication is the mechanism, timing should align with dose, pharmacodynamics, and clinical effect.

Lag discovery may begin exploratorily, but confirmatory claims use protocol-fixed windows or an independently locked validation phase. Multiplicity, clock alignment, and alternative lag structures are carried into uncertainty. Searching until one delay fits can turn noise, shared causes, or observation timing into

retrospective coherence, especially when several channels respond on different clocks.

Match timescale to mechanism. A body signal can inform the Law only at the temporal resolution where it has interpretable relation to the modeled target. The next step is to align the sampling window and mechanism before making a stronger inference.

Response time also determines missingness. A slow inflammatory signal cannot be recovered from a short task, and a fast respiratory shift may be missed by a daily diary. Sampling that is too slow creates false absence; sampling that is too fast can create burden and noise. Cadence should be justified by the mechanism's bandwidth.

20.4.2 — Common Causes and Time-Varying Confounding

Common causes can change over time. Disease severity, medication, movement, sleep, caregiver presence, and device quality may affect both a channel and later report differently across the day. Static adjustment can leave time-varying confounding unresolved.

A common cause moves both the signal and the apparent outcome. Disease severity can increase fatigue and change inflammation. Movement can increase heart rate and alter report. Sleep loss can increase pain and reduce emotional regulation. Medication can reduce distress and change physiology. Environment can change body and mood together (VanderWeele, 2015; Shiffman et al., 2008).

Common causes are especially dangerous because they produce convincing associations. If pain relief and heart-rate variability

improve after a clinical procedure, the improvement may be treatment effect, expectation, movement change, sleep, hydration, reduced fear, or measurement artifact. The pattern can look like mechanism even when the true cause sits outside the proposed path.

Every analysis plan carries a prespecified minimal confound set suited to the mechanism. Movement, posture, sleep, medication, disease severity, device version, time of day, context, and report timing are recorded unless the design gives a principled reason for omission. Omission is sometimes necessary; silence is not.

A causal graph helps because it forces arrows onto the page. If fever moves heart rate and fatigue, the graph says so. If medication moves pain and reportability, the graph says so. If social threat moves breathing, avoidance, and report, the graph says so. Once arrows are visible, hidden assumptions become criticizable.

Sensitivity analysis should ask how strong an unmeasured common cause would have to be to erase the proposed mechanism. If a modest confound would overturn the result, the claim should be presented as fragile. Fragility is not failure; it is honest status.

A missing confound often becomes a label attached to the participant. Clinical and disability studies should therefore model medication, access, motor capacity, communication method, fatigue, pain, and device fit before describing a body as inconsistent or noncompliant. The burden of unexplained variation belongs first to the measurement and causal model.

Common-cause modeling should include the research situation itself. Being observed, prompted, wired, filmed, or asked to explain the body can change physiology and report. A study room is not a neutral window into life. It is an event that may become part of the data-generating process.

20.4.3 — Reverse Causation and Feedback

Feedback makes reverse causation expected rather than exceptional. Report can change attention, attention can change physiology, and action can change both. Lagged association should therefore be interpreted through a causal model that permits reciprocal paths.

Reverse causation occurs when the apparent outcome changes the bodily signal rather than the bodily signal changing the outcome. A person reports fear, then breathes differently. A participant chooses to repair a conflict, then autonomic recovery follows. A clinician offers reassurance, then pain expression changes. The arrow can reverse without announcing itself (Shiffman et al., 2008; Stone et al., 2007; VanderWeele, 2015).

Temporal precedence is informative only after top-down, contextual, and feedback pathways are represented. Meaning changes the body, action changes the body, and social safety changes the body. A genuinely embodied model allows influence to travel in both directions and specifies which perturbation could distinguish them.

Care can change both experience and physiology. When pain relief improves affect, modeling the intervention and its timing helps explain the observed trajectory.

Testing reverse causation requires repeated measurement and temporal ordering. Does the signal change before the report, after the report, or both? Does action precede recovery? Does environmental change precede bodily change? Cross-lag designs and within-person analyses can help, but only when cadence matches the mechanism.

A no-reverse-causation assumption should be visible. If the study cannot distinguish order, the claim should say correlation, association, or co-movement. It should not say mediation, control, or mechanism. The words are part of the evidence standard.

Bidirectional feedback is the default rival to a one-way story. Bodily state can alter attention and report, while appraisal, action, and expectation can alter bodily state. The analysis should test the direction it intends to interpret and retain a reciprocal or unresolved model when cadence cannot separate the arrows.

Reverse causation is particularly important for repair. A person may decide to act, and that decision may lower threat before the action is visible. If the model measures only physiology first and action later, it may falsely conclude that body recovery caused repair. The hidden decision point must be measured where possible.

20.4.4 — Measurement Attenuation and Device Error

Device error includes drift, dropout, placement changes, firmware updates, motion artifact, and differential performance across bodies. Attenuation can hide a real relation, while correlated error can create one. Quality metrics belong in the model, not only in preprocessing logs.

Measurement attenuation occurs when the observed signal weakens because the instrument, body-device coupling, behavior, or communication channel degrades rather than because the target changes. Low movement, low speech, poor contact, edema, altered perfusion, sedation, and device removal can all create apparent quiet. Device-quality and observation-process variables must therefore accompany the target estimate (Bent et al., 2020; Shiffman et al., 2008).

Attenuation can mimic convergence. If physiological variance shrinks because the sensor sees less, a terminal compression plot may look impressive while measuring observation loss. If reports become neutral because communication becomes difficult, neutrality may be a response artifact. If family proxies simplify because distress is hard to witness, the record may become emotionally smoother than the life.

Device-quality and channel-availability fields belong in the analysis. Signal-to-noise, contact quality, wear time, battery, firmware, artifact flags, movement, perfusion, temperature, and missingness determine when a trajectory can support inference. A visually smooth trace without quality metadata remains incomplete evidence.

Negative controls are essential. If unrelated channels attenuate at the same time, device or physiological shutdown may explain the pattern. If movement-sensitive signals change while movement changes, the interpretation must account for it. If a device version alters variance, model claims should be rerun by version.

Attenuation also appears in human observation. A clinician may record less detail during crisis. A family member may stop reporting because the burden is too great. A participant may withdraw consent. These are not holes to patch with imputation by default. They are events in the observation process.

Lower signal may indicate reduced access to evidence rather than a quieter phenomenal state. The observation model should therefore treat channel silence, smoothing, and dropout as competing explanations, especially when illness, motor limits, fatigue, or communication loss make the person hardest to hear.

Attenuation should be plotted beside the target estimate. A graph of apparent variance compression without a graph of wear time, signal quality, movement, medication, and channel availability is incomplete. The viewer should be able to see whether the instrument became quieter before concluding that the person's experience did.

20.4.5 — Multimodal Conflict and Missing Channels

Multimodal conflict may be informative, but missing channels can manufacture apparent agreement. A protocol should report which channel was absent, why, and whether absence depended on state or burden. More modalities do not help when they fail together.

Multimodal conflict occurs when channels disagree: report may indicate calm while heart rate rises; a device may register longer sleep while exhaustion deepens; facial expression may remain flat during severe pain. The first response is not forced consensus but

a channel-specific audit of timing, quality, construct, context, and missingness (Shiffman et al., 2008; Bollen, 1989; Särkkä, 2013).

Conflict is information about the observation model. It may reveal masking, medication, dissociation, cultural expression, disability, device artifact, task demand, social desirability, timing mismatch, or genuine multidimensional experience. Disagreement is therefore treated as a diagnostic event rather than a problem to average away.

A conflict class can be coded with fields: which channels disagree, in what direction, under what context, with what quality flags, and what follow-up is permitted. The model can then learn when reports should dominate, when devices should be demoted, when both should be held as partial, and when no estimate is responsible.

Consider a person with chronic pain who smiles during a clinical visit while reporting severe pain. The smile may reflect politeness, coping, fear of disbelief, cultural habit, or an attempt to protect the clinician. A model that resolves the conflict by downgrading pain because the face looks calm repeats a known measurement injustice.

Multimodal conflict is also a chance for rivals to win. If a device-report conflict is explained by medication or disability, the candidate mechanism loses ground. If conflict reliably predicts later repair or residual burden after confounds, the candidate gains a testable feature. The distinction depends on design, not rhetoric.

Record conflict before resolving it. A science that admits disagreement can protect the person from being overwritten by whichever channel is loudest, newest, or easiest to quantify.

Conflict review should be versioned. If a later expert panel decides that a device channel was invalid in a subgroup, earlier conclusions should be marked under the old interpretation rather than silently rewritten. A conflict history keeps the science honest about how it learned.

20.4.6 — Causal Graphs, Lag Models, and Sensitivity Analysis

Causal graphs identify plausible pathways, lag models specify temporal order, and sensitivity analyses test dependence on unmeasured causes and timing choices. No single tool closes the problem; the combination makes assumptions visible and falsifiable.

A causal graph is a disciplined picture of possible pathways. It names variables, arrows, confounds, mediators, colliders, selection, and measurement routes. In this chapter, the graph keeps interoception from becoming a cloud of plausible associations. It says what would have to be true for a body signal to support a mechanism claim (VanderWeele, 2015; Shiffman et al., 2008).

The graph should include environment, bodily state, central representation, report, action, medication, disease severity, disability context, device quality, culture, movement, sleep, and time. It should also include the proposed Law-relevant construct only as a latent target or candidate mediator, not as an observed

node. The hidden target does not become measured because an arrow reaches toward it.

Sensitivity analysis then asks what happens when the graph is wrong. What if medication is undermeasured? What if trauma history alters report? What if device fit differs by body shape or skin tone? What if pain relief changes both physiology and report? What if missingness is informative? The model should not collapse when the first real-world complication appears.

Causal graphs also help prevent collider bias. If a study includes only people who tolerate a device, only people who can report repeatedly, or only people who survive long enough to be sampled, the sample itself may create associations. A body mechanism inferred from a selected sample may not travel.

Causal language should track the evidence actually available. Association and prediction remain useful outputs; a mechanism claim additionally requires defensible temporal order, intervention or natural-experiment leverage, negative controls, sensitivity to unmeasured causes, and transport beyond the fitted setting. The result should narrow automatically when one of those supports is absent.

The causal graph should be readable by nontechnical reviewers. Participants, clinicians, ethics boards, and disability advisors should be able to see which pathways the study assumes. If only statisticians can understand the graph, the people most affected by misinterpretation may be excluded from correcting it.

Lag choice should be treated as a model parameter with biological and measurement constraints. State-space or distributed-lag

models can represent fast autonomic responses, slower endocrine change, report delay, and device filtering, but the candidate lag family should be declared before the result is inspected (Särkkä, 2013).

Cross-lag coefficients do not by themselves identify direction. Stable unmeasured causes, feedback, cadence mismatch, and measurement error can reverse or create apparent lead-lag relations. Intervention, natural-experiment timing, negative controls, and sensitivity analyses remain necessary for causal language (Bollen, 1989; Hernán & Robins, 2020).

The final graph packet should include the main causal diagram, plausible alternatives, measurement nodes, selection nodes, lag assumptions, and the no-inference zones created by unresolved paths. Reviewers should be able to see exactly which arrow carries the mechanism claim and which evidence could remove it.

20.5 — Medication, Disability, Trauma, and Illness

A body interpreted without its history is an easy place to make error look objective. Medication can alter signal and report. Disability can change baseline and expression. Trauma can change interoceptive precision and safety learning. Chronic illness can sustain fatigue, pain, inflammation, and uncertainty. Aging and terminal illness can alter physiology, communication, and device quality at the same time.

Treatment, disability, trauma, illness, aging, and terminal conditions define important dimensions of the reference class. The model specifies which groups it represents and what additional observations would extend its reach.

The section's local safeguard is structural: do not turn model mismatch into person mismatch. When a signal fails to follow expected norms, the protocol first asks whether the norm, channel, treatment model, device, context, or target is wrong. It does not imply that the person is inaccurate, unreadable, less conscious, less credible, or less suited for care.

Table 20.5. Misread-body case series. Role: validation stress cases, not reported case histories.

Case-like scenario	Likely model hazard	Required design response
Beta-blocker use during stress task	muted cardiac response read as calm	medication window and alternate channels
Autonomic neuropathy with pain	low autonomic variability read as low burden	disability baseline and report priority

Case-like scenario	Likely model hazard	Required design response
Trauma history in safe task	high salience read as current threat	cue history, precision model, safety check
Chronic fatigue flare	low movement read as withdrawal	illness state, energy budget, activity opportunity
Palliative sedation	reduced report read as neutrality	clinical context, endpoint firewall, no estimate if needed
Darker skin tone with optical sensor	device quality read as physiological difference	validation by device, skin tone, fit, and artifact

20.5.1 — Medication Effects and Treatment Versions

Medication effects have treatment versions defined by drug, dose, timing, indication, co-medication, metabolism, and adherence. A physiological change after medication may reflect symptom relief, side effect, altered reportability, or direct sensor influence. Those pathways should be separated before mechanism inference.

Medication can move the signal, the experience, the report, and the ability to report. Analgesics may reduce pain and alter alertness. Sedatives may reduce arousal and communication. Stimulants may raise cardiac signals and attention. Autonomic medications may mute or reshape heart-rate dynamics. Psychiatric medications may alter affective range, sleep, appetite, and interoceptive awareness (Giacino et al., 2018; Khalsa et al., 2018; McEwen, 1998).

A medication effect is not a nuisance if it changes lived experience. Pain relief matters. Breath relief matters. Sleep

restoration matters. Panic reduction matters. The problem arises when the model cannot distinguish the effect on experience from the effect on observation. A sedated person may suffer less, report less, move less, or all three. The design must not choose the convenient interpretation.

Medication timing should be part of the data model. Dose, route, expected onset, peak, duration, side effects, indication, and recent changes should be recorded where ethically and clinically appropriate. Without timing, the model may interpret treatment pharmacodynamics as spontaneous regulation or terminal dynamics.

Clinical expertise is required because the same drug can mean different things across bodies. Opioid rotation, benzodiazepine use, anticholinergic burden, beta-blockade, corticosteroids, stimulants, antiemetics, antidepressants, antipsychotics, anticonvulsants, and sleep medications each alter different observation routes. A generic medication flag is better than nothing but often insufficient.

A safe analytic plan can treat medication as confound, mediator, intervention, effect modifier, or reason to abstain. The status depends on the question. If pain relief is the mechanism being studied, medication may be central. If terminal variance is being studied, medication may be a confound or competing explanation. The model should say which.

The local ethical rule is that treatment never belongs to the theory. Care decisions are made for the person, not for cleaner data. If a

needed medication destroys a signal, the signal is lost. The person is not asked to remain measurable.

Medication modeling also has privacy boundaries. Detailed medication records can reveal diagnoses, stigma-sensitive treatment, addiction history, reproductive status, psychiatric care, or end-of-life decisions. The study should collect enough to interpret signals, but not turn clinical history into a permanent identity file.

20.5.2 — Disability, Access, and Baseline Variation

Access is part of disability-informed calibration. A device, task, prompt, or report format can fail because the protocol was not accessible, not because the participant lacks a valid signal. Baselines and action sets should reflect the person's actual environment and supports.

Disability changes baselines, channels, expression, access, effort, fatigue, movement, communication, and sometimes sensor fit. Treating able-bodied patterns as universal makes the observation model invalid before route inference begins. The issue is not that disabled bodies are difficult to measure; it is that many protocols mistake one body norm for the human norm (World Health Organization, 2001; Khalsa et al., 2018).

Baseline variation can appear in heart-rate dynamics, movement, pain expression, facial movement, voice, sleep, posture, temperature regulation, energy use, and communication timing. A person using a wheelchair, ventilator, feeding tube, communication device, prosthetic, pain treatment, or autonomic

support may generate data that require a different observation model.

Interpretive burden falls on the model. A system trained on narrow movement patterns may call low activity disengagement when movement is constrained by disability, pain, environment, or access. A voice model may misread speech affected by disability as affect. Those failures narrow or retire the model; they do not define the person.

Disability-informed design begins with participation and expertise. It asks what channels are meaningful, burdensome, inaccessible, or misleading. It includes accommodation, alternate routes, longer response windows, assistive technology compatibility, and participant challenge. A disabled participant should not have to become a methodological exception after the model fails.

Calibration should occur within person before cross-person claims. A person's own baseline, range, fatigue cycle, communication style, and support context are more informative than a general norm. Transport from one disability group to another should be earned, not assumed.

The use boundary is to treat disability as a source of scientific knowledge. It reveals where the model was relying on hidden able-bodied assumptions. A science that learns from those revelations becomes more general, not less.

Disability-informed modeling should include device refusal as a valid outcome. A sensor that causes pain, sensory overload, skin irritation, dysphoria, or practical difficulty is not a neutral

instrument. Refusal may tell the study that the observation method is poorly designed, not that the participant is less cooperative.

20.5.3 — Trauma, Hyperarousal, and Dissociation

Trauma can produce hyperarousal, hypoarousal, dissociation, avoidance, and context-dependent safety learning. No single autonomic direction defines the state. Interpretation should be trauma-informed and should never require reenactment or disclosure beyond consent.

Trauma can alter bodily prediction, attention, threat appraisal, salience, startle, sleep, pain, dissociation, and safety learning. Hyperarousal may be visible in some contexts, but trauma can also appear as numbness, shutdown, avoidance, memory gaps, constrained expression, or practiced calm. There is no single trauma signature that authorizes simple interpretation (Khalsa et al., 2018; McEwen, 1998).

A trauma-informed model separates current threat from learned threat prediction. A safe room can still produce bodily danger signals if the room resembles an earlier danger, if authority is present, if consent feels fragile, or if the person expects disbelief. The body may be responding to a history the protocol did not record.

Trauma can produce persistent reactivation, blocking, and difficulty initiating repair. Those patterns may be compatible with queue language, but learning, threat prediction, memory, and unsafe social conditions may explain them fully. A PTVC-linked

route gains no evidential weight until it distinguishes itself from those ordinary accounts under humane tests.

Ethical design avoids surprise, coercive exposure, humiliating tasks, intense bodily focus, or manipulations that amplify symptoms. If interoceptive attention is used, it should be brief, optional, clinically reviewed where necessary, and paired with stop rules. A participant's withdrawal is not missing data to regret; it is information about burden and consent.

Measurement should include safety context, trigger likelihood, dissociation risk, grounding options, report preferences, and aftercare routes. The model should also include cultural and social conditions that make vigilance rational. Trauma physiology is not only inside the person; it is often maintained by environments that remain unsafe.

For this question, the required discipline is never to moralize altered interoception. Hyperarousal, numbness, avoidance, dissociation, or silence are not failures of fairness, faith, courage, or reason. They are conditions under which science must become gentler and more exact.

Trauma physiology may also be quiet in the moment and costly later. A participant can complete a task calmly and then lose sleep, dissociate, or experience delayed symptoms. Follow-up windows and stop rules should therefore include aftereffects, not merely in-session distress.

20.5.4 — Chronic Illness, Inflammation, and Fatigue

Chronic illness may involve inflammation, fatigue, pain, sleep disruption, and fluctuating capacity. These processes can share

channels with affective mechanisms while following different time scales. Clinical context and treatment changes should be modeled as causes, not nuisance labels.

Chronic illness and fatigue stretch mechanism across time. They may alter sleep, movement, pain, cognition, immune state, autonomic function, digestion, mood, social participation, and opportunity. A momentary valence estimate can miss the slow cost of needing to plan every action around energy, symptoms, treatment, uncertainty, and access (Khalsa et al., 2018; McEwen, 1998).

Fatigue is especially easy to misread. Low activity may be depletion, pain avoidance, depression, medication, symptom management, inaccessible environment, or wise pacing. High activity may be recovery, overexertion, necessity, caregiving pressure, or a day that will be paid for tomorrow. The signal needs a time horizon.

Chronic illness also breaks simple rebound stories. A person may adapt to some aspects of illness while remaining burdened by pain, uncertainty, financial stress, lost roles, stigma, and medical work. Resilience should not be used to acquit the conditions that made resilience necessary.

A serious design records energy budget, symptom flare, treatment schedule, care tasks, sleep quality, activity opportunity, access barriers, and post-exertional change where relevant. It also gives the person control over cadence. A measurement plan that worsens fatigue in order to study fatigue has already failed.

The model may need slower lags and delayed outcomes. A body signal today may predict tomorrow's exhaustion rather than today's report. Repair may mean fewer obligations, better treatment, assistive support, or pacing, not emotional closure. Chronic time changes the candidate mechanism and the observation window.

Illness includes the work required to navigate it. Appointments, paperwork, symptom tracking, transportation, side effects, care coordination, and repeated disbelief can move physiology, attention, and report. A model that omits those processes confounds disease with the burden of managing disease.

20.5.5 — Pain, Communication, and Motor Limits

Pain expression and communication can be limited by motor function, language, sedation, fear of disbelief, or learned masking. Absence of report or movement is not absence of pain. Multimodal evidence should widen uncertainty rather than override testimony.

Pain is central and difficult because it is bodily, affective, attentional, cognitive, social, and communicative. It can be intense without visible expression, visible without identical meaning, treated without disappearing, and remembered differently from how it was lived. A pain signal does not become simple because the person has a number scale (Khalsa et al., 2018; Critchley & Garfinkel, 2017).

Communication varies under pain. Some people become quiet, some irritable, some polite, some expressive, some dissociated, some unable to speak. Disability, culture, gender, race, trauma,

clinician trust, past disbelief, and fear of consequences can shape what is said. A model that treats report as pure truth or pure noise will fail in different ways.

Behavioral pain cues are partial. Movement limitation can show pain, fatigue, motor impairment, access constraint, sedation, or protective pacing. Facial expression can be masked, culturally controlled, absent due to disability, or altered by medication. Voice can change because of breath, fatigue, language, neurological condition, or social context.

The chapter's design route is multimodal but person-centered. Pain report, function, medication, context, clinician observation, device signals, and participant history can be integrated under uncertainty. If channels conflict, the model should not automatically downgrade the report. It should ask why conflict occurs.

Pain relief is also a mechanism test. If analgesia changes report, behavior, sleep, autonomic signal, and repair action in a plausible temporal order, the model learns something. If physiological channels remain unchanged despite reported relief, test whether the channels, sampling windows, and detection limits could have captured the predicted change before narrowing their mechanistic role. Both outcomes are useful.

Pain may enter the study as an already present clinical state, a participant-reported outcome, or a response to independently justified care. It may not be induced, prolonged, intensified, or left untreated to sharpen a mechanism contrast. Designs that

cannot separate the scientific question from added harm are narrowed or abandoned.

Pain communication should be evaluated under trust. A participant who expects disbelief may underreport, overexplain, or use numbers strategically. The solution is not suspicion. It is a design that acknowledges the social conditions of reporting and gives multiple routes for expression without punishing inconsistency.

20.5.6 — Clinical Context Before Interpretation

Clinical context precedes interpretation because physiology is clinically entangled. Oxygenation, infection, delirium, sedation, pain, dehydration, fever, organ failure, device tolerance, nursing care, family presence, procedures, and medication changes can all alter body signals and report. A research model outside that context may be precise and wrong (Giacino et al., 2018; Khalsa et al., 2018).

Clinical expertise is required far beyond terminal settings. Chemotherapy, dialysis, surgical recovery, intensive care, psychiatric crisis, rehabilitation, pregnancy, menopause, withdrawal, and chronic pain treatment can alter both physiology and observation. A mechanism claim must be calibrated to the clinical world in which its data were generated.

Clinical context also protects the person from automated override. A wearable alert should not contradict pain care, sedation, palliative judgment, or emergency response because a research algorithm sees an interesting pattern. The care system remains primary. Research interpretation waits.

The data dictionary should include clinical status fields that are meaningful, not merely administrative. Diagnosis group, acuity, treatment changes, sedation scale where appropriate, delirium risk, pain regimen, mobility, communication ability, device interference, and consent status may all be relevant. The model should not ask for every field by default; it should justify the fields it needs.

Clinical expertise should enter before analysis and during adjudication. That does not mean clinicians own the person's inner life. It means they understand the conditions that can move observed signals. The best interpretation may come from combining participant report, clinician context, device quality, and research model uncertainty.

Clinical review includes the option to stop research activity. Illness, fatigue, medication, distress, proximity to a care decision, or changing consent can make further collection disproportionate. Stopping preserves care and also protects the scientific record from data whose conditions no longer match the declared design.

Medication should be represented by active ingredient, dose, timing, route, indication, adherence, and clinically relevant co-medication where proportionate. A device or report change after treatment may reflect therapeutic effect, side effect, withdrawal, interaction, or changed behavior. Pooling those versions can invent a mechanism.

Disability-specific calibration should be planned rather than added after an anomaly appears. Movement, speech, facial expression, heart-rate dynamics, and device placement can differ

for reasons unrelated to valence. Alternative communication and measurement routes should be treated as legitimate study designs, not deviations from a presumed normal body.

Trauma and chronic illness can change baseline, reactivity, recovery time, and tolerance for perturbation. The design should distinguish a mechanism prediction from a learned threat response, fatigue, pain flare, inflammatory change, or care burden. When these explanations cannot be separated, the result remains clinically contextual rather than route specific.

The no-estimate decision should be available at the person-window level. A period can be excluded from one mechanism analysis because of delirium, acute treatment change, device failure, or severe burden while remaining valuable for descriptive clinical understanding. Abstention from the mechanism claim does not erase the person or the data.

20.6 — Intervention and Perturbation Designs

Ethically appropriate changes in state, context, attention, posture, breathing, pain relief, sleep, medication, or environment can test a pathway's predicted channels and temporal order. Such comparisons connect brain-body descriptions with causal questions.

Existing neuroscience provides a concrete example of mechanism-guided recovery. Xia et al. (2025) recorded population activity in stress-susceptible and resilient mice and identified different dynamics linking ventral hippocampus and basolateral amygdala. Manipulating the hippocampal inputs to the amygdala shifted dysfunctional dynamics toward the resilient pattern and reversed anhedonic behavior. The experiment connects an affect-related behavioral difficulty to a specified circuit and shows that intervention can change it. This gives recovery research an experimentally grounded pathway to investigate.

This chapter studies interventions that are independently justified for care, ordinary, low-risk, and participant-controlled, within their approved context of use. Research for the Law must not induce distress, pain, panic, deprivation, or physiological danger. Designs can learn from existing care and safe variation while preserving timely treatment and withdrawal.

Perturbation designs matter because they expose direction. A change in breathing that alters salience before report supports one route. A medication change that alters report before physiology supports another. A posture change that alters device readings but

not report exposes artifact. A negative control that moves the same channel breaks the proposed specificity.

A randomized crossover study illustrates why recovery timing matters. Among 82 healthy participants completing both conditions, Ferstl and colleagues (2022) compared auricular vagus-nerve stimulation with sham stimulation during prolonged effort. Positive mood, a secondary outcome, improved relative to sham during the post-stimulation period; the improvement was not detected during stimulation. The reported difference was approximately 9.6% relative to the model's mood intercept. This provides a concrete brain–body comparison with a measurable lag and suggests testing whether recovery models predict when a benefit appears as well as its magnitude.

Table 20.6. Perturbation-study table. Role: design comparison for safe mechanism tests.

Design	What changes	What it can test	Boundary condition
Naturalistic breathing shift	breathing pattern already chosen or safe	respiratory salience and report lag	no panic induction
Posture and movement control	sitting, standing, walking, rest	artifact and autonomic adjustment	accessibility and disability accommodations
Routine medication transition	clinically indicated treatment	medication as mediator or confound	care decision independent of study
Sleep opportunity change	ordinary sleep schedule or clinical sleep support	recovery and fatigue pathways	no deprivation for theory

Design	What changes	What it can test	Boundary condition
Pain relief window	independently justified analgesia	pain-report-physiology order	relief never delayed
Neutral attention task	harmless focus or distraction	precision and salience weighting	stop rules and symptom monitoring

20.6.1 — Naturalistic State Changes

Naturalistic state changes are the safest first mechanism tests. People already breathe differently, stand, sit, walk, rest, sleep, eat, take medication, receive care, speak, avoid, repair, and recover. A study can learn from those changes when consented and recorded without treating the person as a laboratory object (Klasnja et al., 2015; Nahum-Shani et al., 2018; Khalsa et al., 2018).

Naturalistic design is especially appropriate for palliative, chronic illness, disability, trauma, and everyday-life contexts. The question becomes: when a state changes for reasons independent of the theory, what happens to the proposed channel, report, action, and later burden? The event is not created for science. Science follows with restraint.

Examples include routine pain relief, a scheduled physical therapy session, a safe breathing exercise already part of care, a posture change, a change in sleep opportunity, a supportive conversation, or a reduction in administrative demand. These events can reveal whether physiology, report, and action move in a plausible order.

Naturalistic variation must still be modeled. The fact that an event was not assigned does not remove confounding. People who receive a certain intervention may differ in severity, access, support, trust, timing, or clinical status. The study should declare the estimand and whether the design is descriptive, predictive, or causal.

A careful analysis might use within-person comparisons around repeated routine events, with time-varying covariates and negative-control windows. It should avoid heroic claims when events are sparse or confounded. A naturalistic result can motivate a mechanism; it rarely establishes one alone.

Observe ordinary care without bending ordinary care. If the person needs rest, rest comes first. If the clinician changes medication, the clinical reason controls. The model receives what care leaves available, not the other way around.

Naturalistic designs should record why the change happened. A breathing exercise chosen for comfort, a medication changed for pain, or a posture shift made for access has a different meaning from the same behavior assigned by protocol. The reason is part of the causal story, not an anecdote.

20.6.2 — Safe Interoceptive Perturbation

Safe interoceptive perturbation means a low-risk, consented, reversible change in bodily attention or state that has independent ethical justification. It may include gentle breathing awareness, posture adjustment, brief attention redirection, paced movement, or other innocuous tasks approved for the population. It does not

include provocation that creates clinically meaningful distress (Seth & Friston, 2016; Critchley & Garfinkel, 2017).

The design should state the mechanism it tests. A breathing task may test respiratory salience, not global valence. A posture task may test autonomic adjustment or sensor artifact, not unresolved burden. An attention task may test precision weighting, not hidden truth. The narrower the target, the stronger the inference.

Perturbations should have stop rules visible to participants. A person can stop because of discomfort, boredom, fatigue, pain, trauma cueing, disability access, or simple refusal. The stop is not noncompliance. It is a consent and burden signal that belongs in the protocol record.

The task should also include debriefing and return to baseline where appropriate. If a breathing or attention exercise increases symptom focus, the protocol should not treat that increase as useful data and move on. It should provide grounding, support, and review. A mechanism test that leaves burden behind has violated the chapter's purpose.

Safe perturbations reveal whether the predicted channel responds, whether the response is specific, and whether device artifacts account for the change. Each outcome helps refine the mechanism or measurement.

Proportionality is a scientific and ethical design criterion. The question must justify the participant burden, and the burden must remain small, reversible, consented, accessible, and monitored. A mechanism that can be separated only by turning a person's body into a stress instrument is not available for this research program.

Safe perturbation should be piloted with the population being studied, not only with healthy convenience samples. A task that seems mild to a researcher can be difficult for someone with panic, asthma, pain, trauma, dysautonomia, fatigue, or sensory sensitivity. Feasibility evidence should come from the relevant bodies.

20.6.3 — Within-Person Crossover and N-of-1 Logic

Within-person crossover and N-of-1 logic reduce between-person heterogeneity by comparing safely varied conditions within the same participant. Carryover, period effects, treatment versions, and natural drift still require modeling. The design remains a mechanism test, not a personal fairness score.

Within-person crossover designs compare a person to themselves under different safe states or conditions. This is valuable because interoception and physiology vary greatly across persons. A between-person difference may reflect baseline, disability, medication, fitness, trauma history, culture, or device fit rather than the mechanism being studied (Klasnja et al., 2015; Nahum-Shani et al., 2018; Khalsa et al., 2018).

A randomized crossover can compare assigned, safe conditions in an explicit sequence within each participant. Comparisons after naturally disrupted sleep or before and after clinically indicated pain relief are instead observational within-person contrasts unless condition assignment is part of the design. Both can be useful, but the latter retain event-timing and treatment-selection confounding. Neither design permits induced sleep disruption or delayed relief for Law-specific evidence.

Crossover is not magic. Order effects, carryover, learning, fatigue, expectation, symptom fluctuation, and changing context remain. A person who repeats a task may become less anxious because it is familiar, or more burdened because it is annoying. The design should include washout where appropriate and test order effects.

The candidate mechanism is predeclared. Does the pathway predict reduced avoidance, faster repair action, altered salience, changed report, or different channel lag? If the design only asks whether something changes, it will almost certainly find something. Mechanism requires a pattern, not mere movement.

Within-person designs also support dignity. They avoid treating one person's body as a deviation from another's. The person's own baseline becomes the first comparison. Cross-person generalization comes later and only with transport evidence.

A within-person crossover estimates a local response under specified treatment versions, washout assumptions, and observation windows. Explicit estimands, carryover sensitivity analyses, and no-estimate conditions make the design interpretable.

Crossover designs should also account for meaning change. The second exposure is never identical to the first because the person remembers the first. That memory can be learning, fatigue, dread, boredom, mastery, or distrust. The model should treat repetition as part of the intervention, not merely as a design feature.

20.6.4 — Mechanism-Specific Predictions

A mechanism-specific prediction names the pathway, channel, timing, direction, and failure condition before observing the result. It says, for example, that a safe breathing intervention should reduce respiratory salience before self-reported urgency, while an activity-matched control should not. Or it says that pain relief should alter pain report and sleep before general mood if pain is the mediator (Seth & Friston, 2016; Critchley & Garfinkel, 2017).

Mechanism-specific prediction protects the chapter from biological storytelling. Many channels can be explained after they change. The point is to say what should change first, what should not change, what rival would predict, and what result would make the proposed mechanism less credible.

The prediction should also specify the unit of analysis. Is the expected effect within person, between persons, within site, across devices, across diagnoses, or across states? A result that holds between people may not hold within a person. A result that holds in a healthy lab sample may not travel to palliative care or disability contexts.

A useful prediction includes abstention conditions. If medication changes during the window, if device quality fails, if the participant withdraws, if the channel conflict exceeds a threshold, or if the task becomes burdensome, the mechanism test may become uninterpretable. Declared abstention is not weakness. It is protection against false precision.

Mechanism-specific predictions can be organized in a small matrix: interoceptive inference, allostatic regulation, somatic-marker learning, pain-relief mediation, device artifact, and context change. Each should have unique expectations. If no unique expectation exists, the model is not yet ready for confirmatory testing.

Mechanism-specific predictions make each outcome informative. The protocol states in advance which observations would support the mechanism, which would favor an alternative, and which would call for a better measurement or design.

A prediction table should place the proposed mediator, interoceptive learning, allostatic regulation, and artifact explanations side by side, showing the temporal order expected under each. This makes the comparison interpretable.

Positive affect can also be an explicit target of recovery. In an assessor-blinded randomized trial, Meuret et al. (2026) assigned 98 adults with very low positive affect and impairing depression or anxiety to 15 weekly sessions of Positive Affect Treatment or a comparison therapy focused on negative affect. The positive-affect treatment produced greater improvement in the jointly analyzed measures of positive affect, anhedonia, and depression and anxiety symptoms, with an effect size of $d = 0.27$ for improvement and $d = 0.21$ at one-month follow-up. Both treatments improved self-reported reward anticipation and attainment, with comparable changes in those targets. For this program, the trial supplies a practical model of constructive inquiry: specify a capacity for improvement, compare active approaches, and track experience alongside candidate processes.

The ability to develop rewarding experience becomes a concrete research question with measurable outcomes.

20.6.5 — Negative Controls and Sham Perturbations

Negative controls and sham perturbations match attention, expectancy, movement, and contact without moving the proposed mechanism. They help distinguish a channel-specific response from generic participation effects. The sham must remain credible, safe, and nondeceptive under the protocol's consent rules.

Negative controls are designs in which a matched condition should not move the proposed pathway if the pathway is specific. They are not minor details. In a field filled with correlated bodily signals, negative controls are the difference between mechanism and coincidence (Klasnja et al., 2015; Nahum-Shani et al., 2018; Khalsa et al., 2018).

A respiratory-salience claim might use a movement-matched task that raises heart rate but not breath-related awareness. A wearable-artifact check might use posture change without expected affect change. A pain-relief pathway might compare a nonanalgesic routine procedure that changes attention but not pain. Each control should be chosen for the mechanism, not for convenience.

Negative controls detect device and social artifacts. If a model predicts burden from wrist movement, similar movement in another context tests whether the feature is mere activity. If a voice model predicts distress, fatigued but nondistressed reading can expose prosody confounding.

A good negative control need not be perfect. It must be informative about a plausible false explanation, and that false explanation is named before analysis. Otherwise, control language becomes ceremonial.

When negative controls fail, the result should be taken seriously. If the same signal changes under control and target conditions, the proposed mechanism may be too broad, the channel too nonspecific, or the task too confounded. The response is narrowing, redesign, or retirement, not a stronger paragraph.

Negative controls expose interpretations otherwise assigned to the person. Movement, medication, disability, fatigue, device handling, and cultural expression need controls reproducing the signal without the candidate mechanism. A model failing them is scientifically inadequate before becoming publicly dangerous.

Negative controls should include public-risk controls when possible. A display that makes a model look like mind reading should be tested with nonexpert readers before release. If readers overinfer authority from the visualization, the artifact fails even if the underlying analysis is technically correct.

20.6.6 — No Harmful Provocation

Some experiments would be informative and forbidden. Pain induction, panic provocation, sleep deprivation, social humiliation, deprivation, dangerous breath challenge, medication withholding, or terminal observation pressure could create clean-looking mechanism contrasts. They are outside the chapter's route because they make people carry burden for theory (Seth & Friston, 2016; Critchley & Garfinkel, 2017).

Indirect tests and narrower questions provide useful alternatives when a direct experiment would create harm. Recording which question each design can answer keeps *the research* program both informative and humane.

Safe alternatives exist: observe clinically indicated relief, use mild and reversible attention tasks, rely on naturalistic variation, study routine movement and posture, use archival data under consent, compare device artifacts, and build simulations that do not recruit vulnerable bodies. These alternatives provide practical routes to reproducible and ethically sound evidence.

A protocol should include a provocation audit. Does any task create more distress than everyday minimal risk for the population? Does it amplify symptoms? Does it pressure people to continue? Does it delay treatment? Does it treat withdrawal as failure? If any answer is yes, redesign or stop.

The analysis proceeds by care before contrast. Mechanism science is strongest when it learns from life without making life worse. The person is never the instrument of the theory. When the safest contrast is less statistically efficient, that cost belongs to the design rather than to the participant.

No-harm design forbids implicit pressure to endure. Payment, researcher enthusiasm, scientific or spiritual motives, and fear of disappointing clinicians may press continuation. Consent scripts and staff must make stopping ordinary, not exceptional. Continuation checks should be phrased neutrally and separated from scientific enthusiasm so a participant does not have to resist the project to exercise withdrawal.

Minimal-risk classification must be population specific. A posture change, breath task, or cognitive load mild for healthy adults may be unsafe or exhausting with cardiopulmonary disease, chronic pain, trauma, pregnancy, or disability. Safety review must follow actual participants, not the task label. The protocol should record population-specific contraindications before enrollment rather than discover them through preventable adverse burden.

Stopping thresholds should be observable, participant controlled, and independent of the desired contrast. Symptoms, distress, fatigue, device intolerance, clinical change, or a simple request to stop are sufficient. The analysis should preserve data collected before stopping without treating withdrawal as noncompliance. Stopping-related missingness should be marked by cause and timing, preserving the ethical reason for data loss in later sensitivity analysis.

20.7 — Wearables, Artificial Intelligence, and Humility

Wearables and artificial intelligence are attractive because they seem to bring the body close to continuous evidence. They can record sleep, movement, pulse, rhythm, temperature, voice, prompts, missingness, and context at a scale earlier science could not. That scale is useful. It is also exactly where false authority can grow.

This section treats technology as research support, not sovereignty. A device can help observe a channel. An algorithm can help detect patterns, artifacts, or model failures. A dashboard can help a research team inspect uncertainty. None of these tools knows the person from within, and none may become a public score, care gate, spiritual status, civic trust mark, or substitute for consent.

The local design principle is purpose-limited humility. Collect only what the mechanism needs, document why it is collected, measure device quality, audit performance across bodies and contexts, allow participant challenge, protect deletion routes, and keep the output inside the protocol. A powerful measurement system becomes safer by narrowing its authority.

Table 20.7 converts purpose-limited humility into an auditable governance register. Each technology is assigned one permitted scientific role and one boundary that requires correction, withdrawal, or human review when crossed.

Table 20.7. Technology role-and-boundary register. Role: governance control for device and model outputs.

Technology object	Permitted scientific role	Boundary
Wearable sensor	partial channel observation with quality flags	no direct inner-life inference
Affective model	exploratory or validated classifier under scope	no universal emotion reading
Artificial Intelligence assistant	code, pattern search, documentation support	no autonomous verdict or unsupervised release
Dashboard	internal uncertainty review	no public ranking or eligibility use
Data archive	purpose-limited research record	no archive-as-person or cross-architecture dossier
Participant portal	return, correction, deletion, challenge	no pressure to explain oneself

20.7.1 — Wearable Quality, Context, and Drift

Context and drift are part of wearable quality. A feature validated at rest may fail during movement, illness, temperature change, or a firmware update. The device version and quality thresholds should travel with every derived measure.

Wearable data begin with quality, not interpretation. Contact, battery, firmware, sensor placement, skin properties, motion, perfusion, temperature, edema, sweat, posture, activity, and device version can all shape the signal. A chapter on interoception cannot treat a consumer stream as clean physiology by default (Bent et al., 2020; Nelson et al., 2020; Tabassi, 2023).

Device validation should be context-specific. A sensor may perform well at rest and poorly during movement. It may measure heart rate adequately but fail for rhythm irregularity. It may work differently across skin tones, body hair, perfusion states, tattoos, edema, disability, and clinical contexts. Evidence from one device generation may not travel to another.

The data dictionary should carry device model, firmware, wear location, sampling rate, quality score, artifact detection, nonwear, charge interruption, participant-reported discomfort, and context. These fields can be burdensome, so the protocol should collect what the mechanism needs. But if quality is unknown, interpretation should narrow.

A practical example is a wrist device in palliative care. The band may loosen as weight changes, the person may remove it because it irritates the skin, staff may move it during care, or perfusion may decline. A smooth terminal signal might be physiology, device drift, or both. Quality fields decide whether the graph can speak.

Wearable data should also be checked against alternate channels where feasible. A chest strap, ECG patch, clinical monitor, self-report, or observation may reveal device error. Cross-channel agreement helps evaluate consistency, while disagreement can locate device error or a change in the observation process.

No device output outranks its context. A signal without quality metadata is uninterpretable; a signal with verified quality remains one observation channel whose meaning depends on construct

validity, timing, medication, activity, and the declared context of use.

Wearable validation should be repeated after software updates. A device is not one instrument forever; firmware, algorithms, sensors, and vendor processing can change the data-generating process. Longitudinal studies should treat version change as a scientific event, not an inconvenience in procurement.

20.7.2 — Digital Biomarkers and Clinical Validation

A digital biomarker is a digitally measured characteristic proposed to indicate a biological, physiological, or behavioral process for a defined context of use. The term names a qualification task, not an evidential shortcut. Relevance requires a declared target construct, population, setting, measurement performance, and decision role, and it remains distinct from valence, route state, diagnosis, and inner truth (FDA-NIH Biomarker Working Group, 2016; Coravos et al., 2020; U.S. Food and Drug Administration, 2023).

Fit-for-purpose evaluation separates verification, analytical validation, and clinical or research-context qualification. Verification asks whether the sensor and software operate as specified. Analytical validation asks whether the pipeline estimates the declared physical or behavioral quantity with adequate error under relevant conditions. Context qualification asks whether that quantity is related closely enough to the declared concept and decision for the intended use (Goldsack et al., 2020; U.S. Food and Drug Administration, 2023).

These layers connect sensor reliability, feature extraction, the target construct, and the proposed mechanism. A mechanism claim specifies the supported causal or predictive connection, the intended setting and decision rule, and how uncertainty is propagated through the pipeline.

Qualification belongs to a versioned pipeline. Hardware, firmware, placement, sampling rate, preprocessing, feature extraction, model weights, reference device, quality thresholds, population, and setting define the supported claim. A result therefore travels with its configuration and context of use rather than with a device brand or feature name in general.

The pipeline also needs an explicit route from raw data to action. The DACIA framework separates collection, aggregation, contextualization, interpretation, and action, revealing where a sensor feature acquires meaning and where burden, feedback, or deployment enters. Each transition can fail independently, so classifier performance at the end of the chain cannot certify the earlier measurement and construct links (Daniore et al., 2024).

Representative performance must include conditions that challenge the signal. Skin pigmentation, perfusion, movement, rhythm irregularity, edema, disability, medication, illness, age, environment, and device fit can affect quality. Aggregate accuracy can conceal systematic error in the very subgroup where the mechanism inference is most consequential (Bent et al., 2020).

The causal graph should state whether the digital measure is an observation, mediator, confound witness, quality flag, treatment

modifier, eligibility variable, or outcome. Reusing one feature as both a selection gate and confirmatory outcome can create circularity and collider bias. The role should be frozen before analysis.

Clinical meaningfulness is not the same as statistical separability. A feature may distinguish groups while adding no useful information for a person or decision. The report should state the effect size, uncertainty, decision consequence, subgroup performance, and failure conditions, not only classification accuracy.

Digital biomarkers remain bounded evidence. They can improve cadence, expose artifact, and support safe, purpose-limited studies. When verification, validation, context of use, privacy, or transport fails, the feature is withdrawn or narrowed rather than interpreted more creatively.

20.7.3 — Affective Computing Limits

Affective computing estimates task-defined labels from observable features under a declared context of use. It does not perceive emotion from within, and it does not transform face, voice, posture, physiology, language, or behavior into direct access to lived valence. The target, label source, population, setting, device, and decision use must be stated before performance is interpreted (Picard, 1997; Calvo & D'Mello, 2010).

The ground-truth problem comes first. Self-report, observer annotation, elicitation condition, clinical classification, and behavioral success are different targets. A model trained on one

may predict another through shared context or label leakage while appearing to read emotion. Validation must therefore specify what the label means, who supplied it, when it was supplied, and which uncertainty remains.

Human expression is many-to-many. The same outward pattern can reflect feeling, politeness, pain masking, disability, fatigue, medication, neurodiversity, training, culture, threat management, or social pressure. Conversely, similar experiences may produce different expressions. Context and alternative channels reduce ambiguity but do not abolish it.

Multimodal fusion does not automatically create independent confirmation. Face, voice, movement, and physiology can share the same task cue, annotator, preprocessing pipeline, or missingness mechanism. A larger model may become more confident by combining correlated errors. Channel independence and incremental value must be tested rather than assumed.

A defensible validation program includes calibration, out-of-distribution testing, subgroup and intersectional performance, device and environment shifts, disability and medication conditions, cultural expression variation, missing-channel stress, and abstention. Aggregate accuracy is insufficient when a consequential subgroup carries systematic error or when confidence is poorly calibrated (Autio et al., 2024).

Published benchmarks now make temporal affect prediction a concrete comparison task. SemEval-2026 Task 2 paired ecological essays with self-reported valence and arousal and separated present-state assessment from forecasting change. Its

design included tests involving both previously observed and unseen participants (Soni et al., 2026). A report-channel model can use such a benchmark to test whether apparent accuracy survives future observations and new people, then compare text-based predictions with appropriate history and context baselines. The self-reported labels make forecast performance directly assessable. Existing consent, access conditions, and privacy protections continue to govern reuse.

Useful applications include artifact detection, quality control, exploratory clustering, prompt routing, and task-specific prediction in a demonstrated context of use. Each additional application receives a validation plan matched to its target and intended decision.

Conflict with a participant's report is an identification event, not a contest the device wins by default. The protocol should inspect label mismatch, context, channel quality, timing, medication, communication limits, and model scope. When the channels do not resolve the target, the result is conflict or No adequate estimate.

Public clips, heat maps, and labels should include the model's context of use, calibration, uncertainty, and scope. Standalone review checks whether the intended use and abstention conditions remain understandable when the artifact is viewed separately.

20.7.4 — Artificial Intelligence as Analysis Support

Artificial intelligence may assist feature extraction, artifact detection, code review, simulation, model recovery, sensitivity analysis, and reproducibility under a protocol-fixed, versioned

pipeline. Each output must have one declared analytic role; reused signals cannot silently serve as eligibility criteria, confound controls, outcomes, and explanations in the same analysis.

Record the data version, preprocessing, model or checkpoint, configuration, feature definition, adaptation history, software environment, and human review state. Generated summaries, code, labels, and features are checked against primary data and frozen specifications, and candidate routes and rivals receive comparable computational search and tuning budgets (U.S. Food and Drug Administration, 2025a; World Health Organization, 2025).

Uncertainty and supported-domain checks travel with the output. Human reviewers retain practical authority to reject it, document disagreement, and trigger correction; participant testimony and model output are compared by timing, context, channel quality, and transport rather than status. Privacy, security, withdrawal, and the broader no-AI-sovereignty rule remain governed by Chapter 3 (Autio et al., 2024; Tabassi, 2023).

20.7.5 — Privacy, Security, and Contestability

Contestability requires a person or authorized representative to understand what was collected, challenge an error, request correction or deletion where applicable, and learn how an output affected the study. Security and minimization protect against uses that were never part of consent.

Brain-body data can reveal routines, sleep, pain, medication timing, location, fatigue, relationships, and changes in health.

Privacy and security therefore belong in the study design from the outset (Bent et al., 2020; Nelson et al., 2020; Tabassi, 2023).

Data minimization begins with a channel-by-purpose map. Respiratory timing does not require voice content by default, sleep timing does not require location by default, and device-quality review does not justify indefinite retention of raw streams. Every additional channel must improve a declared estimand, quality gate, or safety function enough to earn its burden and privacy cost.

Security should include access control, encryption, logging, retention limits, versioned datasets, restricted linkage, incident response, and deletion where compatible with the approved protocol. Public release should use aggregated, deidentified, or synthetic displays only after reidentification and hostile-crop review. A beautiful figure can still be unsafe.

Contestability gives the participant a route. They should know what is collected, what is inferred, what is not inferred, who can see it, what can be corrected, what can be withdrawn, and what cannot be changed after analysis. The route should be understandable without technical fluency.

Cross-architecture dossiers remain outside science. Research data cannot be merged into workplace, government, religious, Workgame, donor, clinical, platform, or public-record systems to create a general person file. Purpose-limited linkage to clinical or other research records requires separate authorization and necessity for the approved study. A purpose-limited study becoming a general person file breaks scientific trust.

Contestability should include understandable explanations of uncertainty.

20.7.6 — Mechanism Failure Remains Live

Failure remains active. Interoceptive features may underperform, allostatic measures prove nonspecific, somatic markers transport only within narrow cue classes, wearables prove biased or fragile, Artificial Intelligence features fail out of sample, and medication or illness dominate channels. Any outcome can favor an ordinary rival or retire a mechanism component (Autio et al., 2024; Picard, 1997; Calvo & D’Mello, 2010).

Mechanism failure is classified by the object that failed: identification, prediction, calibration, transport, causal order, construct validity, subgroup performance, device verification, ethical feasibility, or conceptual scope. Each class has its own consequence, from recalibration or reference-class restriction to bridge withdrawal, protocol retirement, or No adequate estimate. Typed failure converts adverse evidence into cumulative design knowledge.

A useful failure-and-abstention rule can be explicit.

Equation 20.4: Failure-and-abstention display. Role: local trigger for abstention pending evidence classification.

$$\text{Abstain}_t = 1 \left\{ \begin{array}{l} q_{\text{signal}}(t) < q^* \vee C_{\text{conflict}}(t) > c^* \\ \vee P_{\text{confound}}(t) > p^* \vee \mathcal{S}_{\text{scope}}(t) = 0 \end{array} \right\}.$$

Apply the canonical evidence states in §§24.2 and 27.4. Low signal, channel conflict, confounding, or scope failure narrows or

blocks only the affected inference; the local diagnostic should not invent a bespoke verdict vocabulary.

Mechanism failure should be published or logged when the protocol permits. A wearable that fails in a disability subgroup, a respiratory task that worsens symptoms, a neural correlate that adds no held-out prediction, or a result explained by medication changes the design obligations of future studies. Negative evidence belongs in the cumulative safety and recovery record, not in an unpublished remainder.

A PTVC-linked interpretation retains only what survives these failures. If ordinary brain-body mechanisms explain the patterns under fair comparison, the route narrows or retires. If a prospectively specified signature survives recovery, perturbation, transport, and strong rivals, the route becomes more answerable without being promoted to the terminal target. Part VII now gives the ordinary rivals full generative force. The route-level result should specify which ordinary mechanism was defeated, because survival against one rival does not imply survival against the rest of the envelope.

The chapter's final rule is practical: devices witness, bodies participate, models estimate, and people remain more than any channel. A science worthy of felt experience must know when another measurement would add knowledge and when putting the instrument down is the more rigorous act. Burden-adjusted information gain can make that judgment explicit by comparing expected inferential value with the participant cost of another channel.

Graceful nonuse is a result. A promising mechanism may be burdensome, privacy-invasive, fragile, clinically disruptive, or easily misused. Science can preserve it as a bounded research question while refusing deployment or public-artifact travel. A nondeployment verdict should state which scientific uses remain permitted, preventing a useful laboratory result from drifting into operational recommendation.

A failure matrix links each failure class to a defined next action. Verification failure stops use of the device output; construct failure withdraws the measured-to-latent bridge; causal failure narrows the object to prediction; transport failure restricts the reference class; ethical failure retires the protocol; open-set failure expands the model library. Typed response preserves more information than a generic unfavorable label. This typed matrix also makes cumulative review easier because later evidence can reopen only the failure class it actually addresses.

Successor mechanisms begin from failed assumptions and unresolved residuals. A new neural or Artificial Intelligence model needs a version identity, recovery benchmark, qualification plan, privacy review, and public-status ceiling. The successor should identify the exact residual pattern the new mechanism is designed to explain so added complexity remains accountable.

Part VII — Rival Models, Inference, and Adversarial Tests

A consequential hypothesis earns scientific trust by entering a contest it can lose. Part VII constructs that contest. Earlier Parts defined PTVC, separated target, route, observation, and verdict, developed measurements and candidate mechanisms, and specified first tests. Here the candidate faces ordinary psychological, physiological, computational, evolutionary, and statistical generators in closed-world, open-set, and transported comparisons (Popper, 1959; Mayo, 2018; Wilson & Collins, 2019).

Rival models are engines of discovery rather than obstacles to the project. Adaptation, opponent processes, homeostatic regulation, allostasis, predictive learning, selection, conditioning, missingness, and model flexibility can each explain patterns that might otherwise be attributed too quickly to PTVC. When one of them wins under common rules, the scientific map becomes clearer and the next study becomes better targeted.

Part VII compares baseline return, terminal-window observations, and cumulative trajectories at independently defined endpoints. Their separate predictions make it possible to identify the information added by each account.

Ordinary life already contains recovery, habituation, numbing, endurance, prediction, regulation, and reorganization. The same outward quiet can follow healing, exhaustion, lost language, sedation, strategic silence, or reduced observation. A rigorous science distinguishes those paths instead of reading one visible outcome as a complete account of lived experience.

An adaptation model can explain reduced reporting while leaving hidden burden unresolved. A missingness model can explain a smooth record by showing who became harder to observe. A treatment model can explain a terminal change without invoking a terminal law. Each explanation keeps only the credit its design and evidence earn.

Equal treatment governs the tournament. Each serious rival declares latent states, parameters, observation kernels, endpoint relations, uncertainty, and protected predictions. It receives the same data, tuning budget, calibration effort, and scoring opportunity as the PTVC candidate. The comparison also leaves room for every listed model to fail, because closed-world accuracy can manufacture a winner when the relevant generator is missing (Gneiting & Raftery, 2007; Vehtari et al., 2017; Wilson & Collins, 2019).

Chapter 21 begins with ordinary regulation because it is the nearest and most credible source of PTVC-like patterns. Adaptation, opponent responses, homeostasis, allostasis, and Ornstein-Uhlenbeck dynamics can produce local return, damped fluctuation, rebound, and apparent concentration. The integrated-process analysis then shows why a returning state and a closing cumulative path remain different mathematical objects.

Chapter 22 moves into prediction, learning, and control. Predictive processing, active inference, reinforcement learning, safe control, bridge constructions, and event-conditioned selection make distinct commitments about states, observations, policies, rewards, preferences, uncertainty, and endpoints. The chapter turns those commitments into common-observation

competitors rather than treating neighboring vocabularies as borrowed support (Lageman et al., 2026; Samara, 2026).

Chapter 23 tests the outer boundaries of the claim. Evolution can favor function without comfort. Population summaries can reverse within-person relationships. Nonlinear systems can mimic convergence. Cross-species, developmental, and synthetic-system evidence can travel only through declared bridges. Recent work on nonergodicity makes the within-person and between-person distinction especially concrete (Hunter et al., 2024; Mistry et al., 2026).

Chapter 24 turns inference into an explicit dependency chain. Unit, target population, estimand, estimator, scientific acceptance region, epistemic uncertainty, observation kernel, delayed entry, competing events, sensitivity analysis, and sequential rule jointly determine what a number can mean. A valid analysis preserves the path from latent question to permitted verdict and reports No adequate estimate when that path cannot be completed (Rubin, 1976; Little & Rubin, 2019; Hernán & Robins, 2020).

Chapter 25 tests the entire pipeline in worlds where the generator is known. Parameter recovery, model recovery, simulation-based calibration, open-set detection, transport stress, challenge logs, and reproducible artifacts expose false confidence before human data receive strong interpretation. Nonstationary recovery work and posterior simulation-based calibration show how sophisticated pipelines can misclassify or miscalibrate. Adversarial collaboration shows how advance agreement can sharpen theory comparison while also revealing the practical difficulty of a genuinely shared test (Schumacher et al., 2025;

Säilynoja et al., 2026; Cogitate Consortium et al., 2025; Ceci et al., 2024; Isch et al., 2025).

Across the series, scientific findings should retain the component and setting in which they were established. This lets the private-life, religious, institutional, legal, peace, and transition volumes draw on a clear and consistent scientific record.

The equations, simulations, tables, and decision rules in this Part are inspectable tests of assumptions and predictions. They test whether a pipeline can recover known generators, predict protected observations, transport across sites and instruments, survive informative missingness, separate target from observation artifacts, and recognize when every offered model is wrong. The results show where a pipeline is ready for use and where it can be improved.

Public communication should name the mechanism that best explains a pattern, whether adaptation, learning, regulation, selection, conditioning, observation, or statistical artifact. This gives later research a precise result to build on.

Part VII gives strong opponents executable models, exposes the preferred account to common rules, and treats adverse results as knowledge. Its reward is not automatic victory, but a research program capable of learning which component, reference class, and evidential stage the data can sustain (Munafò et al., 2017; Nosek et al., 2018; National Academies of Sciences, Engineering, and Medicine, 2019).

Chapter 21 — Adaptation and Homeostasis

Adaptation is familiar, powerful, and easy to overread, which makes it the first major rival to PTVC-specific interpretation. Injury, bereavement, relief, promotion, medication, threat, and care can move affective state, reference range, behavior, and report process on different clocks. Chapter 21 asks how much apparent balance those ordinary processes can generate before any terminal-boundary structure is needed (Solomon & Corbit, 1974; McEwen, 1998; Diener et al., 2006; Kuppens et al., 2010).

Observable recovery can reflect restored function, reallocated attention, revised expectations, or a genuine reduction in distress. It can also reflect exhaustion, learned silence, response shift, limited access to care, or a burden that has become ordinary. The analysis therefore separates latent state, appraisal, memory, behavior, and observation closely enough to distinguish recovery from invisibility.

PTVC asks a stronger question than whether people often recover. It concerns a cumulative phenomenal object within a qualifying conscious stream and a prospectively specified endpoint architecture. Adaptation, opponent processes, homeostasis, allostasis, treatment, frailty, observation loss, and mean reversion receive the first opportunity to explain each visible pattern; only a residual restriction that survives that suite remains PTVC-specific.

The rival field is generative rather than rhetorical. Set-point models specify reference ranges and return rates. Opponent models specify delayed counterresponses. Homeostatic and allostatic models regulate present and anticipated demand. Ornstein-Uhlenbeck families supply continuous-time baselines,

while integrated OU analysis exposes the difference between state return and accumulated-path behavior.

Many favorable-looking signatures can arise from ordinary regulation or ordinary observation. Variance may narrow under mean reversion, reports may quiet through habituation, and terminal records may smooth when treatment, frailty, selection, sensor noise, or measurement cadence changes. Those alternatives should be simulated through the same observation model before any curve is assigned target-level meaning.

Adaptation describes how people reorganize around changing circumstances. Understanding the effort and support involved helps distinguish recovery, accommodation, and continuing needs for care.

Keep one image in mind: a curve returns toward its reference line while the accumulated area beneath it continues to change. The current state has recovered, but the experienced interval remains part of the path. A state model and an integrated ledger therefore answer different questions, and the chapter makes their difference visible in equations and simulations.

Formulas enter because prose can blur the status of a result. The OU equation is a rival generator. The integrated OU variance expression is a mathematical consequence of declared assumptions. Simulations are teaching devices and protocol fixtures. None becomes empirical evidence about lives until real data, prospective specification, observation models, and held-out comparison enter.

Rivals are not treated as simple. Adaptation may be incomplete, asymmetric, event-specific, culture-shaped, report-dependent, and different inside a person than across people. Opponent processes may overshoot, fade, strengthen, or sensitize. Allostatic regulation may protect in the short run while imposing physiological cost over time. Homeostasis may preserve viability without preserving felt fairness.

Prediction and policy learning begin where local regulation ends. Adaptation, opponent processes, allostasis, homeostasis, OU dynamics, integrated ledgers, and their hybrids belong here. Predictive processing, active inference, reinforcement learning, and safe control receive their own generative treatment in Chapter 22, where policies and learned world models require different machinery. Keeping these rival families separated by mechanism prevents a broad word like regulation from hiding differences in information, objectives, and learning dynamics.

Two distinctions should remain after the details fade: recovery can be genuine without being terminal closure, and a rival victory can be genuine progress. Giving ordinary regulation full strength makes the surviving scientific question smaller, clearer, and more worth testing. This also protects the positive case by forcing any remaining PTVC-specific claim to explain structure that ordinary regulation demonstrably does not.

The field expert should finish with a stricter demand. Every adaptation claim must declare its state, baseline, timescale, observation model, individual heterogeneity, missingness structure, and comparison rule. Every OU comparison must distinguish state mean reversion from integrated path behavior.

Every claim of residual PTVC-specific structure must be tested against generated data where the rivals are allowed to be true. Parameter uncertainty and model misspecification should travel with those declarations, because a precisely written rival can still be a poor approximation to the data.

Scientifically, a successful adaptation model narrows the PTVC-specific interpretation; a failed adaptation model opens a stronger comparison rather than a victory declaration. Every curve carries only the meaning its design and evidence support. A residual pattern earns attention only after the adaptation model has been tuned and tested under the same information constraints as the candidate.

21.1 — Adaptation as a Leading Rival Family

Adaptation is the first rival because people often move toward a recognizable range after gain, loss, shock, relief, illness, disappointment, or safety. That return may reflect repair, changed expectation, altered environment, response shift, selective memory, or reduced reporting. A scientifically useful model must distinguish those pathways instead of treating every quieter trajectory as the same process (Brickman et al., 1978; Diener et al., 2006; Lucas, 2007a; Wilson & Gilbert, 2008; Kuppens et al., 2010).

Adaptation is treated as a model family, not a slogan. Each member declares a latent state, moving or fixed reference, return dynamics, event class, treatment path, memory component, report process, and uncertainty. Person-specific baselines, asymmetric gains and losses, incomplete return, and response shift belong inside the rival when the data can identify them.

The central question is what the family explains when the target is cumulative felt exposure and endpoint-sensitive structure. A model that predicts state return may not predict the integral; a model that predicts reports may not recover the private interval; a model that fits remembered evaluation may not describe momentary experience. These distinctions define the residual rather than merely qualifying it.

Two errors should be visible from the start. The first is assuming full return because a later report looks ordinary. The second is assuming PTVC-specific structure because ordinary return is

incomplete. Between those errors lies the actual work: declare the adaptation model, test its channels, and ask what remains.

Adaptation is also where institutions can hide behind human resilience. A clinic, school, insurer, employer, or family can point to reduced expression and treat the problem as resolved. The scientific comparison keeps adaptation strong while refusing to let reduced expression erase the original burden.

21.1.1 — Set-Point and Baseline Accounts

Set-point and baseline accounts explain returns toward ordinary feeling without invoking terminal structure. They posit a person-specific reference range, a disturbance, and relaxation toward that range. Bereavement, promotion, injury, or relocation can therefore produce a curve that resembles repair. A prospective comparison asks whether the declared model predicts the trajectory and what residual remains after uncertainty, reporting, treatment, and context are handled (Brickman et al., 1978).

Set-point accounts become credible when their apparent simplicity is relaxed. The implementation should allow return rates, plateaus, treatment effects, and reporting channels to differ across people and contexts. This gives the comparison a realistic account of adaptation against which additional trajectory predictions can be evaluated.

Consider a job loss followed by partial mood return while debt, shame, and sleep disruption remain. A recovered daily mean does not imply that every burden has resolved: variance, avoidance, opportunity, and bodily strain may follow different trajectories. The set-point account should receive credit only for the features

it predicts, while any proposed residual must be tied to an independently measured feature rather than inferred from what the rival leaves narratively unexplained.

A useful display declares the reference range, shock, return rate, shifted plateau, observation noise, and several admissible paths, including asymmetric or incomplete recovery. Its caption identifies the display as a rival simulation and records the generating model and parameter values.

This mechanism matters because it prevents resemblance from becoming evidence. A curve that looks like repair may have been produced by local regulation, scale change, treatment, or observation loss. Formalizing the rival turns that resemblance into a contest that the preferred theory can lose.

The humane boundary is simple and specific. A rival win can narrow a theory, but it cannot narrow a person's claim to care, privacy, or serious hearing. Endurance, quiet behavior, and changed reports remain facts to interpret cautiously, not permissions to withdraw support.

A runnable comparison must state the data, estimable parameters, discriminating pattern, and candidate-narrowing rule. That precision gives ordinary mechanisms a real contest rather than ceremonial mention.

21.1.2 — Incomplete and Asymmetric Adaptation

A useful adaptation model allows both lasting gains and persistent effects of adverse events, with different rates and limits for each. This gives the comparison a realistic account of human change

and accommodates the diversity of trajectories documented in longitudinal research (Diener et al., 2006; Lucas, 2007a).

Quantitative evidence supports a differentiated and hopeful picture of adaptation. A meta-analysis of 188 publications, comprising 313 samples and 65,911 participants, found that affective and cognitive wellbeing respond differently to life events and follow varied trajectories (Luhmann et al., 2012).

Lindqvist, Östling, and Cesarini studied 3,362 Swedish lottery players 5–22 years after prize events, using randomized prize variation within comparable groups and preregistered analyses. An additional after-tax prize of US\$100,000 in 2011 dollars was associated with approximately 0.037 standard deviations higher overall life satisfaction. The benefit persisted; effects on happiness and mental health were smaller and not statistically distinguishable from zero (Lindqvist et al., 2020). Better circumstances can produce lasting gains, and following evaluative life satisfaction and momentary affect separately helps identify how those gains develop.

Baselines may shift, responses may differ by sign, plateaus may persist, and treatment or context may alter the return process. Representing those variations gives the comparison a realistic adaptation model.

A chronic-pain participant may learn pacing well enough to restore a stable daily routine while continuing to carry vigilance, sleep disruption, and constrained movement. That record distinguishes functional adaptation from disappearance of burden. The model must say which outcome returned, which

remained displaced, and whether treatment, expectation, or reporting practice explains the difference.

Before fitting incomplete and asymmetric adaptation, the protocol must name the state, event class, time window, observation channel, baseline rule, missingness rule, and loss function. Rival and candidate then face the same estimand, so neither receives a cleaner object after the result becomes emotionally attractive.

If the adaptation model explains held-out trajectories with fewer assumptions under the shared observation model, explanatory credit belongs to that model. Any additional PTVC prediction is then evaluated against the explanatory scope established by the comparison.

Public reporting should name incomplete or asymmetric adaptation at the scope supported by the observations. Captions and summaries should preserve the mechanism, population, uncertainty, and limits of the result, and distinguish reduced expression from changes in the underlying experience.

The acceptance gate is implementability. A reviewer should be able to name the state variable, time unit, observation channel, parameter, and rival-win condition without guessing. Specifying those pieces turns the proposed explanation into an executable model for direct comparison.

21.1.3 — State, Report, and Memory

State, report, and memory must remain separate because adaptation can occur in one while another remains altered. Calm reporting may reflect changed expression; later recall may reconstruct an event; life evaluation may diverge from sampled

affect. Candidate-instrument and interval-contribution studies therefore treat reports as timed, contextual evidence about lived experience. Comparing immediate reports with later recollection helps identify which layer changes and on what timescale (Lucas, 2007a).

A credible layered rival permits latent affect, immediate report, later recall, treatment, context, and memory access to adapt at different rates or not at all. The candidate is compared with that layered system, not a single curve standing in for the person.

Consider a widower who reports daytime stability but avoids places saturated with loss. Daytime report, place avoidance, autobiographical memory, and physiological response need not move together. The analysis must distinguish genuine affective adaptation from strategic reporting, context-specific triggering, and memory reconstruction, with each account assigned an observable test rather than a retrospective story.

Disagreement among state, report, and memory calls for a layered observation plan, not indiscriminate surveillance. Sampling cadence should follow the expected lag between immediate affect, public report, and later recollection, while the protocol preserves the person's right to decline a channel. Dense data gathered at the wrong interval can still miss the process the rival proposes and can increase burden without increasing identification.

The layered comparison evaluates predictive accuracy, missingness, and complexity together. Its result identifies how

much of the trajectory is explained by adaptation and which additional path restrictions, if any, remain to be tested.

A reproducible state-report-memory analysis should expose three linked equations or modules: the latent state transition, the contemporaneous report kernel, and the later-memory kernel. Recovery must be demonstrated under channel disagreement and missing reports, then scored on protected sequences. Adaptation is favored when that layered model predicts the observations without a PTVC-specific path restriction; unresolved layer identity yields ambiguity rather than a forced verdict (Brickman et al., 1978; Diener et al., 2006; Lucas, 2007a; Wilson & Gilbert, 2008).

21.1.4 — Within-Person Dynamics

Within-person dynamics make adaptation testable over time. Cross-sectional averages can make people appear to return toward baseline while individual trajectories diverge, reverse, or never recover. The proper unit is the observed stream over time, with person-specific baselines, changing contexts, and measurement error declared in advance. Held-out prediction then tests how much of the trajectory the within-person adaptation model explains and which additional patterns warrant comparison (Wilson & Gilbert, 2008; Brickman et al., 1978).

The adaptation model can represent recovery, partial recovery, changing standards, and persistent alterations. Formalizing those features creates a clear basis for comparing additional PTVC predictions.

The concrete unit is a sequence of observations from the same person surrounding a declared event, with the pre-event range, response, return path, and later context kept on one clock. Such a record can estimate heterogeneity without averaging away the individual dynamics the rival is meant to explain. It also shows where missing intervals prevent a confident account of adaptation.

Within-person dynamics require operational definitions of return, plateau, overshoot, persistence, and transport before fitting begins. Those features should be estimated on a declared clock and evaluated across event classes rather than inferred from a smoothed line. Parameter-recovery analysis then tests whether the model can be estimated from irregular, noisy observations.

Later summaries should identify the within-person model that best explained the trajectory and retain the result's tested setting and scope.

21.1.5 — State Recovery and Accumulated Experience

Adaptation changes the current state and the path that leads to it. After an event, recovery can coexist with delayed effects, altered opportunities, and changed constraints. Recording both the returning state and the accumulated signed area makes these features available for direct model comparison.

A complete adaptation model can combine local recovery, persistent path area, changing standards, and context-dependent reporting. Including those features gives the comparison a realistic account of human change.

A student may return to class after sustained bullying and appear behaviorally recovered while avoiding corridors, friendships, or activities associated with the harm. The example tests whether local functioning, felt safety, memory, and cumulative exposure move together. It does not assume hidden damage; it requires the rival to specify which layer it predicts and how the unobserved interval is represented.

A two-panel display can place momentary state above the signed cumulative area generated by that state. The upper curve may return toward baseline while the lower curve retains the area contributed during the disturbance. This visual distinction is the scientific point: local adaptation and terminal closure are different objects even when they share an attractive endpoint picture.

The value of the rival is that it can make predictions before the Law enters the room. A return rate, lag, plateau, or variance pattern can be estimated, simulated, and scored. If that machinery explains the relevant structure, the chapter has learned something important even when the PTVC-specific reading becomes smaller.

When local recovery without terminal closure explains the observations, public language should say exactly that. The result should not be enlarged into a universal claim, softened into covert support, or used to reinterpret accumulated burden. Naming the ordinary mechanism precisely is part of scientific honesty.

The decisive test freezes an adaptation family on training events and asks it to predict both later state trajectories and the accumulated path proxy in protected events. Baselines, return

rates, asymmetry, response shift, treatment, and observation error must be estimated without terminal leakage. When local adaptation explains the held-out structure and no additional PTVC restriction survives, the candidate interpretation narrows to the residual it can actually defend (Brickman et al., 1978; Diener et al., 2006; Lucas, 2007a; Wilson & Gilbert, 2008).

21.1.6 — Conditions for Rival Victory

Adaptation becomes a genuine adversary when victory conditions are fixed before outcome inspection. It wins this component when the protocol-fixed comparison rule favors the prespecified set-point, asymmetric, and within-person models over the PTVC candidate under the same observation process. It also wins when baseline recovery, report change, care context, selection, medication, or measurement loss generates apparent terminal concentration (Diener et al., 2006; Lucas, 2007a).

The rival family must be able to win in practice. Heterogeneous baselines, asymmetric gains, event classes, treatment, and observation error belong in the prespecified adaptation family. Only a strong ordinary account makes the contest meaningful.

Imagine a prespecified adaptation model that outpredicts a more elaborate PTVC candidate in a protected cohort and stays calibrated across event classes. Protocol-fixed loss, complexity allowance, sensitivity plan, and held-out prediction rule determine the consequence, not which account inspires more. If no distinctive transported restriction remains, the PTVC-specific component narrows.

Conditions for rival victory belong in the estimand and scoring plan before outcomes are seen. State, event, window, channel, baseline, missingness process, and loss function remain common across models. Otherwise victory is vulnerable to a quiet change in what the analysis was asked to estimate. The scoring plan should also fix how complexity and calibration are penalized, so flexibility cannot be converted into an unpriced advantage after fitting.

The victory rule should be executable from the protocol alone. It identifies the common estimand, candidate and rival families, tuning budget, complexity adjustment, protected split, uncertainty rule, and score margin. A tie or unstable advantage remains Model-ambiguous; a reproducible rival advantage triggers the prospectively specified narrowing or retirement rather than a new post hoc contest (Brickman et al., 1978; Diener et al., 2006; Lucas, 2007a; Wilson & Gilbert, 2008). Executable rules should be tested on synthetic ties and near-ties so unstable ranking behavior is known before real outcomes create pressure to choose.

A practical adaptation protocol therefore preserves at least three distinguishable objects: current state or report, the slowly moving reference against which change is appraised, and the cumulative exposure history. The first describes the present observation, the second describes learned normality, and the third preserves what was carried while the baseline moved. Conflating them lets adaptation explain everything and identify nothing. Separating these objects also allows adaptation to be modeled as a change in reference without retroactively erasing cumulative exposure.

This is where the Law of Fairness question becomes precise. It asks not whether people recover, but whether local recovery curves, response shifts, and incomplete adaptation exhaust the stronger pathwise patterns the formal hypothesis requires. Comparing strong rivals identifies the features they explain and the additional structure a PTVC model predicts. The most informative residual is one predicted prospectively by PTVC and missed by well-calibrated adaptation rivals, not one discovered after inspecting their errors.

21.2 — Opponent Processes and Local Counterweights

Opponent-process theory deepens the rival field by specifying a delayed counterresponse after a primary affective movement. Pleasure may be followed by flatness, danger by relief, repeated exposure by tolerance, and withdrawal by an acquired opposite state. These dynamics can resemble balancing, but their domain is an event history with identifiable lags and gains, not a complete-stream terminal guarantee (Solomon & Corbit, 1974; Koob & Le Moal, 2001).

The key science is temporal and multichannel. The model asks how quickly the primary response rises, when the opponent response begins, whether repetition changes either component, and how physiology, report, behavior, and memory reveal different portions of the process. Sampling cadence must resolve those differences rather than averaging them into one smooth curve.

A simple response model makes the area question explicit. Let

$$h(t) = Ae^{-at} - Be^{-bt}, \quad A, B, a, b > 0, \quad t \geq 0.$$

The integrated response is

$$\int_0^{\infty} h(t) dt = \frac{A}{a} - \frac{B}{b}.$$

The zero-area case therefore imposes the relation $A/a = B/b$. Amplitudes and time constants can be estimated from the response profile and used to compare this constrained case with an unconstrained two-component model. Repeating that comparison across settings turns an apparent counterweight into

a quantitative question about response shape, duration, and shared parameters.

21.2.1 — Primary and Opponent Responses

Primary and opponent responses provide a temporal model of counterweights. An initial affective response may be followed by a delayed movement in the opposite direction, producing rebound, overshoot, or settling. The comparison specifies both response kernels, their lags, and the observations needed to recover them (Solomon & Corbit, 1974).

Local counterresponses are measured phenomena. In three human psychophysical studies, Leknes et al. (2008) found that relief depended on preceding pain and its decline, with cooling increasing the intensity, pleasantness, and duration of relief in the tested conditions. Franklin et al. (2013), studying forty participants, used separate startle-response indicators to show that pain offset could both increase positive affect and reduce negative affect. The timing and intensity conditions mattered. Together, the studies justify measuring relief in its own right, with positive and negative channels distinguished.

A later study of 122 healthy adults measured pleasant relief for four minutes after an aversive stimulus ended. Relief differed across groups identified from their preceding pain trajectories, making person-specific response dynamics empirically tractable (Henri et al., 2022). These timing and individual-difference findings provide concrete targets for comparisons using existing data and observations during timely pain relief.

An opponent-process model can accommodate primary responses, delayed counterresponses, tolerance, withdrawal, and channel-specific timing that vary across people and events. Those features define the baseline against which additional trajectory restrictions can be compared.

Consider relief after a threat ends, followed by shaking, fatigue, or an unfamiliar calm. The primary response may stop before the opponent response reaches its maximum, so the visible sequence should be analyzed for timing, sign, and dose dependence rather than treated as one undifferentiated recovery curve. A fairness-specific route becomes relevant only if it predicts a prospective feature that a well-specified opponent process does not reproduce.

Opponent responses are clarified by measurements timed to the proposed mechanism, not by collecting every available signal. The sampling grid should resolve the primary rise, delayed counterresponse, and any rebound after exposure ends; a cadence too coarse to separate those phases cannot adjudicate the model. Channel choice should follow the hypothesized process, with burden minimized when additional sensors would add redundancy rather than identification.

Primary and opponent responses are tested through a frozen impulse-response model across repeated exposures. The analysis should recover primary amplitude, opponent lag, rebound size, and dose dependence under the actual sampling and observation process, then predict a protected exposure sequence. A stable delayed counterresponse favors the opponent account; failure to recover or distinguish the kernels leaves the mechanism unresolved (Solomon & Corbit, 1974; Koob & Le Moal, 2001).

A complementary circuit result comes from rats with postsurgical pain. Local-anesthetic blockade of input from the injury produced preference for the associated location, activated ventral tegmental dopamine cells, and increased dopamine release in the nucleus accumbens; blocking accumbens dopamine signaling prevented the place preference (Navratilova et al., 2012). This connects relief to a causal reinforcement pathway and gives the human findings a mechanistic comparison. Temporally defined relief, behavior, and circuit activity can therefore be studied together.

Safety can acquire a learned biological value that sustains future action. Macdonald et al. (2026) identified a pathway from the paraventricular thalamus to the nucleus accumbens that developed a response when mice successfully avoided threat. The signal weakened when the action's safety value was reduced. Silencing the pathway at safety onset reduced subsequent avoidance and willingness to work for safety; computational fits attributed the behavioral change primarily to lower estimated safety value. The researchers also identified plasticity at connections to accumbens cholinergic interneurons that helped regulate dopamine release. This provides a concrete mechanism through which an improved situation gains motivational value. It gives the book's relief models measurable components: learned safety, outcome valuation, circuit plasticity, and the timing of future action.

21.2.2 — Habituation, Tolerance, and Withdrawal

Habituation, tolerance, and withdrawal show how repeated exposure changes the state space itself. A stimulus that once carried strong affect may fade with repetition, while the absence

of a familiar stimulus can become its own disturbance. These mechanisms can produce relief, craving, numbness, agitation, or return toward ordinary functioning. Their local process models describe how response patterns change with exposure history (Koob & Le Moal, 2001; Solomon & Corbit, 1974).

Habituation, tolerance, and withdrawal enter the contest in their strongest ordinary form. They can explain diminished response, escalating dose, delayed rebound, and discomfort after cessation without a terminal-boundary mechanism. The remaining question is whether a prospectively specified candidate predicts the rebound, withdrawal, and cross-timescale structure more accurately on protected data.

Repeated analgesic exposure can reduce one response while a delayed withdrawal or rebound process grows. The measurable changes are in amplitude, lag, and recovery across exposures. Modeling treatment indication and dose history helps distinguish treatment-related effects from other sources of a counterresponse.

Habituation, tolerance, and withdrawal must be implementable rather than merely respectable. Parameters need units, observations need an error model, and all candidates must share participant windows, censoring rules, and endpoint definitions. This prevents inherited prestige from deciding the comparison.

21.2.3 — Timescale Dependence

Timescale dependence prevents opponent-process language from becoming a single curve stretched across every phenomenon. Some counterweights arise in seconds, others across days, seasons, treatment cycles, grief processes, or years of exposure. A

model that fits daily self-report may fail at minute-level physiology, and a terminal pattern may disappear when sampled at the wrong cadence. The chapter therefore asks each rival to declare its clock before its success is interpreted (Solomon & Corbit, 1974).

Fast regulation, slow learning, seasonal context, and developmental change can produce different apparent baselines. A multiscale model specifies their joint predictions and tests whether those relationships carry across new observation windows.

A process sampled hourly can look monotone while minute-level measurements reveal overshoot and delayed return; an excessively dense record can also magnify transients irrelevant to the proposed kernel. Timescale analysis should compare prospectively specified resolutions and aliasing consequences with selection rules fixed before model comparison.

The timescale figure should overlay one opponent-process trajectory under several prospectively specified sampling grids and lag assumptions. Mark which rebound features each cadence resolves, aliases, or misses, so the figure directly informs study design.

Sampling resolution affects which mechanism can be identified: a coarse window may resolve adaptation while a finer window reveals rebound. Report the result at its prospectively specified resolution (Solomon & Corbit, 1974; Koob & Le Moal, 2008).

Expert disagreement here should be localized to the response kernel, sampling grid, lag distribution, and criterion for cross-

timescale transport. Reviewers can then ask whether apparent rebound is aliased, whether the prior over delays is influential, and which additional window would separate the models. The dispute becomes a finite design problem rather than a referendum on the entire hypothesis (Solomon & Corbit, 1974; Koob & Le Moal, 2008).

21.2.4 — Event-Specific Versus Global Processes

Event-specific and global processes must not be collapsed. A person can adapt to a commute, medication side effect, or repeated social cue while remaining deeply altered by grief, coercion, illness, or chronic fear. Local counterweights can make one channel look repaired while the broader stream still carries pressure elsewhere. The model must state whether it explains a discrete disturbance, a recurring context, or a global affective tendency (Koob & Le Moal, 2001; Solomon & Corbit, 1974).

A useful contrast places bereavement, injury, reward loss, and repeated aversive exposure inside one hierarchical model while allowing each event class its own kernel. If a common opponent component transports across events, the global account gains credibility. If the parameters remain event-bound, the scientific conclusion should stay local rather than becoming a lifetime mechanism.

Test the local-versus-global distinction with a hierarchical kernel model and leave-one-event-class-out prediction. If event-specific kernels transport but a constrained shared component does not, retain the local mechanisms and retire the global counterweight claim (Solomon & Corbit, 1974; Koob & Le Moal, 2001).

21.2.5 — Generative Simulation

Generative simulation is included to make the rival executable. The chapter can specify an event, a primary response, an opponent response, a delay, a decay rate, and an observation model, then ask whether that system reproduces apparent repair. The useful result is a recoverable model that can later be compared against data under common rules (Solomon & Corbit, 1974).

Generative simulation converts verbal assumptions into trajectories before the human data are interpreted. By varying opponent delay, tolerance, exposure schedule, observation error, and missingness, the benchmark can reveal which signatures are recoverable and which are shared by several mechanisms. A route that cannot be distinguished in its own simulated worlds is not ready to explain an observed one (Wilson & Collins, 2019; Talts et al., 2018).

The simulator should generate repeated exposures with controlled primary amplitude, opponent lag, tolerance, withdrawal, observation noise, and missingness. Analysts then fit the prospectively specified rival families without access to the generator label. Recovery across near-miss settings, not recognition of an idealized rebound, is the evidence that the planned test can discriminate.

A successful recovery benchmark shows that the pipeline can recognize the rival under the simulated conditions. It does not establish that the rival generated human observations. If the rival subsequently wins on empirical prediction, calibration,

parsimony, and transport under the common rules, the PTVC-specific interpretation loses that component.

Simulation outputs remain synthetic design objects. Generator parameters and recovery scores do not transfer into participant profiles or eligibility decisions.

The simulation gate requires the complete observation pipeline to recover opponent, adaptation, and null generators across realistic noise, missingness, and parameter overlap. Calibration, family confusion, and abstention rates should be reported by regime. A mechanism label is not carried into human data when the pipeline cannot identify that mechanism in synthetic worlds built to resemble the planned study (Solomon & Corbit, 1974; Koob & Le Moal, 2001).

21.2.6 — Rival-Unique Predictions

Opponent-process models predict overshoot, aftereffects, sensitization, tolerance, withdrawal, and lags. Their distinctive patterns can be tested at the relevant timescale with negative controls and protected data (Koob & Le Moal, 2001; Solomon & Corbit, 1974).

A rival-unique prediction must survive heterogeneity rather than depend on an idealized average. Event class, channel, exposure history, treatment, and baseline can alter both the magnitude and timing of an opponent response. The candidate Law should face the strongest version of that prediction before any residual pattern is called distinctive.

Consider a delayed aftereffect that grows across repeated exposures. Sensitization, tolerance, anticipatory learning, and

changes in reporting can all produce such growth, but they imply different relations among dose, latency, and recovery. A rival-unique prediction must therefore specify which relation should change first and how that prediction will be scored on exposures not used to tune the model.

Rival-unique predictions need a cadence matched to the proposed delay, rebound, and dose history rather than an ever-denser record by default. The protocol should specify which channel is expected to move first, how long the counterresponse should persist, and what pattern would be absent under a simple adaptation model. A record that does not resolve those temporal contrasts cannot be treated as a test of opponent dynamics.

Before protected data are examined, specify the expected channel order, lag, rebound, repetition effect, and decay after exposure. Evaluate that joint temporal pattern out of sample against calibrated alternatives with the same information, then report which discriminator succeeded, remained unresolved, or failed. Any broader conclusion remains limited to the predictions entailed by the tested branch (Solomon & Corbit, 1974; Koob & Le Moal, 2001; Koob & Le Moal, 2008). A gain difference and a lag difference should receive separate estimates, since the same peak can arise from different trajectories.

Opponent-process studies estimate two time constants: one for the primary response and one for the delayed counterresponse. Both can change with repetition, so habituation and a growing delayed component can make the same event feel different across exposures. Recording exposure history connects those changes to the observed response. This calls for observations before, during,

and after the primary response rather than a single post-event rating.

Opponent responses can change how repeated pleasure, relief, or absence is experienced. Their timing and persistence make aftereffects useful targets for clinical observation and model comparison. Follow-up after exposure ends can distinguish a persistent counterresponse from a brief change in reported intensity.

21.3 — Homeostasis, Allostasis, and Mean Reversion

Homeostasis and allostasis are stronger rivals than simple rebound because they model systems that actively regulate current and anticipated conditions. Temperature, glucose, sleep pressure, arousal, inflammation, pain responses, and threat vigilance move around ranges, thresholds, and predicted demands. Those processes can generate stability, recovery, and variance change while optimizing viability rather than terminal phenomenal closure (McEwen, 1998; Sterling, 2012; Bobba-Alves et al., 2022; McEwen & Wingfield, 2003).

PTVC targets a cumulative phenomenal object. Homeostasis targets regulated variables, and allostasis targets adaptive control under anticipated demand and accumulated load. These domains interact inside embodied life, but none can be substituted for another; a system may preserve function while experience remains painful, narrow, vigilant, or exhausted.

Disease progression, treatment, medication, frailty, caregiving, changing reserve, and observation shutdown are therefore part of the rival generator, not nuisance notes. If the joint ordinary model explains the apparent concentration, that pattern leaves the PTVC-specific evidence set.

Regulation often sounds reassuring because it keeps organisms alive. Yet a system can remain viable through narrowed choice, chronic vigilance, fatigue, medication, avoidance, or reduced expression. Viability therefore enters as a rival object rather than a synonym for fairness.

The central empirical demand is context. A regulatory curve without illness stage, treatment, sleep, activity, care setting, and missingness may be mathematically clean and scientifically thin. The model must see the conditions that produced the return.

21.3.1 — Homeostatic Set-Point Control

Homeostatic set-point control provides an explicit model of regulation. Temperature, glucose, sleep pressure, pain avoidance, and autonomic regulation offer examples for examining feedback, recovery rates, and changing reference states (McEwen, 1998).

Regulation has also been studied directly in everyday affect. Smartphone observations from more than 28,000 people showed a state-dependent activity pattern: lower mood preceded mood-enhancing activities, while better mood preceded useful activities with less immediately pleasant consequences (Taquet et al., 2016). A later analysis examined 28,212 smartphone participants and 30,116 participants in six-country population data, finding weaker mood-homeostasis patterns with low mood and a history of depression (Taquet et al., 2020). The later report extends the smartphone analysis with population data; the smartphone participants overlap across reports. These observational findings reveal a measurable feedback relation between feeling and activity selection, with substantial variation in how it operates.

Set points, gains, delays, and observation channels can differ across people and settings. A useful homeostatic model represents regulation in treated, aging, and context-sensitive systems.

Breathing support, medication, and social reassurance can help panic settle through partly different channels. A homeostatic

account can predict their timing and interactions, and additional route models can specify further relationships for comparison.

A feedback diagram identifies the regulated variable, reference signal, sensor, comparator, control action, delay, and saturation in the homeostatic rival. Distinct arrows connect the latent state, reports, and physiological observations, locating the feedback relations available for testing.

The comparison can begin from measured affect dynamics. Kuppens et al. (2010) used two experience-sampling studies to examine a diffusion model with an affective homebase, variability, and attractor strength. Separately estimating these features allows researchers to compare models of current state, ordinary return dynamics, and longer-term history while preserving person-specific baselines and observation error.

Research records should include the effort, pain, environmental conditions, and treatment that accompany stable function. These contextual variables help explain how regulation operates within a person's circumstances (McEwen, 1998; Sterling, 2012; Bobba-Alves et al., 2022).

Homeostatic control is evaluated by estimating feedback gain, delay, saturation, and reference movement around ethically permissible perturbations or natural changes. The fitted controller forecasts recovery and overshoot in a protected sequence, with uncertainty carried into the comparison (McEwen, 1998; Sterling, 2012; Bobba-Alves et al., 2022).

The biological feasibility of precise regulation has direct experimental support. In bacterial chemotaxis, adaptation

accuracy can remain robust while pathway protein levels change; integral-feedback analysis explains how the network retains this property under specified biochemical conditions (Alon et al., 1999; Yi et al., 2000). Aoki et al. (2019) went further by engineering an integral controller in living cells and demonstrating robust growth-rate regulation in *E. coli*. These findings make cumulative error integration a concrete biological capability. They give PTVC a productive mechanistic starting point: identify a carrier of cumulative information and investigate its relationship to experienced valence.

Natural cellular regulation also supplies an empirical example. Muzzey and colleagues (2009) combined single-cell measurements of volume and Hog1 signaling with assays of glycerol accumulation during changes in external osmolarity. Their perturbations and systems analysis supported an integral-feedback account and helped locate the feedback mechanism in the network regulating glycerol synthesis. The study demonstrates how measurements of several linked quantities and responses to different input shapes can reveal a history-sensitive controller in a living system.

An integral controller also makes signed response area directly analyzable. Let its internal state obey $dz/dt = k_I(r - y)$, with constant reference r , constant positive integration gain k_I , and an integrable output y . Integrating between a and b gives

$$\int_a^b (y - r) dt = -\frac{z(b) - z(a)}{k_I}.$$

Output recovery, $y \rightarrow r$, can coexist with a retained integral-state change. Zero signed response area occurs exactly when $z(b) = z(a)$. Measuring both the output and the internal state under safe perturbations would distinguish these dynamical outcomes (Yi et al., 2000).

The feasibility case extends to stochastic biological systems. Antithetic integral feedback provides a reaction architecture for robust mean regulation under its stability and ergodicity conditions (Briat et al., 2016). Frei et al. (2022) implemented a related circuit in mammalian cells, maintaining tunable transcription-factor expression despite increased degradation or changed feedback structure. Additional proportional feedback reduced variability while retaining adaptation. Noise and biological complexity can thus be incorporated into experimental studies of precise regulation.

An exact molecular count identity and a mean regulation identity make different predictions. In a nonexplosive reaction model with one event at a time and the required compensator integrability, consider two counts Z_1, Z_2 whose births have predictable intensities μ and θY_s and whose paired annihilation removes one of each. For $D = Z_1 - Z_2$, annihilation cancels exactly, while compensated birth counts leave the reaction martingale M :

$$D_t - D_0 = \int_0^t (\mu - \theta Y_s) ds + M_t.$$

A return of D therefore need not make the integrated rate error zero on that realization. This follows directly by subtracting the actual birth counts and their compensators; replacing them by

their means discards the remaining fluctuation. Such reactions provide a concrete architecture to investigate, with mean regulation, event accounting and experiential accumulation measured separately.

A fixed potential of a locally finite pure-jump state is constant between jumps. If its change equals minus an absolutely continuous ledger, continuity also forces it to remain unchanged at every jump, leaving no nontrivial accumulation on that branch. A continuous integrating coordinate, explicit time dependence or an independently justified atomic contribution measure changes the model and requires its own bridge.

The same bookkeeping supplies a quantitative precision test. For a fixed molecular coordinate $q(X)$, let reaction j change q by d_j at intensity a_j . Its drift b , martingale variance rate c and coordinate-changing activity A satisfy

$$b = \sum_j a_j d_j, \quad c = \sum_j a_j d_j^2, \quad A = \sum_{j:d_j \neq 0} a_j, \quad b^2 \leq Ac.$$

The inequality is weighted Cauchy–Schwarz. At a measured upper activity bound, a specified drift therefore demands a minimum innovation variance. This is a restriction on reaction noise, not a lower bound on final variance under feedback. A molecular candidate must show which events write its record, which preserve it, and how its fluctuations relate to independently calibrated experience.

Complex regulation can also improve when complementary mechanisms work together. Hu and Murray (2022) engineered

layered feedback in *E. coli* and found improved joint robustness and response speed under chemical, temperature and nutrient disturbances compared with the component single-layer designs. This gives a concrete reason to investigate coordinated routes. A model linking independently measured layers could predict signed-area recovery, timing and uncertainty across new conditions, with the layers and their coupling specified before the test.

Precision and resource availability can be studied together. Lan et al. (2012) linked adaptation accuracy, response speed and energy dissipation in a sensory-feedback model and tested its implications in *E. coli*. As cells became less energized, adaptation slowed while accuracy was maintained. This finding motivates joint measurement of reserve-related variables, response times and error. Their coupling offers a quantitative target for an affective-regulation model that also includes a calibrated cumulative valence measure.

A recurring response shape becomes more informative when it survives a specified transformation. Fold-change detection predicts that multiplying a sensory input history and its background by the same factor preserves the complete output response (Shoval et al., 2010). Bacterial experiments tested such response rescaling at pathway and population-behavior levels (Lazova et al., 2011). This supplies a useful design precedent: state the transformation, predict the entire dynamical relation, and test its transfer to new conditions without refitting.

Recent control research also makes the variability question more concrete. Lim and colleagues developed a combined molecular

mean-and-noise controller that preserves specified stationary first and second moments under ergodicity and finite-second-moment conditions. Their analysis and simulations extend mean adaptation toward control of output dispersion, with openly archived code for replication (Lim et al., 2026). The study's calibrated simulation of an *Escherichia coli* DNA-repair system illustrates an application of the controller.

For the present program, this creates a stronger executable benchmark: compare candidate routes with controllers that can regulate both the average and the variance, rather than only a set point. A candidate that transports additional joint predictions beyond this richer controller would make a more substantial contribution than one that merely reproduces mean recovery.

21.3.2 — Allostatic Prediction and Load

Allostatic prediction widens the rival by allowing reference ranges and control activity to shift before a demand arrives. Threat, poverty, caregiving, illness, discrimination, and unstable work can produce anticipatory cost while outward behavior appears steady. Apparent stability may therefore be maintained pressure rather than resolved burden (Sterling, 2012; Bobba-Alves et al., 2022).

Allostatic prediction and load should be represented with shifting demands, anticipatory control, channel coupling, and person-specific reserve. A simplified fixed-baseline model would miss the very mechanisms that make allostasis a leading explanation. The Law must compete with the expert version rather than a caricature.

A caregiver may sleep lightly for months because a fall, seizure, or call for help could occur at night. Daytime reports can look stable while anticipatory regulation remains costly. The case gives allostasis an observable structure: expected demand, altered sleep, physiological preparation, and recovery after the caregiving contingency changes.

Allostatic prediction and load require an estimand that distinguishes anticipated demand, current state, cumulative load, treatment, and observation. The protocol should fix the relevant clocks, channels, baselines, missingness rules, and loss before comparison. That common object prevents the favored account from receiving a post hoc advantage.

If anticipatory demand and cumulative allostatic load predict the protected trajectory better than the PTVC-specific account, that pattern is assigned to allostasis. The result may leave a narrower endpoint question open, but it removes preparation, vigilance, and load from the candidate's distinctive evidence. Later summaries must carry the same allocation rather than recovering the lost pattern rhetorically.

Allostatic prediction should be tested by forecasting responses to anticipated demand rather than only reacting to completed events. The protocol must distinguish current state, expected demand, cumulative load, and treatment, then examine whether the model transports when demands change. A successful anticipatory model narrows any fairness-specific interpretation that relied on the same pre-event preparation pattern (McEwen, 1998; Sterling, 2012; Bobba-Alves et al., 2022).

21.3.3 — Viability Without Fairness

Viability models explain how life, function, or action are maintained under constraint. Measuring the accompanying experience allows physiological continuation and felt welfare to be studied together (Bobba-Alves et al., 2022).

Viability regulation should be tested in the form biology actually permits, with shifting baselines, unequal reserves, and multiple coupled channels. A process may preserve function while burden accumulates, and it may fail differently across illness, treatment, disability, and age. That stronger rival is the appropriate comparison for any fairness-specific claim.

An older patient may reduce movement to avoid falls while losing access to valued activities. A useful model represents both the protective effect and changes in loneliness, autonomy, and opportunity, helping identify supports that improve the overall situation.

Viability and fairness can be separated with mechanism-matched observations rather than a broader invasion of private life. Functional reserve, task completion, pain, fatigue, and reported valence may change on different clocks, so the protocol should sample only the channels needed to distinguish them. More data are not more informative when the design never states which divergence would favor viability control over a terminal-closure interpretation.

The viability test places function, survival-relevant behavior, symptom burden, and valence-related observations in a joint model without equating them. It asks whether control actions

preserve performance despite continued adverse experience and whether that relation predicts new contexts. If viability variables explain persistence and adaptation, the result supports ordinary regulation while leaving terminal closure unestablished (McEwen, 1998; Sterling, 2012; Bobba-Alves et al., 2022).

21.3.4 — Frailty and Disease Progression

Frailty and disease progression are leading terminal-window rivals because ordinary biological change can narrow both the latent state and the record. Diminished reserve, fatigue, inflammation, medication, delirium, care transitions, and reduced expressive capacity may all produce a quieter observed trajectory. A terminal curve therefore requires a joint clinical and observation model before it receives PTVC-specific interpretation (McEwen, 1998; Sterling, 2012).

Frailty and disease progression deserve a model that permits nonlinear decline, treatment response, competing events, and state-dependent observation. These features can create apparent terminal concentration without a fairness-specific mechanism. Their inclusion is therefore part of rival adequacy, not an optional complication.

In advanced illness, responsiveness may narrow as fatigue, delirium, medication, and disease progression alter both experience and what can be observed. A quieter record is therefore not self-interpreting. The analysis must separate clinical state, care decisions, sensor availability, report capacity, and the latent quantity the terminal claim concerns.

Frailty and disease progression should be fitted only after the target trajectory, competing events, treatment pathways, observation windows, missingness, and loss have been declared. The PTVC candidate and ordinary clinical rival must answer the same question. A favorable reinterpretation after inspection is not model comparison.

Report frailty and disease-progression findings with the affected cohort, treatment context, observation coverage, and competing events.

Frailty and disease progression require a joint longitudinal, treatment, competing-event, and observation model. Simulation should show that the analysis can recover clinical decline and distinguish it from device loss or reduced reporting before the model is applied to terminal windows. If the apparent contraction is absorbed by those clinical processes, the PTVC-specific signature is withdrawn for the tested cohort (McEwen, 1998; Sterling, 2012; Bobba-Alves et al., 2022).

21.3.5 — Medication and Care Effects

Medication and care effects are not nuisance variables added after theory; they are part of the data-generating process. Analgesics, anxiolytics, antidepressants, sedation, sleep treatment, physical support, and relational care can change reports, physiology, behavior, and sampling availability. Those changes may be humane and necessary, but they can also mimic variance compression or rebound. The analysis must model care as care first and as evidence only after its mechanism has been specified (Sterling, 2012).

Medication and care alter both the trajectory and its visibility. Dose changes, analgesia, sedation, rehabilitation, communication support, and hospice practice can shift symptoms, arousal, reports, and sensor availability on different clocks. Modeling those pathways prospectively can remove an apparent terminal signature before any fairness-specific mechanism is invoked (McEwen, 1998; Sterling, 2012; Bobba-Alves et al., 2022).

A medication change made during palliative care can alter pain, arousal, communication, sleep, and sensor quality on different schedules. The analytic record should place dose, route, indication, symptom response, care goal, and observation availability on a common timeline. Only then can a terminal change be separated from treatment and care effects.

A treatment figure can use a causal timeline to connect medication, indication, care decisions, physiological responses, reported experience, communication capacity, and observation availability. Separate nodes or intervals make time-varying confounding and observation change visible.

Medication and care pathways belong in the model of the observed trajectory and in its later summaries. Preserving their timing and effects makes clinical findings easier to interpret and reproduce.

Medication, symptom, care, and communication variables are collected to separate treatment pathways from candidate mechanisms. They should not be recombined into a private score of burden, compliance, credibility, or prognosis beyond the clinical and research purposes that authorized them. Access

controls and retention rules must reflect the sensitivity of the care record as well as the limits of the inference (McEwen, 1998; Sterling, 2012; Bobba-Alves et al., 2022).

Medication and care effects should be evaluated on a time-aligned causal record that includes indication, dose, route, care goal, symptom state, communication capacity, and observation availability. Randomized variation, natural changes, or target-trial methods can then estimate which divergence occurs first. A pattern that follows care exposure rather than the candidate route belongs to the treatment mechanism (McEwen, 1998; Sterling, 2012; Bobba-Alves et al., 2022).

21.3.6 — Generic Regulation as Default Rival

Living systems stabilize many variables, making homeostasis, allostasis, frailty, treatment effects, mean reversion, and their combinations useful comparison models under shared observations (Bobba-Alves et al., 2022; McEwen, 1998).

The rival must be strong enough to represent expert expectations. A flexible state-space family can include person-specific baselines, nonlinear return, plateaus, latent states, observation error, treatment effects, and changing control regimes. It receives the same information and tuning budget as the PTVC candidate and is judged on model recovery, calibration, held-out prediction, intervention response, and transport. Model discrimination requires a controller that adequately represents those mechanisms.

Data collection should resolve the rival's actual state and control variables rather than demand a maximal dossier. If return rate, set-

point movement, intervention timing, or observation error cannot be estimated without burdensome or speculative measurement, the comparison narrows instead of expanding collection without limit.

The ordinary model must include clinic, household, and care context. Oxygen, opioids, inflammation, delirium, disease stage, caregiver anticipation, and observation-channel changes can move a terminal curve toward quiet without implying a fairness constraint. Allostasis makes the contest harder by allowing anticipated demand to shift the operating range around vigilance or safety (McEwen, 1998; Sterling, 2012; Bobba-Alves et al., 2022).

When generic regulation reproduces held-out state trajectories and intervention responses, those results support the regulatory model for the tested components. The accumulated-path and endpoint targets remain separate questions for the comparison, with their own observations and prospectively specified predictions.

A mainstream control victory classifies a model-data relation, not a life. PTVC remains distinctive only where a prospectively specified joint restriction survives after the strongest ordinary regulatory family has been fully spent.

21.4 — Ornstein–Uhlenbeck State Dynamics

OU dynamics remove ambiguity from mean reversion by specifying drift toward a reference, stochastic innovation, an initial law, and a time scale. The model is simple enough for exact calculation yet rich enough to expose irregular sampling, observation error, hierarchical variation, and parameter confusion. That makes it an executable rival rather than a metaphor (Uhlenbeck & Ornstein, 1930; Øksendal, 2003; Särkkä, 2013).

The OU process is a baseline, not a claim that affect is exactly Gaussian, linear, stationary, or Markovian. Real trajectories may be nonlinear, heteroskedastic, regime-switching, person-specific, treatment-dependent, and only partially observed. Those departures belong in extensions or rival families, while the simple model tests how much apparent balance ordinary mean reversion already creates.

Displayed mathematics earns its place by exposing assumptions and testable consequences. The drift coefficient, innovation scale, initial condition, observation map, and time unit must remain visible enough to estimate, simulate, and challenge; typography is never a substitute for recovery.

Equation 21.1: OU state equation as rival generator

$$dX_t = -\kappa X_t dt + \sigma dW_t, \kappa > 0, \sigma > 0$$

Status: Equation 21.1 is a rival data-generating model for state dynamics. It is not a Law definition, not a measure of a person, and not a statement about cumulative closure.

Equation 21.2: OU conditional mean

$$E[X_t|X_0 = x_0] = x_0 e^{-\kappa t}$$

Status: Equation 21.2 is a prediction for state return under the OU rival. It shows why local recovery can be ordinary without settling the integrated ledger.

21.4.1 — OU State Equation

The OU state equation gives ordinary mean reversion a precise continuous-time form. It defines a signed state, a return rate, a reference, and an innovation scale, making the rival implementable rather than metaphorical. Its simple structure makes smooth returns, shrinking deviations, and stable-looking records quantitatively tractable, providing a useful first comparison for additional trajectory restrictions (Uhlenbeck & Ornstein, 1930).

Hierarchical drift, diffusion, starting state, observation error, and irregular sampling can differ across people and settings. Allowing those differences produces a flexible stochastic baseline that can be compared with PTVC under the same information budget.

Consider a centered daily affect series after a mild event. An Ornstein-Uhlenbeck model can generate apparent return, persistence, and mean-reverting fluctuations from a small set of parameters. The scientific question is not whether the trajectory looks balanced, but whether a prospectively estimated alternative predicts a feature of later paths that the OU process systematically misses.

The OU equation is tested by observations that resolve drift, diffusion, and measurement error at the relevant timescale, not by

adding channels without a model. The likelihood should use the actual irregular intervals and preserve uncertainty about the latent state. When the cadence cannot distinguish mean reversion from smoothing or reporting noise, the OU comparison remains underidentified.

The OU specification is evaluated through its drift, diffusion, covariance, and residual predictions under the protocol-fixed observation model. Successful predictions identify the features explained by mean reversion; departures identify the additional structure that competing models must address. The comparison records the performance of each model on those features (Uhlenbeck & Ornstein, 1930; Gardiner, 2009).

The OU state equation should be fitted with a continuous-time state-space likelihood that uses the actual observation intervals and measurement error. Conditional drift, diffusion, autocovariance, and residual diagnostics must agree with the fitted parameters in protected data. Failure of linear mean reversion or constant diffusion rejects this OU specification; success establishes an ordinary stochastic rival, not a terminal law (Uhlenbeck & Ornstein, 1930; Øksendal, 2003).

21.4.2 — State Mean Reversion

State mean reversion is the visible behavior that makes the OU rival tempting. A deviation decays toward a reference, and the process appears to heal itself even though stochastic shocks continue. This can resemble emotional recovery, clinical stabilization, or terminal quieting. The analysis therefore asks whether state return explains the observed pattern and what

happens to the accumulated path while it does so (Øksendal, 2003; Uhlenbeck & Ornstein, 1930).

Mean reversion is visible in conditional increments: observations above the reference level should tend to move downward, and observations below it should tend to move upward, after accounting for elapsed time and measurement error. That signature can be estimated without invoking a terminal law. The integrated process then asks a separate question about accumulated area.

State mean reversion needs an estimand for return rate, reference level, lag, variance, and prediction horizon before the OU fit is interpreted. Those definitions make it possible to separate a genuine stochastic advantage from a visually persuasive curve.

State mean reversion is tested by relating conditional increments to the current deviation from the estimated reference across several horizons. The return coefficient should transport across protected segments after measurement error and irregular timing are modeled. If the sign or magnitude of drift changes arbitrarily with the window, the simple OU account fails and a richer rival must be named before PTVC is considered (Uhlenbeck & Ornstein, 1930; Øksendal, 2003).

21.4.3 — Stationary and Nonstationary Starts

Stationary and nonstationary starts determine what the OU rival is allowed to claim. A process already in equilibrium behaves differently from one beginning after a shock, treatment change, diagnosis, bereavement, or acute illness. If the start is chosen after looking at the data, the rival can be made to appear better than it

is. The starting condition must therefore be declared before model comparison (Uhlenbeck & Ornstein, 1930).

Stationary and nonstationary starts must be compared without granting either the favorable initial condition by default. Early transients, regression to the mean, and uncertainty about the pre-observation state can all imitate rapid correction. A stricter claim earns attention only if it predicts the consequences of initial-state uncertainty across new trajectories rather than after conditioning on the favorable start.

Two OU processes with identical drift and diffusion can produce different early trajectories when one begins at stationarity and the other begins far from its reference level. That transient can resemble repair or convergence. A fair comparison keeps the starting-state law visible and asks whether the apparent distinction survives after the initial condition is modeled.

A covariance plot should compare stationary and displaced initial conditions under the same OU parameters. The early transient, long-run variance, and uncertainty from the observation model should be visible in separate bands. Its purpose is to show how the start law changes finite-window inference, not to make one initialization look naturally privileged.

Stationary and nonstationary starts are tested under an adverse rule: the candidate account must add a frozen restriction beyond what initial-condition choice already explains. Reserve-linked structure, an integrated-ledger consequence, endpoint discipline, or transported held-out advantage would qualify; mere compatibility would not.

The starting-state law is an inferential choice, not a fact about the person's essential condition. Sensitivity to stationarity or displacement should narrow the model claim rather than invite labels about resilience or chronicity. The ethical response to uncertain initialization is methodological modesty, not stronger surveillance (Uhlenbeck & Ornstein, 1930; Gardiner, 2009).

The stationary-start question should be auditable through the assumed initial distribution, burn-in rule, and sensitivity to displaced starts. A reviewer may challenge stationarity without challenging the OU equation itself, and the report should show exactly which finite-window conclusion changes. That separation keeps initialization from becoming a hidden source of confidence (Uhlenbeck & Ornstein, 1930; Gardiner, 2009).

21.4.4 — Time-Varying and Hierarchical OU

Time-varying and hierarchical OU models give the rival realistic flexibility: drift, diffusion, mean level, starting state, measurement error, symptom regime, and response to care may vary across time and participants. The candidate should not win because a fixed-parameter baseline was made easy to reject; the richer rival must instead pay for flexibility through prospective specification, recovery tests, complexity-adjusted held-out prediction, and transparent parameter interpretation (Øksendal, 2003; Uhlenbeck & Ornstein, 1930).

After a stroke, a person's apparent return rate may change across rehabilitation phases as treatment intensity, fatigue, and motor access evolve. A single fixed OU coefficient can misread that sequence as noise or stable mean reversion. A time-varying or

hierarchical model earns its extra flexibility only if those shifts are estimated prospectively and improve transport.

A time-varying hierarchical OU analysis needs a prospectively specified state, parameter hierarchy, time unit, observation law, censoring rule, and scoring target. Those choices determine what the model is allowed to explain. Freezing them before fitting keeps both rival and candidate attached to one estimand.

When the hierarchical OU family recovers person and population parameters and transports across protected cases, time-varying mean reversion becomes the preferred account for that component. The candidate cannot preserve the same flexibility under another name. Any remaining claim must be expressed as a new joint restriction that the fitted hierarchy does not already satisfy.

When a time-varying hierarchical OU model best explains the observations, summaries and graphics should identify its fitted mean reversion, diffusion, and tested range.

Time-varying and hierarchical OU models should be evaluated with nested recovery: person-level parameters are generated from a population distribution, the observation schedule is reproduced, and the fitted hierarchy is asked to recover both levels. Held-out persons and sites then test transport. Flexibility is accepted only when it improves calibrated prediction rather than merely absorbing every trajectory (Uhlenbeck & Ornstein, 1930; Øksendal, 2003).

21.4.5 — Observation Error and Irregular Sampling

Observation error and irregular sampling often decide whether OU evidence is credible. Sparse reports, missed prompts, device dropout, clinic-only observations, and terminal low-signal windows can create mean-reversion artifacts or hide genuine change. The rival and the PTVC candidate must therefore use the same measurement burden. A model that wins only because it receives cleaner observations has not earned scientific victory (Uhlenbeck & Ornstein, 1930).

Irregular observation belongs inside the OU rival, not in a footnote after fitting. Sampling cadence, device error, dropout, treatment, and state-dependent observation can change the apparent rate and variance of return. A fair comparison therefore lets the rival generate the data as they are actually collected before asking which mechanism is favored.

Consider prompts missed during high distress and devices dropping out during restlessness. The missingness mechanism can make the observed series appear calmer, more regular, and closer to its center than the latent process actually was. The analysis must model response probability and device availability jointly with the state process, then show whether any route-specific signature survives plausible informative-missingness scenarios.

Irregular sampling should be handled through an explicit continuous-time state and observation model, not by interpolating a convenient curve and treating it as observed. The recorded visit process, device gaps, and person-specific cadence belong in

simulation and recovery checks. A model that succeeds only after regularizing away the actual observation pattern has not explained the data that the study collected.

An observation-model failure defeats the inference that depended on that bridge. If irregular sampling, sensor error, or reporting noise can reproduce the apparent advantage, the latent-dynamics verdict is withdrawn until a stronger observation model is validated. The participant record is not blamed for exposing the weakness (Uhlenbeck & Ornstein, 1930; Gardiner, 2009).

Irregular sampling and observation error may reflect burden, care, access, disability, or device limits. An explicit observation model and sensitivity analysis can determine which quantities remain estimable, with No adequate estimate reported where needed (Uhlenbeck & Ornstein, 1930; Gardiner, 2009).

Observation error and irregular sampling are tested by simulating from the fitted continuous-time process on the exact visit and device schedule, then refitting through the declared observation model. Coverage, bias, and model-selection error should be reported as cadence and noise worsen. An OU advantage that disappears under the actual schedule is not evidence for the latent dynamics (Uhlenbeck & Ornstein, 1930; Øksendal, 2003).

21.4.6 — OU as a Model That Can Win

Allowing Ornstein-Uhlenbeck models to win turns mean reversion into a genuine contest. A low-dimensional continuous-time process can reproduce return, autocorrelation, and finite-window concentration without a terminal constraint, especially

under irregular timing and observation error (Uhlenbeck & Ornstein, 1930; Øksendal, 2003; Gardiner, 2009).

The protocol fixes the state equation family, prediction target, horizon, observation and missingness laws, complexity burden, and rival-victory threshold. The OU family may include recoverable person-specific baselines, hierarchical structure, or prospectively fixed regimes, but cannot be either a toy rival or an unlimited family that never loses.

A bounded OU victory requires parameter recovery, conditional-drift and covariance reproduction, calibrated uncertainty, protected prediction, and transport under the common observation process. Parsimony counts only after adequacy; a simple wrong model does not win by simplicity alone.

If OU performs at least as well and the PTVC candidate adds no transported restriction, the ordinary stochastic account owns that component. Fitted parameters remain research objects, not person-level labels of emotional order, reliability, or worth.

The baseline is useful because every choice is inspectable: relaxation, innovation, initial state, time unit, heterogeneity, and change points. Asking whether those ordinary choices already produce the signature gives any surviving PTVC residual scientific meaning.

PTVC earns distinctiveness only through a frozen consequence that remains after this strong but finite ordinary family has been fully fitted and allowed to win.

21.5 — The Integrated OU Ledger

The integrated OU ledger is the chapter's mathematical hinge. If X_t is a mean-reverting state, A_t is its time integral and therefore a different stochastic object: state return can coexist with path-dependent accumulation and long-horizon variance growth. The calculation supplies a baseline that terminal-closure claims must outperform, not a phenomenal conclusion by itself (Uhlenbeck & Ornstein, 1930; Øksendal, 2003; Gillespie, 1996; Särkkä, 2013).

The OU result separates the dynamics of the current state from the dynamics of its accumulated integral. The chosen specification and observation model determine the quantitative prediction to compare with other candidates.

The display begins with a deliberately clean baseline: zero-mean OU, fixed start, continuous time, and no measurement error. Empirical use must then add uncertain initial state, irregular sampling, observation error, treatment, heterogeneity, and model misspecification. The simple derivation reveals the state-integral distinction before those layers are introduced.

State recovery and accumulated experience are complementary quantities. The first describes the current condition; the second records the signed area along the path that produced it.

The integrated OU result gives the comparison a precise task: build the regulatory model, test recovery, and compare its held-out predictions with those of the PTVc candidate.

Equation 21.3: Integrated OU state

$$A_t = \int_0^t X_s ds$$

Status: Definition of the accumulated state in the OU comparison model.

Equation 21.4: Variance of the integrated OU state

$$\text{Var}(A_t) = \frac{\sigma^2}{2\kappa^3} (2\kappa t - 3 + 4e^{-\kappa t} - e^{-2\kappa t})$$

Status: Variance consequence of the zero-start OU model under the stated assumptions.

Equation 21.5: Long-time integrated OU approximation

$$\text{Var}(A_t) \sim \frac{\sigma^2}{\kappa^2} t \text{ as } t \rightarrow \infty$$

Status: Long-time variance behavior of the integrated OU model.

Equation 21.6: Expected integrated OU state from fixed start

$$E[A_t | X_0 = x_0] = \frac{x_0}{\kappa} (1 - e^{-\kappa t})$$

Status: Equation 21.6 is a fixed-start OU consequence. It shows that an initial deviation contributes to the integrated path even while the state mean decays.

21.5.1 — Integrated State Definition

The integrated state definition prevents the integrated OU ledger from remaining a loose reference. It defines the accumulated area under the OU state, not the state value at a single moment. That accumulated quantity is the object that matters when a rival is being compared to a cumulative ledger claim. The definition keeps the chapter from treating a calm present as if it

automatically accounted for the path that preceded it (Uhlenbeck & Ornstein, 1930).

The integrated OU process is itself an ordinary stochastic comparator. It supplies a cumulative-path distribution against which a PTVC candidate must predict an additional restriction. The integral need not be unique to the favored theory to be useful; its role is to show what ordinary mean reversion already implies.

Let the state process describe momentary deviation from its reference and let the integrated state record the signed area accumulated on the declared clock. The two objects have different units, covariance structures, and scientific roles. Naming both prevents state mean reversion from being promoted into cumulative closure by notation alone.

The mathematical display defines the OU state and its time integral on an explicit clock, with units stated for both. A covariance or variance relation shows how bounded state variance can coexist with growing integrated variance under the model's assumptions.

A model contributes by explaining a specified component under shared comparison rules. That result clarifies which features subsequent models can build on and which remain to be explained.

The integrated-state definition should expose its units, integration clock, centering convention, and relationship to the observation model. Disagreement can then focus on whether the state is scalar, whether the clock is appropriate, or whether omitted intervals dominate the path functional. These are technical objections with

corresponding tests, not semantic resistance to the larger project (Uhlenbeck & Ornstein, 1930; Gardiner, 2009).

21.5.2 — Closed-Form Variance

Closed-form variance gives the rival a measurable consequence. Under the declared zero-start OU baseline, the integrated state has a variance expression that can be plotted, simulated, and checked against numerical implementation. A mean-reverting state can have an accumulated integral whose uncertainty continues to grow (Øksendal, 2003).

Parameters estimated from the OU state process imply integrated uncertainty across horizons, enabling a check without refitting each window. Agreement or systematic departure reveals which cumulative features the specified model captures (Uhlenbeck & Ornstein, 1930; Gardiner, 2009).

Closed-form variance is useful only after the target quantity, starting-state law, horizon, parameter regime, and observation error have been fixed. Those choices determine whether the formula addresses finite-window dispersion, long-run growth, or a measured proxy rather than the latent path.

Closed-form variance may defeat a fairness-specific reading without defeating the value of the analysis. When the ordinary result predicts, calibrates, and transports better, explanatory credit stays with it. The chapter preserves the mathematical lesson and narrows the stronger claim.

Closed-form variance should be checked by propagating independently estimated OU parameters into predictions for the integrated process at several horizons. Empirical variance and

covariance, corrected for the observation model, are then compared with simultaneous uncertainty bands. Systematic failure rejects the analytic rival in that regime; agreement removes the pattern from the candidate's unique evidence (Uhlenbeck & Ornstein, 1930; Øksendal, 2003).

21.5.3 — Asymptotic Linear Growth

The OU result illustrates a general distinction between recovering a state and cancelling its accumulated path. For real, centered, covariance-stationary equal-exposure increments X_k with finite second moments, write $A_n = \sum_{k=1}^n X_k$ and $\gamma_h = \text{Cov}(X_0, X_h)$. Counting covariance pairs gives

$$V_n := \text{Var}(A_n) = n\gamma_0 + 2 \sum_{h=1}^{n-1} (n-h) \gamma_h.$$

If $\sum_{h \in \mathbb{Z}} |\gamma_h| < \infty$, division by n and dominated convergence give $V_n/n \rightarrow \ell = \sum_{h \in \mathbb{Z}} \gamma_h = 2\pi f(0)$, using $f(\omega) = (2\pi)^{-1} \sum_h \gamma_h e^{-ih\omega}$. Positive ℓ yields growing cumulative dispersion even though $E[(A_n/n)^2] \rightarrow 0$. For a Gaussian process and fixed $\varepsilon > 0$,

$$\Pr(|A_n| \leq \varepsilon) = 2\Phi\left(\frac{\varepsilon}{\sqrt{V_n}}\right) - 1 \sim \sqrt{\frac{2}{\pi}} \frac{\varepsilon}{\sqrt{n\ell}}.$$

A non-Gaussian central limit theorem with positive limiting variance also makes the fixed-band probability tend to zero, but does not by itself provide this rate. Summable covariances alone do not establish that central limit theorem. These stationary-

process comparisons extend the OU example to wider accumulation architectures.

For stationary AR(1) increments $X_k = \phi X_{k-1} + e_k$, $|\phi| < 1$, with independent centered innovations of variance q , $\ell = q/(1 - \phi)^2$. In contrast, $X_k = e_k - e_{k-1}$ gives $A_n = e_n - e_0$ and $V_n = 2q$. This ordinary cancellation mechanism has bounded cumulative variance while generally retaining a nonzero terminal residual. More generally, an absolutely summable linear filter has $\ell = q(\sum_j h_j)^2$, so zero-frequency cancellation requires its net response to vanish.

For a real centered jointly measurable stationary continuous-time process with finite second moments and covariance $C(u)$, $\text{Var}(\int_0^T X_t dt) = 2 \int_0^T (T - u) C(u) du$. Absolute integrability of C gives the corresponding variance-per-time limit. Keep stationary and zero-start initial laws distinct. Centering a rival mathematically does not identify phenomenal neutrality: subtracting each completed record's own mean forces apparent closure by construction. Compare held-out window-length variance predictions, with dependence, measurement error and unobserved low frequencies included. This can discriminate accumulation mechanisms before complete-stream evidence is available.

21.5.4 — Initial-Condition Variants

Section 21.4.3 fixed the OU starting-state law and the protocol for comparing stationary, displaced, and uncertain starts. The integrated-ledger question is narrower: how that starting law

propagates into the mean and covariance of the time integral over the study window.

With the same OU drift, diffusion, observation law, and horizon, stationary, fixed displaced, post-event, and hierarchical starts can produce different finite-window cumulative means and covariances. The analysis must report which ledger conclusions depend on the start model, first recorded value, or burn-in rule (Uhlenbeck & Ornstein, 1930; Gardiner, 2009; Øksendal, 2003).

Candidate and rival ledger models must share the same starting-state distribution and scoring rule. If a terminal-looking cumulative pattern disappears under a defensible start model, the result is Model-ambiguous rather than support.

Initial-state assumptions describe the beginning of the analyzed window. Reports identify their effect on cumulative estimates and preserve start-model sensitivity in subsequent summaries.

21.5.5 — Worked Calculation and Parameter-Sweep Design

A worked calculation makes the state–integral distinction concrete. Use dimensionless model units, $X_0 = 0$, $\kappa = 1$, and $\sigma = 1$. The OU state variance is $\frac{1-e^{-2t}}{2}$, while Equation 21.4 gives the integrated variance. At $t = 1, 5$, and 10 , the state variances are approximately 0.4323 , 0.5000 , and 0.5000 ; the corresponding integrated variances are 0.1681 , 3.5135 , and 8.5001 . The state variance settles while the integrated variance continues to grow. With the same dynamics but a fixed start $X_0 = 1$, the expected state at $t = 5$ is only 0.0067 , whereas Equation 21.6 gives an expected integral of 0.9933 . These calculations follow from the declared OU model (Øksendal, 2003).

An analytic parameter sweep also shows the role of return rate. Keep $X_0 = 0$, $\sigma = 1$, and $t = 5$. Substituting $\kappa = 0.5, 1$, and 2 into Equation 21.4 gives integrated variances of approximately 9.2864, 3.5135, and 1.0625. At fixed κ and t , doubling σ multiplies the variance by four. Starting-state assumptions matter too: with $\kappa = \sigma = 1$ and a stationary start, the integrated variance at $t = 5$ is $5 - 1 + e^{-5}$, approximately 4.0067, rather than the zero-start value 3.5135. These calculations provide numerical checks for an implementation.

A simulation sweep can hold cadence and the observation rule fixed while varying mean-reversion rate, diffusion scale, starting-state law, horizon, and measurement error. Shared scoring rules then reveal regimes of finite-window contraction, observational ambiguity, and useful model separation.

Testing separation from bridge or reserve-coupled candidates requires fully specified competing generators and a shared observation model. A simulation sweep should measure recovery error and model confusion across drift, diffusion, horizon, and cadence. This comparison can identify where the models are distinguishable (Uhlenbeck & Ornstein, 1930; Gardiner, 2009).

Public summaries of a parameter sweep should report the full pattern across settings, including successful, unresolved, and weak-performance regions.

Any such simulation sweep must be reproducible from a fixed grid, seed set, solver tolerance, and observation schedule. For each regime it should report parameter recovery, model confusion, integrated variance, and which tested design changes improve separation. The sweep passes when another analyst can

recreate both favorable and adverse regions, not only an illustrative panel (Uhlenbeck & Ornstein, 1930; Øksendal, 2003).

21.5.6 — Consequences for Model Comparison

The integrated OU derivation gives the comparison a calculable cumulative trajectory, with explicit dependence on drift, diffusion, horizon, and initial conditions (Uhlenbeck & Ornstein, 1930).

The OU baseline quantifies persistence and mean reversion at the measured scale. A candidate route can specify an additional restriction and test it against that baseline.

Mean reversion of the OU state can coexist with a growing variance of its accumulated integral. These quantitative predictions can be compared under the declared measurement and observation models.

Explicit parameter units, observation errors, windows, censoring rules, and endpoint definitions make the OU calculation reproducible and identify the settings in which it informs model comparison.

The calculation earns no PTVC-specific implication merely by being exact. A candidate route must add a prospectively specified restriction, such as independently measured reserve coupled to drift and innovation, endpoint discipline not built into the path law, or transported held-out advantage. Otherwise the integrated OU process remains the ordinary baseline.

The OU derivation can pressure an interpretation without settling the phenomenal target. If the observed path follows the ordinary variance law, the candidate loses a claimed signature; if it does

not, the OU specification loses that regime. In neither direction does the equation authorize personal prediction, care delay, or a story about why suffering occurred (Uhlenbeck & Ornstein, 1930; Gardiner, 2009).

Reviewers should separate three questions: whether the OU derivation is correct, whether the process approximates the latent state, and whether the observation bridge is adequate at the relevant horizon. A correct theorem can coexist with a rejected empirical model, while an imperfect approximation can remain an informative rival. Reporting these layers separately prevents mathematical correctness from being mistaken for construct validity or measurement adequacy.

The central intuition is concrete. A thermostat can return room temperature to its set point while a meter continues recording how long the room was cold. Likewise, a state can be pulled toward zero while its accumulated area retains history. Present recovery and accumulated exposure are different scientific objects. The same distinction applies when a baseline itself moves: local restoration can coexist with a cumulative history that remains far from zero.

The integral preserves duration as well as sign and intensity, so many small deviations can accumulate even when the current state appears ordinary. Measuring the accumulated path therefore adds information to the description of state recovery. This makes the integral a direct rival discriminator whenever competing theories predict similar state recovery but different accumulated exposure.

21.6 — Generative Rival Comparison

Generative rival comparison keeps the chapter from becoming a taxonomy. Each rival produces latent histories under declared assumptions, passes through the same observation kernel, and is scored by the same protected rule. Only this shared pipeline can show which component a PTVC candidate retains or loses (Gneiting & Raftery, 2007; Vehtari et al., 2017; Yao et al., 2018; Wilson & Collins, 2019; Talts et al., 2018).

The rival set includes set-point adaptation, incomplete adaptation, opponent processes, homeostatic regulation, allostatic load, frailty and illness progression, treatment and care effects, OU state dynamics, integrated OU behavior, and hybrids among them. Some are simple; some are complex. The comparison penalizes unnecessary complexity while refusing weak caricatures.

Each comparator generates the planned observations and is evaluated for recovery and predictive performance under the specified scoring rule. This turns a named mechanism into an executable benchmark.

Hybrid rivals are necessary because real trajectories may combine adaptation, treatment, frailty, allostatic load, observation loss, and mean reversion. They receive declared component structure and complexity penalties rather than unlimited flexibility. A hybrid may win, but it must remain identifiable and capable of losing.

Table 21.1. Model-recovery matrix plan.

True generator	Common confusion	Required diagnostic	Status consequence
Set-point adaptation	PTVC candidate or OU	event-specific return and plateau checks	PTVC-specific language narrows if return explains data
Opponent process	adaptation or rebound story	lag, overshoot, repetition effects	local counterweight replaces closure language
Allostatic model	homeostasis or PTVC candidate	load markers and context shifts	regulation under demand becomes primary
OU rival	PTVC candidate	integrated variance and state-return recovery	ordinary mean reversion can win
PTVC candidate	OU or hybrid rival	reserve-coupled joint restriction and endpoint independence	candidate survives only if recovered under fair rules

Table 21.2. Rival-dominance decision rule.

Dominant rival	What it explains	PTVC-specific consequence	Public-language update
adaptation	local return after events	retire local-return support	describe adaptation, not closure

Dominant rival	What it explains	PTVC-specific consequence	Public-language update
opponent process	lag, overshoot, withdrawal	route rebound to local counterweight	avoid balance language
allostatic model	stability under chronic demand	treat load as regulation cost	name allostatic burden
OU or mean reversion	state return and variance pattern	require integrated residual or withdraw	call mean reversion mean reversion
hybrid ordinary rival	combined treatment, frailty, regulation, report dynamics	narrow to unexplained regions only	remove PTVC-specific status from explained pattern

21.6.1 — Common Synthetic Observations

Common synthetic observations create a fair arena for model comparison. Each candidate sees the same cadence, noise, missingness, endpoint uncertainty, treatment flags, and observation limits. Without that common record, the favored model can win by receiving cleaner data or easier assumptions. The synthetic fixture is therefore a scientific fairness rule, not a decorative simulation (Gneiting & Raftery, 2007).

Common synthetic observations should be generated so that each rival receives the same visible record and no privileged latent channel. The exercise should vary cadence, missingness, noise, endpoint rules, and latent dynamics while preserving equal fitting budgets. A stricter signature is credible only if the same observed

record yields recoverable and transportable differences under that equal-information design.

A benchmark can share the same exogenous event schedule across an OU rival, an adaptation model, an opponent process, a reserve-coupled candidate, and a hybrid world. Each generator produces its own latent response trajectory, which then passes through the common observation and missingness model. Every fitted candidate receives the same observed dataset for that benchmark replicate.

The comparison asks which joint predictions the PTVC candidate adds to common synthetic observations: reserve-linked structure, integrated-ledger consequences, prospectively defined endpoints, or transportable out-of-sample performance. Distinctive predictions make that comparison informative.

A synthetic-data confusion matrix shows which generators the pipeline distinguishes under the chosen assumptions. It can identify improvements to the design before participants are recruited (Talts et al., 2018; Hernán & Robins, 2020).

The synthetic-observation benchmark should make generator coverage and observation-kernel choices inspectable. Critics can propose a missing rival, a harder missingness process, or a dependence structure that changes recovery, and the release should show where that addition enters. A benchmark becomes stronger when disagreement produces a new executable world rather than an unresolvable rhetorical exchange (Talts et al., 2018; Hernán & Robins, 2020).

21.6.2 — Parameter Recovery

Parameter recovery asks whether a model's parameters can be estimated when its generator is known. Realistic simulations reveal which return rates, lags, loads, and variances the proposed observations can recover. These results guide sampling and determine which parameter-level interpretations the subsequent comparison can support (Vehtari et al., 2017; Yao et al., 2018).

Test each generative family for identifiability and estimation bias before cross-model discrimination. Recovery diagnostics show where misspecification could affect the comparison and which design changes improve it.

A recovery study can vary return rate, diffusion, opponent lag, observation error, and missingness while preserving known truth. Bias, interval coverage, multimodality, and nonidentifiability should be reported by parameter and regime. A method that estimates the candidate well but fails on rival parameters creates an unfair downstream contest.

Parameter recovery must be an executable, symmetric test. For every generator, the parameter units, observation law, protected data, tolerances, failure thresholds, confusion rules, and model identity are fixed in advance. Candidate recovery cannot be declared adequate while rival failures are ignored, and no model inherits victory merely because its parameters are easier to name.

Poor parameter recovery is a failure of the estimator, design, or identifiability conditions, not a defect in the people or records from which observations arise. The response is to repair the pipeline, narrow the estimand, or abstain before interpretation. No

amount of public enthusiasm can turn biased recovery into evidence (Talts et al., 2018; Hernán & Robins, 2020).

Parameter-recovery disputes should be tied to identifiability, prior influence, interval coverage, and tolerance by regime. A reviewer can ask whether the sample schedule identifies the return rate but not the diffusion, or whether several parameter combinations yield the same observations. The report should state which uncertainty blocks the downstream comparison and which design change could remove it (Talts et al., 2018; Hernán & Robins, 2020).

21.6.3 — Model Recovery

Model recovery asks a harder question: can the analysis distinguish the true family from plausible alternatives? A set-point model may masquerade as an opponent process, an allostatic shift may look like OU drift, and treatment-related quieting may look like terminal concentration. The confusion matrix makes those substitutions visible. The PTVC-specific interpretation earns space only when the recovery design can tell what generated the pattern (Wilson & Collins, 2019).

Model recovery must confront the heterogeneity and measurement disorder present in the intended study. Parameter variation, missingness, treatment, channel error, and competing generators should be represented in the simulation bank. Recovery across that range tests the pipeline’s readiness for the intended human observations.

Consider a recovery matrix showing confusion between an OU generator and a Law-candidate model under noisy sampling. The

matrix should report which parameter regions, cadences, and missingness levels produce each error, not merely an average accuracy score. If the candidate cannot be recovered under conditions close to the intended study, the correct conclusion is design inadequacy or model ambiguity rather than evidentiary support.

The model-recovery display should be a confusion matrix whose rows are generating families and whose columns are selected or abstained outcomes. Hybrid and open-set generators need their own rows, and uncertainty intervals should accompany the cell rates. The matrix tests the analysis pipeline; it does not classify participants or convert model selection into a human score.

Model recovery fails when the true generator is confused with a rival or when the pipeline is confidently wrong on an open-set world. That failure blocks the corresponding human-data verdict, even if parameter estimates look precise inside the selected model. A later redesign must pass fresh synthetic tests before the component can reenter confirmatory use (Talts et al., 2018; Hernán & Robins, 2020).

Model confusion reveals the resolution of the proposed design. If OU, adaptation, hybrid, and reserve-coupled generators remain indistinguishable, the result identifies where measurements or contrasts need improvement before a mechanism can be selected (Talts et al., 2018; Hernán & Robins, 2020).

Model recovery must fit every prospectively specified family to data from every generator under the planned observation and missingness process. The confusion matrix should include hybrid

and open-set rows, calibrated abstention, and uncertainty across replicates. A human-data verdict is blocked wherever the true family is routinely misclassified or where the candidate receives a structural recovery advantage (Gneiting & Raftery, 2007; Vehtari et al., 2017; Yao et al., 2018; Wilson & Collins, 2019).

21.6.4 — Hybrid Rival Models

Hybrid rival models are necessary because real lives need not be governed by isolated mechanisms. Adaptation, treatment, frailty, allostatic regulation, observation shutdown, and conditioned dynamics may coexist and jointly produce a terminal pattern. The candidate earns force only if it adds transportable structure after those plausible combinations are fitted under the same observation model and complexity discipline.

Consider chronic illness combining adaptation, medication effects, allostatic cost, and frailty. A credible hybrid rival should allow these mechanisms to operate simultaneously and at different timescales, because forcing them into separate models can manufacture a false advantage for the preferred route. The candidate earns distinction only through a joint restriction that the hybrid cannot reproduce under the same observation model.

Hybrid rivals require measurements that identify their interacting components, not an indiscriminate expansion of the dataset. The design should target contrasts that separate adaptation rate, treatment effect, observation shutdown, and any reserve-linked term, while allowing abstention when the components remain aliased. A large record cannot compensate for a design in which several mechanisms produce the same observable path.

A hybrid explanation may combine ordinary mechanisms without implying that persons or streams can be combined. Mixture weights describe a generator inside the model; they are not shares of responsibility, value, or experiential debt. The result remains a bounded account of observed dynamics (Talts et al., 2018; Hernán & Robins, 2020).

Test hybrid mixtures across component strengths ranging from clearly identifiable to nearly aliased. The pipeline should recover components where information permits and report open-set or ambiguous outcomes elsewhere (Gneiting & Raftery, 2007; Vehtari et al., 2017; Yao et al., 2018; Wilson & Collins, 2019).

21.6.5 — Held-Out Prediction

Held-out prediction protects the chapter from fitting stories to completed lives. Frozen models must predict observations not used for fitting, under prospectively specified scoring, calibration, interval-coverage, and clinically meaningful error rules. Training must include realistic heterogeneity in participants, contexts, treatments, channels, and observation schedules while keeping the protected module inaccessible; otherwise a clean holdout score may reflect an impoverished training world rather than a discriminating mechanism (Gneiting & Raftery, 2007).

Consider training on early post-event data and predicting later recovery or another site. The holdout must preserve the distribution shift that matters, such as a different endpoint regime, measurement cadence, or care environment, rather than becoming a random slice of the same trajectories. Transportable advantage is demonstrated by prospectively specified performance and

calibration on that protected target, not by retrospective refitting after failure.

Held-out prediction depends on protected information boundaries and mechanism-relevant inputs, not on collecting every signal before the split. The training module, tuning module, and final holdout should be separated by person, site, time, or endpoint window as the dependence structure requires. Features created with future or terminal information must be excluded before any score is called prospective.

The result should change language before it changes allegiance. When held-out prediction accounts for the observed pattern, the chapter calls it by that name rather than translating resemblance into support. What remains for the Law is a residual, prospectively specified question, not a saved conclusion.

Failure on a held-out site or cohort narrows transport; it does not mark that population as anomalous or less credible. The report should identify the shifted measurement, care, event, or context process and preserve the possibility that the model rather than the people failed. Human standing is invariant to predictive performance (Talts et al., 2018; Hernán & Robins, 2020).

Held-out prediction requires a frozen pipeline and splits respecting person, site, time, and endpoint dependence. Report proper scores, calibration, and residual structure alongside average loss, with no feature built from the protected outcome. Treat an advantage confined to random observation-level splits as insufficient evidence of transport, and investigate leakage,

dependence, and distribution shift (Gneiting & Raftery, 2007; Vehtari et al., 2017; Yao et al., 2018; Wilson & Collins, 2019).

21.6.6 — Rival Dominance

Rival dominance tells when ordinary mechanisms narrow or retire a PTVC-specific interpretation. It requires reliable held-out results, recoverable parameters, transport, and no hidden ethical or measurement advantage. Then narrowing is scientific progress (Vehtari et al., 2017; Yao et al., 2018).

Competitive implementations govern the contest. Each model gets defensible heterogeneity, observation structure, and tuning freedom before complexity penalties and held-out scoring. A Law-specific route narrows when an ordinary rival wins fairly.

Repeated outperformance by adaptation, allostasis, or an OU process changes the program. The candidate is narrowed, redesigned, or retired for the declared class, with each consequence tied prospectively to replicated performance rather than answered by new unmeasured structure.

Dominance requires equal information and scoring, not greater surveillance. Every candidate shares the admissible history, missingness, and transport conditions. Unequal context or endpoint access diagnoses the contest, not the mechanism.

The comparison reports predictive accuracy, mechanism identification, calibration, and measurement performance separately.

Dominance is a protocol-fixed scientific relation, never a hierarchy among people. It can retire a mechanism or narrow a

class while care, rights, privacy, and participation remain unchanged; the winning model remains correctable (Talts et al., 2018; Hernán & Robins, 2020).

Recovery, calibration, held-out prediction, transport, uncertainty, and multiplicity share one decision table. Mixed results remain component-specific rather than becoming a single winner label.

One shared observation file gives every model the same simulated streams, events, treatments, missingness, censoring, noise, and endpoint uncertainty. No candidate receives latent truth while another receives the messy record.

Recovery rehearses interpretation. A pipeline unable to recover opponent or OU generators from realistic synthetic observations cannot declare those rivals defeated in empirical data. Confusion matrices, calibration checks, and frozen fixtures expose the weakness before participants carry its cost.

21.7 — Empirical Separation and Defeat

The empirical comparison links cumulative behavior, independently estimated reserve, endpoint structure, observation robustness, and protected prediction. Joint restrictions across these features give PTVC a specific contribution to evaluate alongside established regulatory models (Talts et al., 2018; Hernán & Robins, 2020; Munafò et al., 2017; Nosek et al., 2018; Wilson & Collins, 2019).

A clear comparison assigns observed patterns to the models that predict them best, including adaptation, care pathways, and ordinary stochastic dynamics. This connects scientific interpretation with reproducible reporting.

Adverse outcomes are classified by the component they reach. A failed discriminator retires that signature; repeated component failures narrow a route or reference class; a gate-valid counterresult may pressure or defeat the declared branch. Each outcome identifies a concrete next step for the program.

Later summaries should retain the mechanism, observation model, and setting identified in the original result. Consistent attribution makes findings easier to compare and extend.

Accurate defeat language is a form of care. When scientific scope narrows, captions, summaries, guides, and public replies narrow with it. The project should prefer a clean loss over an unsafe sentence preserved by ambiguity.

21.7.1 — Reserve-Coupled Joint Restriction

A reserve-coupled restriction links independently estimated reserve with drift, innovation, horizon, and cumulative behavior. Estimating reserve through separate observations makes the joint prediction testable.

The reserve-coupled joint restriction should be compared with ordinary mechanisms that can mimic each component separately. Adaptation may reproduce the state path, prognosis may reproduce the shrinking horizon, and selection may reproduce endpoint concentration. The joint restriction matters only if their combination is recovered and transported when those ordinary mechanisms are allowed to mimic each component.

The reserve-coupled candidate should be tested on simulations in which reserve is observed imperfectly, acts only through a declared transition law, and competes with ordinary regulation. The joint restriction must predict more than a smooth endpoint. It should constrain how reserve, state, covariance, action, and endpoint risk move together in held-out modules.

A graphical model can show reserve, observed state, latent valence-related state, actions, endpoint hazard, and measurement channels as distinct nodes. The candidate restriction should be highlighted only on the edges it actually constrains, while ordinary causal paths remain visible. This prevents the reserve route from acquiring information or authority that the protocol did not supply.

The reserve-coupled joint restriction must not absorb a rival victory by redefining the restriction after the result. Its component

predictions, allowable rescue conditions, and target consequence are frozen beforehand. A winning ordinary account remains a winning ordinary account.

Reserve variables represent specified relationships among state, action, and endpoint risk within the approved research model and purpose (Talts et al., 2018; Hernán & Robins, 2020).

The reserve-coupled restriction should expose the operational definition of reserve, its causal parents, its observation channels, and the endpoint information allowed at each time. Reviewers can then challenge route-state validity or endpoint coupling without disputing every other component. The text should identify the observation or intervention that would decide each objection (Talts et al., 2018; Hernán & Robins, 2020).

21.7.2 — Prospective Endpoint Independence

Define the endpoint rule through independent channels before evaluating the accumulated trajectory. Compare candidates using the same prospective endpoint information, with death and observation loss represented according to their distinct roles (Hernán & Robins, 2020).

Prospective endpoint independence prevents the analysis from learning the ending before it predicts the path. Hazard models, feature construction, and data splits must use only information available at the declared decision time. If a signature disappears when terminal knowledge is removed, it has not been established as a prospective signature under that information set. Conditioning and selection become primary rival explanations; distinguishing them from a causal endpoint-coupled route

requires the declared joint model and additional discriminating evidence (Aalen et al., 2008; Hernán & Robins, 2020).

Prospective endpoint discipline fixes the pre-endpoint information set and audits when endpoint information enters the analysis. Statistical endpoint independence is a separate, branch-specific claim involving the endpoint-time law, risk interval, observation process, and declared dependence structure; it requires its own identification and diagnostics.

Reports should identify any dependence on realized endpoint information. A revised endpoint rule receives a new version and fresh evaluation, keeping the original result and its assumptions traceable.

Endpoint-hazard features and independence diagnostics are used to choose the correct scientific branch, not to forecast an individual's death, inner balance, or entitlement to intervention. Person-level outputs should remain restricted, and public artifacts should present aggregate or synthetic diagnostics whenever feasible. The endpoint firewall applies to deployment as well as estimation (Talts et al., 2018; Hernán & Robins, 2020).

Statistical endpoint-independence claims are tested separately with a hazard model and feature set frozen at each decision time. Diagnostics assess whether residual endpoint risk remains associated with past state, treatment, observation, or route variables after protocol-fixed adjustment, while simulations quantify power against plausible dependence. Evidence of coupling changes the branch; lack of identification yields

abstention rather than an independence claim (Talts et al., 2018; Hernán & Robins, 2020).

21.7.3 — Integrated-Ledger Consequence

Integrated-ledger analysis compares accumulated behavior across OU, adaptation, allostatic, and PTVC models under the same observation rules. Their joint predictions show which aspects of path history each account explains.

The integrated-ledger consequence must be tested across plausible starts, sampling schemes, and participant-specific dynamics. Fixed and stationary initial conditions, hierarchical parameters, observation error, and treatment changes can alter finite-window behavior without changing the rival's basic mathematics. The candidate Law should be asked to outperform that full family rather than a single textbook path.

During caregiving, daily distress, event-triggered spikes, sleep disruption, and accumulated vigilance may follow different trajectories. Specifying the path functional and observation coverage helps distinguish accumulation from memory, sampling, and scale effects.

The integrated-ledger consequence is tested by resolving the state path and observation law that determine the integral, not by treating a person's life as an unlimited data source. Cadence should be dense only where it materially reduces uncertainty in the path functional, and unobserved intervals must remain represented rather than silently filled. The analysis should report how much of the apparent distinction survives coarser, less burdensome sampling.

The integrated-ledger consequence is where state recovery and path closure finally separate mathematically. A mean-reverting state can keep returning while its time integral retains variance and history. Testing that path functional across horizons asks whether the candidate adds a joint restriction beyond ordinary return, rather than treating a calm final state as evidence about the accumulated stream (Uhlenbeck & Ornstein, 1930; Gardiner, 2009).

Recent control research shows how integrated responses can distinguish mechanisms. Gupta and Sontag (2025) studied cumulative dose response, the integrated output over a fixed interval as a function of input dose, motivated by immune-cell response data. The incoherent feedforward models they analyzed impose monotone cumulative responses even where instantaneous responses can be nonmonotone; their integral-feedback model can produce a nonmonotone cumulative relation. Thus the area can distinguish mechanisms that a final level or single response peak leaves unresolved. A concrete next step is to compare cumulative-response predictions on existing data from independently justified studies, using independently calibrated response variables, common horizons, and the same observation information for each regulatory model.

If ordinary integrated dynamics explain the observed path, that result identifies the relevant generator and helps refine the next comparison (Uhlenbeck & Ornstein, 1930; Gardiner, 2009).

The integrated-ledger test estimates the state dynamics and the signed path functional under one clock, then compares their joint mean, variance, and covariance across horizons. Ordinary mean

reversion should be allowed to explain state return while the candidate is scored only on an additional frozen path restriction. A distinction that vanishes after observation error or initial-state uncertainty is included remains unresolved (Talts et al., 2018; Hernán & Robins, 2020).

21.7.4 — Observation-Model Robustness

Observation-model robustness ensures that a separation result is not an artifact of how the data were seen. The comparison must survive alternate assumptions about missingness, treatment, frailty, device drift, reporting changes, and low-signal terminal windows. Sensitivity to observation assumptions identifies a measurement question that the next study must resolve before claiming mechanism separation (Talts et al., 2018; Hernán & Robins, 2020).

Robustness across observation models evaluates the reliability of a measurement bridge, not the credibility of the participant. A channel that performs poorly may require recalibration, narrower use, or withdrawal, while reports and care needs retain their independent standing. No device-quality or model-sensitivity result becomes a score of inner truth (Talts et al., 2018; Hernán & Robins, 2020).

Implementation: refit the frozen comparison across the prospectively specified channel kernels, calibration maps, error bounds, and missingness laws, then report the region in which model ordering, calibration, and verdict remain stable (Talts et al., 2018; Hernán & Robins, 2020).

21.7.5 — Out-of-Sample Advantage

Out-of-sample advantage is the practical threshold for scientific seriousness. The PTVC candidate must improve prediction or calibration beyond complexity penalties in data it did not use to fit itself. The advantage should appear in the right variables, at the right timescales, and under the right endpoint firewall. Otherwise, the additional theory is not earning its cost (Hernán & Robins, 2020).

Out-of-sample advantage must be earned against rivals given the same training record, tuning freedom, and protected holdout. One favorable split is not enough; calibration, uncertainty, and failure modes must be reported across prespecified replications. The relevant question is whether the advantage persists across sites, endpoint regimes, and perturbations without access to information unavailable to the rivals.

A persuasive transport example trains the candidate and its rivals in one set of sites, freezes every preprocessing and tuning choice, and evaluates them in sites with different cadence, care practice, and event mix. The result should show not only score differences but calibration and failure by stratum. Transport is earned when the advantage survives those shifts without widening the information budget.

The transport figure should compare held-out proper scores and calibration across sites, cohorts, and endpoint windows after all models are frozen. Complexity penalties and uncertainty should appear beside the point estimates, with failures rather than only

averages shown. The figure supports an out-of-sample comparison, not a universal ranking of theories or people.

Out-of-sample advantage loses meaning if the favored model, metric, or holdout changes after scoring. The protected module, complexity budget, and consequence rule must remain fixed. That discipline turns a good score into evidence rather than an editorial preference.

A held-out predictive advantage changes the status of a model only within the frozen target, population, and observation system. It cannot become a personal forecast, a judgment of credibility, or a reason to expand data collection beyond consent. The public summary should state the gain, uncertainty, transport domain, and remaining unresolved target in the same breath (Talts et al., 2018; Hernán & Robins, 2020).

Disagreement about out-of-sample advantage should be traceable to the split, dependence structure, scoring rule, complexity allowance, or transport population. Each choice can be varied through a protocol-fixed sensitivity plan, and the conclusion should show where model ordering changes. This turns broad skepticism into an explicit map of robust and fragile claims (Talts et al., 2018; Hernán & Robins, 2020).

21.7.6 — Defeat by Mainstream Explanation

Defeat by mainstream explanation is an honorable scientific outcome. If adaptation, opponent processes, allostasis, OU dynamics, treatment effects, frailty, observation processes, or their hybrids explain the protected patterns better, the PTVC-specific interpretation narrows or retires for that domain. Care

remains untouched, and the program retains the measurement, comparison, and clinical knowledge produced along the way (Talts et al., 2018).

Defeat must be operationally possible. The ordinary rival suite receives defensible flexibility and faces the same prospectively fixed state, path functional, endpoint rule, channels, missingness model, information budget, and held-out loss. It wins when it recovers reliably, predicts and calibrates at least as well, transports at least as well, and explains the conjunction more parsimoniously.

The decision retires or narrows the exact component that lost and names the winning family, tested domain, uncertainty, and consequence in the headline-level summary. A new route requires a new prediction and fresh protected evidence rather than relabeling the winner as how fairness acted.

The distinctive burden is conjunctive: independently estimated route variables where relevant, prospective endpoint definition, accumulated-path consequences, resistance to observation alternatives, and out-of-sample advantage after complexity control. A mainstream account that explains the pattern without that conjunction changes the claim's status.

Defeat propagates through later chapters, summaries, figures, and public artifacts. Useful care or measurement lessons remain, but a defeated resemblance cannot survive as implied support. A science that can lose precisely becomes more capable of earning support.

Chapter 22 — Predictive Processing and Learning Rivals

This chapter asks which commitments make predictive-processing, active-inference, reinforcement-learning, safe-control, bridge, and selection accounts empirically distinguishable under the same observation stream. The objective is not to borrow their vocabulary for PTVC, but to force each account to state protected predictions, information requirements, and failure conditions before comparison (Rao & Ballard, 1999; Friston, 2010; Sutton & Barto, 2018; Lageman et al., 2026; Samara, 2026).

These families can generate many PTVC-like appearances. Prediction error can fall. Policies can change after pain. Controllers can avoid states with poor return options. Conditioned processes can drift toward an endpoint already built into the probability law. Clinical samples can concentrate because referral, treatment, survival, and observation jointly selected the record. Each mechanism deserves a fitted, testable form.

A theory name is not a competitor. Each rival must declare its predictand, latent states, observations, error proxy, uncertainty, pathways, policies or actions, objective, endpoint relation, and discriminating prediction. It threatens PTVC only when this executable specification reproduces the relevant pattern and predicts protected data better under equal rules (Samara, 2026; Lageman et al., 2026).

Predictive processing provides models in which perception and action depend on expectations and prediction errors. Such models can explain why familiar contexts reduce alarm, why attention follows uncertain signals, and why some disturbances become less salient. Those achievements belong to prediction and

perception unless an additional bridge connects them to the cumulative phenomenal target.

Reinforcement learning supplies a different rival architecture. Reward prediction errors, exploration, memory, planning, and horizon length can reshape behavior and reports over time. Reward remains a model variable, not an automatic measure of felt valence, and policy adaptation remains distinct from closure of a phenomenal ledger.

Safe and constrained controllers can avoid danger, maintain viable states, and preserve future options. Specifying their constraints, feasible actions, state information, controller class, and observation process turns these abilities into executable comparisons.

PTVC is stronger than local error reduction, policy adaptation, or safety maintenance. Its latent target concerns a completed conscious stream, while its empirical burden concerns measurable consequence structures under uncertainty. The comparison therefore defeats rivals through predictions and recovery, never through labels that merely sound less profound.

The comparison uses one common observation room. PTVC candidates and every computational rival receive the same channels, cadence, calibration, missingness, endpoint information, action availability, tuning budget, and protected scoring. No model receives oracle access or a simpler measurement problem.

Every skeptical branch remains live. A predictive, learning, control, conditioning, or selection model may win; several models

may remain nonseparable; every listed model may fail absolute-fit or open-set checks. Each result changes the next design and PTVC scope without becoming a judgment about the participant.

Two positive contributions follow. Computational rivals receive enough structure to win, and any surviving PTVC-specific remainder becomes explicit enough for a new test. A residual after fair comparison is a research target, not a trophy.

Technical depth is earned because the rivals are technical. Equations and tables expose commitments that prose can hide: a generative equation defines a model, a scoring rule defines a comparison, and a bridge defines a conditioned process. None acquires target-level warrant from mathematical elegance. Formalization also reveals when two rivals differ only by parameterization, preventing redundant models from being counted as independent explanatory alternatives.

These rivals supply the model families later inference and red-team chapters must adjudicate. The sequence matters: specify the model and observation interface first, then test recovery, separability, and protected prediction. Adjudication cannot rescue a rival that was never made executable. A sealed recovery benchmark should precede substantive comparison, showing that the pipeline can identify each rival when that rival generated the data.

Comparisons identify the mechanisms that best account for each observation and the features that remain unexplained. Unexplained residuals should be carried forward as targets for the next comparison rather than automatically assigned to PTVC.

22.1 — Predictive Processing and Error Dynamics

Predictive-processing accounts begin with a structured claim: observations are interpreted through learned expectations, hierarchical latent states, precision weighting, attention, bodily context, and prediction errors. A hallway sound, symptom, or social cue is not processed as raw input; its effect depends on what the system expects and how uncertain that expectation is (Rao & Ballard, 1999; Friston, 2010; Clark, 2013; Seth, 2013; Samara, 2026).

That makes predictive processing a powerful rival because many changes in felt experience can arise from changes in expected input, precision, attention, and model revision. A signal that once dominated consciousness may soften when it becomes predictable. A familiar routine may reduce arousal. A threatening uncertainty may become less intense when the world begins to make sense (Clark, 2013; Friston, 2010; Hodson et al., 2024).

These dynamics can make distress fall, variance narrow, and attention reorganize without any commitment to cumulative terminal neutrality. The section therefore asks which prospective prediction follows from the computational model and which residual, if any, requires a different target-level explanation.

Prediction success is not felt goodness. A model can predict a harmful environment accurately while the stream still carries fear, vigilance, humiliation, or pain. Accuracy may reduce surprise without reducing the burden that matters to the person.

Equation role: Rival generative template. For a fixed action sequence, this equation defines a hierarchical observation model for comparison.

$$p_{\theta}(o_{1:T}, s_{1:T} \mid a_{1:T-1}) = p_{\theta}(s_1) \prod_{t=1}^T p_{\theta}(o_t \mid s_t) \prod_{t=1}^{T-1} p_{\theta}(s_{t+1} \mid s_t, a_t)$$

Equation role: Prediction-error diagnostic. This loss measures precision-weighted error inside a rival model, not felt value or terminal neutrality.

$$L_{PE} = \sum_{t=1}^T (o_t - \delta_t)^{\top} \Pi_t (o_t - \delta_t)$$

Table 22.1. Predictive-processing rival components.

Component	What it models	How it can mimic a PTVC-like pattern
Latent state	Hidden causes inferred from observations	A cause estimate stabilizes and the observed signal looks repaired
Prediction error	Difference between expected and observed input	Error declines after repeated exposure, producing apparent relief
Precision	Weight assigned to an error channel	Attention narrows or quiets without cumulative closure
Model revision	Learning of hidden causes over time	A new expectation changes reports and arousal

22.1.1 — Hierarchical Generative Models

A hierarchical generative model treats observation as the visible edge of a hidden process. Higher levels predict lower-level

causes, lower levels return residual errors, and the system updates beliefs when the world does not fit. Rao and Ballard's predictive-coding tradition made this architecture concrete for visual cortex, but the logic travels more broadly as a modeling family (Rao & Ballard, 1999; Friston, 2010; Clark, 2013; Seth, 2013).

Nothing here requires every cortical circuit to implement one canonical predictive algorithm. The relevant fact is that hierarchical models can generate settling, salience, and surprise reduction without invoking terminal fairness. A noisy scene can feel calmer because the system learned its causes, and that ordinary explanation deserves its own test (Clark, 2013).

The data object is not the person. It is a sequence of observations, latent state estimates, prediction errors, and precision weights. In a phone-based affect study, for example, a participant's report after a repeated alarm may change because the alarm is now expected, not because a burden has been balanced across the life.

A simple rival template defines latent states, observations, and a predictive distribution. The model's work is to minimize expected discrepancy between observation and prediction under its current beliefs. If that work explains the trajectory, the terminal-closure-specific interpretation must retreat from that component.

The failure case is overreach by abstraction. A researcher may see error decline and write as if the felt stream has been repaired. That would confuse a model's epistemic success with a person's relief. Good reporting keeps the two apart, especially in trauma, illness, and coercive settings where accurate prediction may accompany continuing harm.

The comparison rule is direct: predictive-processing rivals must predict the same observations the PTVC candidate uses, not a simplified mood curve. When the hierarchical model explains report shifts, physiological settling, and attention change under held-out data, the result belongs to predictive processing unless a separate terminal-closure-specific residual remains.

A decisive benchmark should vary hierarchy depth rather than assume it. Recent work on testable predictive-processing explanations argues for explicit minimal commitments that connect abstract predictive language to discriminating design and reporting choices (Samara, 2026). Shallow models may explain rapid sensory accommodation, while deeper models may be needed for social expectations, interoceptive beliefs, and context-dependent affect. The comparison should ask whether the apparent long-range pattern survives after each level is allowed its own learning rate, volatility, and precision. If a deeper predictive hierarchy absorbs what looked like cumulative closure, the result favors a richer ordinary learning account. If a stable residual remains across plausible hierarchical specifications and transports to held-out contexts, that residual becomes a sharper scientific target rather than a remainder defined by model weakness (Clark, 2013; Hodson et al., 2024).

22.1.2 — Prediction Error and Affect

Prediction error is the difference between what the model expected and what the world delivered. In affective life, that difference may matter because unexpected pain, unexpected relief, unexpected rejection, or unexpected safety can change what experience feels like. The rival begins with this measurable

relation between expectation, outcome, and affect (Rao & Ballard, 1999; Friston, 2010; Clark, 2013; Seth, 2013).

Momentary happiness already has quantitative experimental models. Rutledge et al. (2014) combined repeated happiness reports with a monetary-choice task and neuroimaging in twenty-six participants, then replicated the behavioral model in 18,420 smartphone participants. Recent expectations and reward prediction errors predicted reported happiness better than current task earnings alone. Blain and Rutledge (2020) subsequently separated reward magnitude from learned win probability in seventy-five participants: in that task, learning-relevant probability errors accounted for happiness better than prediction errors in learning-irrelevant reward magnitudes. These results show that the temporal organization of expectations and outcomes can be measured and tested against feeling.

The question is whether affect tracks raw error, signed error, precision-weighted error, changes in uncertainty, or a more complex appraisal of bodily and social meaning. A familiar hospital sound may stop startling one person while the same sound keeps another awake because it predicts bad news. The sign and context of error matter (Friston, 2010; Hodson et al., 2024).

Expected money and expected feeling can contribute different learning signals. In a repeated social-exchange task with 41 participants, Heffner et al. (2025) measured both expectations before outcomes and recorded EEG. Differences between expected and reported emotion were associated with subsequent choices, especially early in learning about a partner. Reward discrepancies more consistently tracked the feedback-related

negativity, while emotional discrepancies more consistently tracked the later P3b response; P3b activity was also linked to subsequent choice. This gives a temporal affect model two experimentally distinguishable inputs. Recording what people expected to receive and how they expected to feel makes the evolving relation between events, appraisal, and action more directly testable.

Prediction can reduce uncertainty while leaving other aspects of experience unchanged. A patient may understand a diagnosis more clearly while still needing support for fear, discomfort, and practical demands.

A rival model can represent affective change as a function of prediction error and precision. The empirical test should ask whether changes in reported burden, arousal, attention, and behavior follow these error terms across time. If they do, the rival has earned explanatory space.

The hostile quotation risk is subtle. A sentence such as error reduction feels good can be cropped into a claim that adaptation to harm is good. The chapter's local language should say something stricter: error reduction may reduce one component of distress while leaving the burden of the condition morally and scientifically visible.

After fitting a prediction-error model, compare its account of cumulative paths, endpoint-independent signatures, reserve-linked relationships, and cross-context patterns with the additional predictions of PTVC.

Better-than-expected and worse-than-expected outcomes can have different temporal profiles, bodily signatures, and learning consequences even when their absolute magnitudes match. A protocol can estimate these asymmetries and compare the contributions of surprise, valence, controllability, and their interactions to immediate feeling and later adaptation (Friston, 2010; Hodson et al., 2024).

The mapping is also experimentally discriminable. In two experiments involving three hundred participants, Forbes and Bennett (2024) found that the affective influence of negative reward prediction errors depended on free choice and the absence of counterfactual feedback; positive prediction errors did not show a significant effect in their analyses. This contextual result supplies three useful design variables: agency, outcome sign, and information about unchosen alternatives. Their interactions can be specified in advance and tested in held-out conditions.

22.1.3 — Precision and Attention

Precision is the model's estimate of how much weight an error deserves. A small error with high precision can dominate experience, while a larger but unreliable signal may be ignored. This gives predictive processing a refined account of why some burdens become loud inside consciousness and others pass quietly (Rao & Ballard, 1999; Friston, 2010; Clark, 2013; Seth, 2013).

Attention can be modeled as precision control. The organism does not simply receive errors; it allocates gain. A veteran in a crowded grocery store, a parent waiting for a medical call, or a student after a public humiliation may experience ordinary cues as unusually

salient because the model gives those channels high precision (Hodson et al., 2024).

Precision-weighted prediction systems can repeatedly direct attention to cues that remain uncertain or action-relevant. This provides a concrete model of recurring attention and state allocation.

The rival should therefore be implemented with precision parameters, attention allocation, and channel-specific uncertainty. A model that can explain recurrent salience, avoidance, physiological arousal, and report changes through precision dynamics has not merely used a metaphor; it has supplied a data-generating competitor.

A recurring cue can be studied through attention traces, the person's account, and contextual observations. Precision remains an estimated model parameter whose interpretation depends on these channels.

If precision dynamics explain the pattern, the terminal-closure-specific interpretation should not treat the same event as evidence of unresolved burden. The honest result may be that attention and uncertainty, not terminal fairness, produced the path. That is a rival victory, and it should be recorded as such.

Precision should be independently estimated or varied through benign, consented tasks where feasible. Cue reliability and neutral attentional demands can distinguish a precision mechanism from a retrospective label for salience. Threat-related contrasts must use existing data or naturally occurring variation within Chapter 3's safeguards, not induced threat for Law-specific evidence. The

comparison tests whether constrained precision parameters predict held-out responses and whether the closure candidate adds a further transported restriction (Friston, 2010; Clark, 2013).

22.1.4 — Learning and Model Revision

Predictive systems learn. They revise generative models when repeated evidence makes old expectations unreliable. This is why a first panic in an elevator may differ from a tenth ride after successful treatment, and why a first night in hospice differs from a later night when routines and caregivers are known (Rao & Ballard, 1999; Friston, 2010; Clark, 2013; Seth, 2013).

Model revision can create relief by changing expected causes. It can also create burden by teaching a person that the world is unsafe. A child who learns that shouting predicts danger has not achieved balance because the prediction became accurate. The model may have improved while the life became heavier (Clark, 2013; Friston, 2010).

For the rival, learning is not decorative. It must specify update rates, priors, volatility, context changes, and the time scale over which the generative model changes. A single observation can surprise; repeated observations can alter the structure that makes surprise possible.

The empirical design should separate rapid error reduction from slower model revision. Experience sampling, passive context, and task-based uncertainty measures can help identify whether the system merely habituated to a cue or changed its beliefs about the hidden causes behind that cue.

A common failure is to call every model revision repair. Some revisions are costly adaptations to unsafe conditions. The chapter keeps repair as a lived-experience and trajectory question, not as a synonym for learned prediction. A person can learn a dangerous world perfectly and still deserve rescue from it.

The decisive prediction must be prospectively specified at the level of latent variables, observation channels, timing, and protected scoring. A post hoc story about prediction error can fit almost any pattern; an executable model must risk a different forecast than its competitors.

Model revision should also be tested for renewal and context specificity. A response that appears extinguished in one room, relationship, or physiological state may return when the context changes. That pattern is expected under many learning accounts and can imitate incomplete repair. Longitudinal designs should therefore include context transitions, reinstatement probes, and volatility changes rather than treating a smooth training curve as a permanent transformation. If the effect renews exactly where a learned model predicts, ordinary learning receives the credit. If the hypothesized cumulative relation remains invariant across those transitions, the closure program has identified a more demanding target (Sutton & Barto, 2018; Gershman, 2018).

22.1.5 — Predictive Success Versus Felt Value

Predictive success concerns how well an internal model anticipates events. Felt value concerns how those events are experienced. Studying their relationship connects changes in

expectation with the temporal pattern of lived valence (Rao & Ballard, 1999; Friston, 2010; Clark, 2013; Seth, 2013).

A practical example separates prediction from wellbeing. A caregiver learns exactly how long a benefits office will place her on hold, which forms will be rejected, and which phrase will trigger another transfer. Her predictions improve. Her burden does not therefore become lighter, and the institution has not become fair (Friston, 2010).

Prediction may reduce surprise while administrative labor, fear, and fatigue continue. Measuring both expectation and experienced burden helps identify which part of the situation has changed.

Reporting connects predictive adequacy with experiential interpretation: the model's forecast is evaluated against the observation, and the observation's meaning is specified through the measurement model.

PTVC's possible role requires separating predictive success from felt value. If the target is cumulative felt trajectory, ask whether the rival explains that trajectory rather than merely forecasting accompanying observations.

The separation can be made operational by scoring two outcomes independently. One score evaluates forecasts of reports, behavior, physiology, and context; the other evaluates the adequacy of the proposed bridge from those observations to the declared experiential estimand. High predictive accuracy with a failed bridge is not evidence about cumulative felt value. Conversely, a defensible experiential estimate with poor forecasting does not

validate the generative model. Reporting both prevents a single metric from absorbing epistemic success and phenomenal interpretation. It also makes partial victories visible, which is essential when the same model can predict a person accurately while misunderstanding what the prediction means (Gneiting & Raftery, 2007; Hernán & Robins, 2020). A third report column can state whether disagreement between predictive and bridge scores changes only the generative model, only the measurement bridge, or both.

22.1.6 — When Predictive Processing Wins

Predictive processing wins locally when explicit states, observations, precision, update rules, and held-out performance explain the targeted signature better than the terminal-closure-specific candidate. It need not explain every life; it must win the declared study under equal observation and model-recovery rules (Rao & Ballard, 1999; Friston, 2010; Clark, 2013; Seth, 2013). Local victory should be tested for transport before it becomes a general explanatory claim, because predictive success may depend on one task or care context.

In a terminal-room routine study, familiarity, lower novelty, medication timing, caregiver continuity, and precision-weighted expectation may explain reduced arousal. The result should then be reported as predictive and contextual stabilization, with any humane gain credited to reduced uncertainty or threat rather than terminal neutrality (Hodson et al., 2024; Clark, 2013). A corresponding negative control can test whether similar stabilization appears in nonterminal periods with comparable familiarity and care structure.

The victory rule is fixed before results: predictive superiority narrows the relevant PTVC-specific mechanism, mixed evidence remains mixed, and collective model failure remains open. The candidate may not rebrand the winning rival after the fact as the mechanism through which fairness operated. Any successor model that incorporates the winning predictive mechanism must be labeled as a new version and retested against the original rival independently.

Allowing predictive success to be enough protects both care and the formal claim. Ordinary explanation owns what it explains, leaving any remaining target sharper and less ambiguous. The remaining PTVC question then concerns structure that predictive regulation does not already explain, reducing overlap between candidate and rival.

22.2 — Active Inference and Expected Control

Active inference changes the rival from passive prediction to action selection. An agent may update beliefs to fit sensations, act so future observations become more consistent with expected states, or trade immediate cost against information and pragmatic value. That architecture is relevant to horizon, reserve, repair, and admissible-path questions because it offers a future-directed ordinary generator (Seth & Friston, 2016; Friston et al., 2017; Lageman et al., 2026).

The danger is semantic capture. A model may contain prior preferences, expected free energy, epistemic value, pragmatic value, and policy precision, and those words may sound like values in the moral or experiential sense. But a prior preference in a generative model is not a judgment of human worth, and expected free energy is not the hidden ledger (Friston et al., 2017; Seth & Friston, 2016; Badcock & Davey, 2024).

Active inference enters as an executable competitor with its own latent states, policy set, prior preferences, epistemic term, pragmatic term, precision, observation model, and recovery burden. It can explain exploration, avoidance, uncertainty reduction, body regulation, and future-oriented behavior without terminal neutrality. It becomes discriminating only when the model yields a different protected prediction under shared observations (Lageman et al., 2026).

Equation role: one conventional active-inference rival objective. This policy-selection quantity belongs to a generative model; it is not the phenomenological ledger.

$$G(\pi) = E_{q(o,s|\pi)}[\ln q(s|\pi) - \ln p(o, s|C)]$$

Table 22.2. Shared terms that must not be merged.

Term	Meaning in the rival	Boundary for this book
Preference	Prior over expected outcomes	Not moral value, not human worth, not candidate interval contribution
Policy	Possible action sequence	Not destiny and not a proof-bearing path
Free energy	Model evidence bound or expected objective	Not $L(t)$ and not an exact valence derivative
Precision	Confidence or gain on an error channel	Not importance of a person

22.2.1 — Policies and Expected Outcomes

A policy in active inference is a possible course of action evaluated through expected outcomes. The agent selects among policies not merely by immediate reward but by predicted observations, hidden states, uncertainty, and prior preferences. This already gives the rival a way to model future pressure without invoking a fairness constraint (Seth & Friston, 2016; Friston et al., 2017).

A policy is an explicit object in the model, not a poetic tendency. It specifies available actions, predicted state transitions, expected observations, uncertainty, and a horizon. Choosing whether to

answer a difficult message, ask for help, rest, or avoid a place can then be modeled as selection among policies under uncertainty (Friston et al., 2017).

The PTVC candidate often speaks about admissible paths and remaining opportunity. Active inference can produce similar-looking behavior because some policies are expected to increase uncertainty, pain, risk, or bodily instability. A policy may become unattractive without any ledger pressure beyond the generative model's own expectations.

Compare the observed action sequence with the sequence predicted from expected outcomes under active inference, then identify any additional temporal relationships predicted by PTVC.

Policy preference describes the action a model favors under its stated assumptions. Comparing that prediction with the person's choices and account of the situation makes the interpretation testable.

Policy choice, latency, exploration, avoidance, and report change provide measurable outcomes for comparing active inference with additional path constraints.

Policy evaluation becomes especially important when actions change what can later be observed. Avoidance may reduce immediate prediction error while shrinking the evidence available to revise beliefs; exploration may increase short-term discomfort while improving future control. A fair comparison must model those feedbacks instead of treating action as an external covariate. It should ask whether the trajectory follows expected policy

consequences, information gain, or a separate cumulative constraint. When active inference predicts both choice and subsequent affect from the same declared policy set, it supplies a strong ordinary rival. A closure-specific residual must then appear in outcomes that were not already built into the policy objective (Friston et al., 2017; Badcock & Davey, 2024).

22.2.2 — Preferences and Prior Beliefs

Prior preferences in active inference are model ingredients over outcomes. They can represent expected bodily ranges, safe temperatures, social cues, or sensory conditions the organism is organized to seek or maintain. They should not be read as moral preferences, life goals, spiritual evidence, or proof of what the person consciously values (Seth & Friston, 2016; Friston et al., 2017).

This distinction matters because prior preferences can look like a hidden standard. A model may encode a preference for low pain, stable glucose, social safety, or predictable breath. That does not make the model a fairness theory. It makes it a generative account of regulation and action under expected states (Seth & Friston, 2016; Badcock & Davey, 2024).

A hospital patient may prefer dim light and fewer interruptions because those outcomes reduce arousal and pain. The active-inference model may represent that as preferred observations. The humane interpretation is straightforward: care conditions matter. The scientific interpretation is narrower: prior preferences may explain policy choice and burden change.

Prior preferences can influence trajectories. Representing their relationship to the latent ledger explicitly keeps the accumulated quantity and its predicted boundary separately defined and available for model evaluation.

Empirical work should declare whether preferences are fitted from behavior, self-report, physiology, clinical context, or task structure. If the model is allowed to infer whatever preference makes the path look sensible, it will explain too much and discriminate too little.

A preference-based active-inference rival wins when protocol-fixed priors and policy rules explain observed actions, reports, and physiological changes under protected testing. It fails when preferences become retrospective names for whatever happened. The distinction is prospective specification and recovery, not rhetorical elegance.

Prior preferences must be empirically distinguished from learned beliefs about what is likely. A person may expect pain without preferring it, or prefer safety while believing it is unavailable. Conflating these quantities can make any observed action look optimal after the fact. The model should therefore state which parameters encode desired outcomes, which encode expected outcomes, and how each is estimated or constrained. Cross-context tests can then ask whether the same preference structure transports when beliefs change. If flexible priors merely absorb every discrepancy, the active-inference rival becomes protected rather than predictive; if constrained priors forecast behavior and feeling, the rival has earned explanatory force (Friston et al., 2017).

22.2.3 — Epistemic and Pragmatic Value

Active inference can distinguish epistemic value from pragmatic value. Epistemic value concerns reducing uncertainty through information-seeking. Pragmatic value concerns outcomes aligned with prior preferences. This distinction matters because curiosity, checking, reassurance-seeking, and avoidance can otherwise be flattened into one vague control story (Seth & Friston, 2016; Friston et al., 2017).

A person waiting for a biopsy result may refresh a portal because information itself has value, even when the result could be frightening. Another person may avoid the portal because the pragmatic cost of exposure is too high. Both behaviors can be modeled without turning them into ledger balancing (Badcock & Davey, 2024).

Recurring attention may reflect information seeking, uncertainty reduction, policy rehearsal, or avoidance. Matching available information lets the comparison test different predictions for future choice or affect.

The model should specify expected information gain, outcome preference, and policy precision separately. If all three are combined into a single vague pressure term, the rival becomes difficult to test and the PTVC candidate can win too easily. A serious rival keeps its own variables distinct.

The public safeguard is against interpreting information-seeking as obligation. A participant who checks, reports, or refuses to check is not proving character. The behavior may reveal

uncertainty dynamics, not loyalty, courage, weakness, holiness, readiness, or denial.

Epistemic-pragmatic models win when they explain checking, avoidance, reassurance, exploration, and report timing under common observation. A terminal-closure-specific account must then either identify a residual pattern or concede that information and outcome expectations explain the local dynamics.

Epistemic and pragmatic value can pull in opposite directions. A diagnostic test may be unpleasant now but reduce uncertainty; a comforting routine may feel better while preserving ignorance. This tradeoff offers a discriminator when the information structure, action costs, and predicted choice pattern are protocol-fixed, then compared across active-inference and reinforcement-learning accounts (Friston et al., 2017; Sutton & Barto, 2018).

22.2.4 — Homeostatic and Allostatic Coupling

Active inference often meets the body through homeostatic and allostatic regulation. The organism expects some bodily states and acts to keep or regain them. Hunger, breathlessness, pain, temperature, exhaustion, infection, and safety signals can all enter policy selection through expected bodily outcomes (Seth & Friston, 2016; Friston et al., 2017).

Chapter 22 incorporates interoception and adaptation into generative policy models, connecting the earlier mechanism chapters with active-inference and control comparisons (Friston et al., 2017; Seth & Friston, 2016).

A concrete example is breathlessness after a stair climb in a person with chronic lung disease. Prediction, prior bodily range,

panic, action options, medication timing, and environmental control can all shape experience. A model may explain the change through interoceptive policy selection rather than through hidden terminal pressure.

The model should declare body-state variables, observation noise, control actions, and horizons. If treatment, rest, posture, social reassurance, or oxygen changes the trajectory, the rival must be allowed to own that explanation where it predicts the data.

The local ethical boundary is care appropriation. If better care reduces burden, the result first honors better care. It is not evidence that life is secretly fair. It is evidence that the body, environment, and trusted support were changed in ways the person could feel.

Homeostatic and allostatic active-inference rivals win when body-state regulation and policy selection explain observed trajectories under shared testing. The terminal-closure-specific claim remains only where it predicts additional structure beyond ordinary regulation and care conditions.

Multilevel models can connect interoceptive observations with behavior and reported valence while representing slower allostatic changes in expected states (Seth & Friston, 2016; Sterling, 2012).

22.2.5 — Free-Energy Change Is Not the Ledger

The free-energy framework offers a unified language for perception, action, learning, and self-maintenance, but variational free energy, expected free energy, prediction error, surprise, and the PTVC phenomenal ledger are different mathematical objects.

Free-energy quantities may enter as modeling objectives, bounds, proxies, or comparison features; any proposed link to cumulative felt experience needs a separately validated bridge (Seth & Friston, 2016; Friston et al., 2017).

If a proposed valence rate is the time derivative of a state function, its integral equals the final state value minus the initial value. Telescoping alone does not make that difference zero. Zero becomes an identity only when equal boundary values are also imposed, or the function is chosen to force the result. An independently specified potential could instead be an empirical model, but it would still need a validated bridge to phenomenal valence.

Free-energy quantities can generate predictions for reports, arousal, exploration, avoidance, recovery, and policy selection. Their contribution can be compared directly with the corresponding PTVC predictions.

The public language should be plain. Free-energy reduction can describe a model's inference or action process; it does not tell a person that their suffering was optimized, needed, chosen by nature, or paid forward. The words optimization and preference require careful translation before they reach ordinary readers.

Evaluate expected-free-energy dynamics against the declared observations and assumptions. A proposed connection to PTVC should specify additional predictions for a subsequent comparison.

22.2.6 — Distinctive Versus Shared Predictions

Active inference shares many predictions with other control accounts: reduced uncertainty, policy change, body-state regulation, and environmental sampling. The PTVC candidate may also discuss repair, admissibility, horizon, and reserve. Without distinctive predictions, the theories can appear to agree while saying different things (Seth & Friston, 2016; Friston et al., 2017).

A distinctive prediction is not a beautiful phrase. It is a pattern a model expects more strongly than its rivals under the same observations. It may concern timing, channel mismatch, variance shape, reserve interaction, endpoint independence, or a failure of prediction-only accounts in a specific task (Badcock & Davey, 2024; Friston et al., 2017).

Label predictions shared by the models. For example, reduced arousal after gaining reliable control over a room can guide investigation of control-related change, while an additional predicted feature may distinguish the mechanisms.

The comparison should include a table of shared and distinctive predictions before data are analyzed. Policy precision, prior preferences, prediction error, reserve interaction, terminal concentration, and held-out calibration should not be treated as one blended evidence cloud. For each contrast, state the expected direction and observation window so competing models can be scored on the same quantity.

Active inference supplies a developed comparison framework. Specifying an additional measurable relationship gives PTVC a

distinct prediction to evaluate across settings. A predicted difference in recovery timing, for example, should be assessed separately from agreement about the direction of change.

The section closes with a rule later chapters make operational: shared predictions receive no model-specific credit, while a distinctive prediction must be fixed in advance and allowed to fail. This is how vocabulary becomes a test rather than a source of borrowed authority. The comparison then turns on the remaining quantitative difference, even when both models describe the observed improvement well.

22.3 — Reinforcement Learning and Policy Adaptation

Reinforcement learning asks how behavior changes through consequences. Agents may learn values, policies, transition models, and action tendencies from reward, punishment, prediction error, exploration, and planning. Computational reward enters as a task-defined learning signal; its relationship to felt valence is a separate measurement question (Daw et al., 2005; Keramati & Gutkin, 2014; Sutton & Barto, 2018).

Homeostatic reinforcement learning supplies a concrete physiological architecture for this comparison. Keramati and Gutkin (2014) define primary reward through reduction of distance from a physiological set point. Under their assumptions, policies maximizing discounted reward also minimize discounted homeostatic deviation, and learned cues support anticipatory regulation. This is a mathematical result within a specified model, supported by comparisons with existing behavioral findings. It shows how reward seeking and bodily stability can share a computational objective. The model also supplies a useful algebraic comparison: an undiscounted sum of rewards defined as state differences telescopes to the initial-to-final change. In simulation and ethically available observational records, compare the declared PTV route with this internally motivated learning model under the same state information, observation process, and complexity budget.

Learning gives adaptation a temporal structure. People avoid what hurt, repeat what relieved pressure, plan around scarcity, and

change strategies when old actions fail. These dynamics connect observed behavior with evolving state allocation and time horizons (Sutton & Barto, 2018; Daw et al., 2011; Gershman, 2018).

A learning model becomes a useful comparator when it predicts the observed path under declared states, actions, rewards, horizons, and partial observability. Its reward and return variables should be defined in the units of the task.

Equation role: POMDP belief update. Here η is the normalizing constant that makes the posterior sum to one, and the summation runs over prior hidden states s . The update defines partial observability for learning rivals and prevents oracle-state comparisons.

$$b_{t+1}(s') = \eta p(o_{t+1}|s') \sum_s p(s'|s, a_t) b_t(s)$$

Equation role: Temporal-difference rival update. This is a learning rule for value estimates, not a measurement of felt experience.

$$Q_{t+1}(s_t, a_t) = Q_t(s_t, a_t) + \alpha \left[r_{t+1} + \gamma \max_a Q_t(s_{t+1}, a) - Q_t(s_t, a_t) \right]$$

Table 22.3. Toy-environment simulation plan.

Environment feature	Learning rival prediction	Discriminating question
Changing reward	Policy shifts after value update	Does PTVC add a transported restriction beyond updated return?
Hidden state	Belief tracking and checking behavior	Does uncertainty, not burden closure, explain recurrence?

Environment feature	Learning rival prediction	Discriminating question
Finite horizon	Urgency and conservative choices near the end	Can horizon pressure appear without terminal neutrality?
Offline replay	Delayed policy change after memory simulation	Can planning explain reactivation?

22.3.1 — State, Action, Reward, and Return

A reinforcement-learning decision process specifies states, actions, transition probabilities, rewards, and a policy. Its return is a discounted or finite-horizon sum of the defined rewards (Daw et al., 2005; Keramati & Gutkin, 2014; Sutton & Barto, 2018).

A task reward may consist of points, money, social feedback, relief from a stimulus, or another modeled signal. Defining its role and units makes the learning model interpretable (Sutton & Barto, 2018).

In a short-horizon laboratory task, a participant may choose between a safe small gain and a risky large gain as time expires. The model represents the task’s rewards, returns, and changes in choice as the remaining opportunities shrink.

A serious RL rival should define the state variables available to the agent, the action set, the reward function, the transition model, the horizon, and the policy class. If these are fitted after the fact, the model may explain too much and teach too little.

The public-risk sentence belongs near the model: reward in a study is an instrument, not a measure of inner worth. A participant

who chooses one policy over another has not been ranked as fair, rational, holy, loyal, or healed.

Declared rewards and transitions generate predictions for behavior, reports, and physiological change. Held-out comparisons can assess those predictions alongside the additional trajectory restrictions proposed by PTVC.

A reward variable organizes the model's policy updates and may represent an engineered proxy, delayed label, or task outcome. Comparing several specified encodings shows which one the data identify. Potential-based reward shaping is a classic example of a reward transformation that can preserve the optimal policy under defined Markov-decision-process conditions, underscoring that computational reward representations can change without establishing a new phenomenal quantity (Ng et al., 1999). Constraints on the reward function make predictions of choice and feeling across tasks more informative (Sutton & Barto, 2018; Daw et al., 2011).

An independent close behavioral replication with 50 participants largely reproduced the main findings of Rutledge's computational happiness model. Its preregistered individual analyses obtained a mean within-person fitted R^2 of 0.54, compared with 0.47 in the original report (Vanhasbroeck et al., 2021). This provides an independently reproduced quantitative account of how expectations and recent outcomes relate to reported happiness.

Affect can improve the explanation of learning itself. Teoh et al. (2026) compared three models in 75 participants: reward-based learning alone, an additional affective influence on choice, and

affect-informed updating of expected value. Jointly fitting choices and explicit expectations favored the updating model, whose average participant-level WAIC model weight was 0.651. A separate 55-person study reproduced the behavioral findings, and a 95-person experiment found that valence tracked expectations during passive learning under varying predictability. Positive feeling was associated with more favorable expectations after accounting for received rewards. These results supply an empirical architecture linking present feeling, developing expectations, and future action. For the PTVC program, that architecture provides a concrete starting point for testing how accumulated affective history shapes later trajectories.

22.3.2 — Temporal-Difference Learning

Temporal-difference learning updates value estimates from the difference between expected and observed future value. Its signed updates provide a timing model for studying disappointment, relief, surprise, and related subjective changes (Daw et al., 2005; Keramati & Gutkin, 2014; Sutton & Barto, 2018).

The temporal-difference error updates predicted value. Its relationship to subjective change and neural signals can be tested within the specified task and observation model (Daw et al., 2011; Gershman, 2018).

At the neural level, Bayer and Glimcher (2005) recorded individual dopamine neurons while monkeys learned when to make an eye movement for juice reward. Activity tracked the difference between the current reward and a weighted history of earlier rewards for better-than-expected outcomes. The sign

asymmetry is informative and belongs in models of the response. Nervous systems can represent recent reward history and compute a learning-relevant update, providing a concrete computational component for theories linking history, expectation and affect.

A repeated-feedback task can track learning after outcome probabilities change. When a cue predicts an adverse outcome less often, reports, reaction times, and arousal may change together. A temporal-difference model can predict the sequence and size of those adjustments.

The empirical question is whether TD errors, learning rate, volatility, and reward prediction explain the path. If they do, the Law should not claim the same evidence as hidden balancing. The outcome belongs to a local learning mechanism unless a prospectively specified residual remains.

The failure mode is neural storytelling. A dopaminergic or prediction-error correlate can become a post hoc decoration if it was not prospectively specified and compared against rivals. The chapter therefore treats neural signals as auxiliary predictions, not as definitions of the Law or of the person.

Temporal-difference rivals win when their update structure explains timing and direction better than terminal-closure-specific alternatives. They lose when their local updates fit behavior but miss cumulative path restrictions, endpoint-independent variance behavior, or reserve-linked signatures that were specified before analysis.

Temporal-difference errors create a distinctive sequence of anticipatory shifts. As learning proceeds, responses can move

from outcome to cue, and value can propagate backward through a chain of states. That backward movement can look like a burden being redistributed through time even though it arises from ordinary prediction updates. Experiments should track cue responses, outcome responses, choice, and affect simultaneously, then test whether the predicted transfer occurs. A terminal-closure account should not claim such movement as evidence unless it predicts a residual beyond temporal-difference dynamics. The rival wins when the timing and magnitude of the shift follow the learned value function under held-out conditions (Sutton & Barto, 2018; Daw et al., 2011).

22.3.3 — Partial Observability

Human decision systems rarely know the full state. They act through beliefs under partial observability: the body may be ambiguous, the social scene uncertain, the horizon hidden, and the future noisy. A POMDP is therefore a stronger rival than a fully observed toy decision process (Daw et al., 2005; Keramati & Gutkin, 2014; Sutton & Barto, 2018).

Partial observability matters because uncertainty can look like burden. A caregiver may not know whether a symptom is temporary, whether a form was received, or whether a clinician will call back. The action policy changes because the hidden state is uncertain, not necessarily because the unresolved-state process has intensified (Gershman, 2018).

The belief-state update should be explicit. Observations change the probability distribution over hidden states, and policies are selected from those beliefs. This can create checking, waiting,

avoidance, reassurance-seeking, and delayed action without invoking terminal closure.

The PTVC candidate may still ask whether the resulting path carries cumulative felt cost. But the learning rival first asks whether belief updates explain the observable behavior and reports. A model that sees uncertainty honestly is harder to defeat than a model that pretends the person had perfect information.

Consent and interpretive humility set the boundary. A belief state is an inferred research object. It should never become a claim that the researcher knows what the participant truly believed, hid, deserved, or should have done.

Partial-observability rivals win when belief updates, observation noise, and action selection predict trajectories under common data. They fail when they require hidden-state freedom so broad that any path can be explained after it happens.

Partial observability matters because the agent and the researcher may each lack different information. The agent acts on a belief state inferred from incomplete cues, while the analyst observes only a subset of actions, reports, and contexts. Hidden-state models should therefore separate environmental state, agent belief, and research observation. Otherwise, unexplained residuals may simply reflect information that the model omitted. A closure-specific effect becomes more credible only after plausible belief-state dynamics and observation gaps have been modeled. When a partially observable learning model recovers the same apparent long-range pattern, the scientific interpretation

should narrow accordingly (Sutton & Barto, 2018; Gershman, 2018).

22.3.4 — Changing Rewards and Horizons

Rewards and horizons can change. A relief that mattered in the morning may lose force after exhaustion. A choice that was reversible last month may become irreversible after a deadline. A policy that made sense under abundant time may become unattractive when the horizon collapses (Daw et al., 2005; Keramati & Gutkin, 2014; Sutton & Barto, 2018).

This gives reinforcement learning a way to explain horizon pressure without the Law. Finite-horizon decision-making can produce urgency, narrowing, risk aversion, or desperate exploration simply because remaining opportunity has changed. The model need not contain terminal neutrality to generate these effects (Sutton & Barto, 2018; Daw et al., 2011).

A laboratory task should not confuse this with a life. If participants learn that a game ends after twenty trials, their late choices may change. That tells us about finite-horizon learning under a protocol. It does not reveal a universal endgame of conscious existence.

The rival should declare whether rewards are stationary, drifting, state-dependent, context-dependent, or horizon-dependent. It should also declare what the agent knows about the horizon. If the true endpoint is unknown, the model must use a belief over time remaining rather than omniscient countdown.

The public language should keep finite-horizon pressure from becoming sacrifice logic. A model that predicts late urgency is not

a recommendation to induce deprivation, risk, stress, or self-denial. Research tasks must be low-burden instruments, not moral rehearsals for suffering.

Changing-reward and changing-horizon RL wins when it explains urgency, avoidance, and policy reversal under shared observation. The terminal-closure-specific account must then identify a residual beyond ordinary finite-horizon control or accept narrowing in that domain.

Rewards and planning horizons can change with development, illness, scarcity, medication, social role, and approaching deadlines. A fixed-horizon model may falsely attribute these changes to an external closure pressure. The comparison should allow prospectively specified horizon shifts and test whether they explain increased immediacy, altered risk tolerance, or changing affect. Crucially, the horizon is a decision-model parameter, not a license to infer a person's endpoint or remaining life. If changing horizons predict the observed policy and feeling trajectories, they weaken a distinct terminal mechanism; if they fail under fair flexibility, the residual becomes more informative (Sutton & Barto, 2018).

22.3.5 — Offline and Model-Based Planning

Learning does not occur only while acting. Humans remember, simulate, dream, rehearse, and plan. Model-based and offline learning can reorganize policy before the next observable behavior, which makes them important rivals to any theory of delayed repair or delayed policy reactivation (Daw et al., 2005; Keramati & Gutkin, 2014; Sutton & Barto, 2018).

A person may replay a humiliating meeting on a bus ride home and answer differently the next day. A dream may recombine fear and unfinished speech. A caregiver may rehearse a phone call before challenging a denial. These changes can arise from memory and simulation without being terminal-closure-specific (Daw et al., 2011).

Distinguish cached model-free values from model-based search, replay, planning depth, and memory consolidation. Their different timing predictions make delayed actions and reports useful evidence for comparison.

A model of offline processing predicts which changes occur, when they appear, and how they can be observed. These predictions make processing, repair, learning, and state-allocation accounts directly comparable.

Offline and model-based rivals win by outpredicting terminal-closure alternatives on delayed behavior, report revision, and planning signatures. Memory language fails without a generative model, timing predictions, and recoverable parameters.

Replay, imagination, counterfactual evaluation, and memory consolidation can reorganize future choices during rest or sleep. Studies can compare reported experience during the interval, neural or behavioral evidence of replay, and later policy change to evaluate these mechanisms of delayed adjustment (Gershman, 2018; Sutton & Barto, 2018).

22.3.6 — Learning-Rival Victory

A learning rival wins without privileged information through comparable or better protected prediction, calibrated uncertainty,

interpretable parameter recovery, model recovery, and transport for the declared target. Parsimony follows adequacy. Sealed recovery tests must include reinforcement-learning, PTVC, active-inference, bridge, selection, and open-set worlds (Daw et al., 2005; Gershman, 2018; Keramati & Gutkin, 2014; Sutton & Barto, 2018).

If the pipeline fails the required recovery thresholds in those worlds, it is not qualified for the affected confirmatory comparison. Under a valid analysis, adequate but inseparable models yield Model-ambiguous, while failure of every declared model to meet adequacy criteria yields Open-set inadequate. If learning wins, the series may not rename it as how PTVC operated unless that bridge was prespecified and independently tested; the route status changes.

Learning-rival victory can redirect humane practice toward information, agency, environment, or uncertainty reduction while retiring a terminal-closure mechanism. Defeating a route can still reveal where burden was hidden, shifted, or reduced.

22.4 — Safe and Constrained Control Baselines

Safe and constrained control is the primary ordinary comparator for claims about admissible paths, reserve, no-return states, and finite horizons. The next subsections distinguish constraint-based safety, barrier and viability methods, and their failure modes (Altman, 1999; García & Fernández, 2015; Ames et al., 2019; Brunke et al., 2022).

Engineered controllers can maintain a system within a viability kernel under declared assumptions. The design specifies which states, actions, and constraints produce that result and provides a model for comparison with biological regulation (Altman, 1999; García & Fernández, 2015; Wachi et al., 2024).

Safe and constrained baselines receive comparable state information, action freedom, and optimization capacity. Their predicted trajectories then provide explicit comparisons for reserve, viability, and finite-horizon behavior.

Equation role: Constrained-decision baseline. This is a safe-control rival that optimizes return under declared cost limits.

$$\max_{\pi} E_{\pi} \left[\sum_{t=0}^T \gamma^t R(s_t, a_t) \right] \text{ s. t. } E_{\pi} \left[\sum_{t=0}^T \gamma^t C_j(s_t, a_t) \right] \leq d_j$$

Equation role: Deterministic control-barrier condition. This enforces forward invariance for an engineered controller under declared dynamics.

$$L_f h(x) + L_g h(x)u + \alpha(h(x)) \geq 0$$

Table 22.4. Safe-control baseline comparison.

Baseline	Can mimic	Specification to record
CMDP	Tradeoff between reward and harm cost	Declared cost functions and constraint thresholds
Risk-sensitive control	Avoidance of volatile paths	Risk-sensitive objective and risk parameter
Barrier controller	Trajectory remaining inside a safe set	Dynamics, safe set, and invariance condition
No-return avoidance	Urgency near irreversible states	Irreversible region and transition uncertainty

22.4.1 — Constrained Markov Decision Processes

A constrained Markov decision process extends ordinary reward optimization by adding costs or safety constraints. The agent may maximize return while keeping expected harm, energy use, risk, or constraint violation below declared bounds. This provides a direct rival to PTVC-like trajectory narrowing (Altman, 1999; García & Fernández, 2015; Ames et al., 2019; Brunke et al., 2022).

The model object is explicit: states, actions, transition probabilities, reward, cost functions, thresholds, and policy class. A constraint can represent avoiding pain above a threshold, keeping fatigue below a limit, or preserving access to future actions. None of those constraints is automatically terminal fairness (Altman, 1999).

A practical example is a rehabilitation task in which a person chooses effort levels while avoiding pain flare-ups. A constrained model may explain why the person takes smaller steps, rests earlier, or refuses a higher reward. The behavior reflects safety constraints under the task, not a moral ledger.

The empirical comparison should include a CMDP baseline whenever the PTVC candidate predicts avoidance of no-return paths or preservation of reserve. Without that baseline, the Law may appear distinctive only because ordinary constrained control was not allowed to compete.

Safe-control studies use minimal burdens, simulated stakes, or existing clinical data within approved care-first governance. Research for the Law must not create suffering to estimate a parameter.

CMDP rivals win when explicit reward-cost tradeoffs reproduce the policy and trajectory signatures under the same observations. The PTVC candidate must then narrow to residual features not explained by constrained optimization.

Constrained Markov decision processes separate reward optimization from explicit safety or resource limits. This is scientifically useful because a trajectory can bend away from danger without any terminal balancing objective. The model should declare the constraint cost, threshold, state transitions, and policy class, then test whether the observed avoidance and recovery follow those objects. A flexible constraint should not be inferred from the same path it explains. When prospectively specified constraints predict action and affect under new

conditions, constrained control becomes a strong rival to any claim that apparent guardrails reveal PTVC (Altman, 1999; Wachi et al., 2024).

22.4.2 — Risk-Sensitive and Robust Control

Risk-sensitive and robust control models do not optimize only the average outcome. They may penalize variance, worst-case loss, tail risk, ambiguity, or model uncertainty. This makes them strong rivals because real burden often lives in the tail, not in the mean (Altman, 1999; García & Fernández, 2015; Ames et al., 2019; Brunke et al., 2022).

A person who refuses a high-upside option after trauma may not be irrational or ledger-driven. The policy may be risk-sensitive because the worst case has become too costly. A family declining additional monitoring near the end of life may be protecting quiet from a risk the protocol undervalues (García & Fernández, 2015; Wachi et al., 2024).

The model should specify the risk measure: variance penalty, entropic risk, conditional value at risk, worst-case transition uncertainty, or robust policy. Each choice has a different implication. Calling them all caution would be too vague for science.

Risk-sensitive objectives can reduce predicted variability by favoring less volatile states. Robust objectives can favor cautious actions when model estimates are uncertain. Both provide quantitative accounts of path selection for comparison.

Risk avoidance can be a rational or learned response to uncertainty, history, and present constraints. Representing those conditions improves the behavioral model.

Risk-sensitive and robust models can be evaluated through held-out predictions of path selection and variance. Fixing the risk parameter's estimation rule before comparison makes these tests informative.

These families can generate conservative action, reserve-like behavior, and apparent no-return boundaries without a fairness ledger. The comparison should vary tail risk and model uncertainty independently, then ask whether behavior and feeling respond as each control account predicts. If the observed path is driven by risk aversion or robustness, the closure interpretation must retreat. A distinctive PTVC result would need to survive those controls and transport beyond the environments used to tune them (García & Fernández, 2015; Wachi et al., 2024).

22.4.3 — Control Barriers and Viability Kernels

Control-barrier functions and viability kernels formalize safety under dynamics. A barrier can certify that allowed controls keep a state inside a safe set. A viability kernel identifies states from which at least one admissible policy can keep the system within constraints (Altman, 1999; García & Fernández, 2015; Ames et al., 2019; Brunke et al., 2022).

This is an elegant mathematical language for future preservation. It is also a dangerous analogy if mishandled. A barrier condition can be true for an engineered controller while saying nothing

about whether a person's felt life closes at neutrality (Wachi et al., 2024).

The chapter uses barriers as baselines because they can mimic no-return avoidance. If a simulated agent avoids states from which recovery is impossible, its path may show narrowing, urgency, and apparent repair. The mechanism is safety preservation under declared dynamics, not fairness.

A clean barrier model must define the state, safe set, control set, dynamics, and probability guarantee. Deterministic and stochastic barriers should not be mixed casually. If stochastic dynamics are present, the condition must match the stochastic theorem rather than borrowing deterministic language.

Construction-is-not-evidence is the public-risk control. A figure showing a safe set and a trajectory inside it should be labeled as a candidate control baseline or engineering analogy. It should not be publicized as a map of the soul or a proof that lives self-correct.

Barrier and viability rivals win when their declared safe sets and dynamics reproduce trajectory restrictions without terminal-closure-specific terms. They fail when the safe set is chosen after seeing the result or when the controller is given information unavailable to the organism.

Barrier functions and viability kernels identify regions from which safety constraints can be maintained. Their feasible sets may shrink as resources decline or disturbances grow. Compute these regions from independently specified dynamics and constraints, then compare predicted action boundaries with

observed trajectories and any additional predictions for experience or endpoint behavior (Altman, 1999).

22.4.4 — No-Return Avoidance

No-return avoidance is a powerful ordinary explanation for apparent moral urgency. Many systems avoid states from which future options collapse. Bodies avoid injury, animals avoid traps, people avoid irreversible decisions, and institutions create guardrails because some losses are not easily repaired (Altman, 1999; García & Fernández, 2015; Ames et al., 2019; Brunke et al., 2022).

Compare no-return avoidance through safe-control models with the predictions derived from PTVC's admissible paths and reserve variables (Altman, 1999; García & Fernández, 2015).

A concrete study might track decisions in a low-burden planning task where some choices remove future options. If participants avoid irreversible branches as the horizon shrinks, finite-horizon safe control may explain the pattern. The task should not be described as evidence about terminal sacrifice.

No-return states should be declared before analysis. They can be defined by task structure, clinical risk, physiological thresholds, or option-set collapse. If they are identified only after the path is known, the model becomes a story rather than a test.

Anti-sacrifice is the boundary. No-return avoidance models should intensify the duty to prevent avoidable harm, not imply that people should endure harm for later balance. The model's safest interpretation is early protection, not delayed meaning.

No-return rivals win when they explain urgency, narrowing, avoidance, and repair attempts through declared option loss. The terminal-closure-specific account remains only where the observed pattern exceeds no-return avoidance under the same horizon and information constraints.

No-return avoidance can arise whenever some states make future objectives unreachable. A patient conserves breath, an animal avoids a depleted patch, or a controller preserves battery because entering a region would destroy future options. The model should distinguish physical irreversibility, learned danger, institutional barriers, and phenomenal burden. Each can produce abrupt avoidance. A closure account should not infer terminal fairness from the mere existence of a boundary in action space. The rival wins when an independently estimated reachability model predicts the boundary and its movement as conditions change (García & Fernández, 2015; Wachi et al., 2024).

22.4.5 — What Constructed Controllers Contribute

A controller can be built to do almost anything its designer asks, within mathematical limits. It can close a gap, minimize a cost, reach a target, stay inside a set, or avoid a boundary. The existence of such a construction does not show that the living world implements it (Altman, 1999; García & Fernández, 2015; Ames et al., 2019; Brunke et al., 2022).

Constructed controllers are useful as rival generators and identifiability tests. Simulation can expose their assumptions, parameter sensitivity, and signatures under known truth; figures should label the generator, setting, assumptions, and scientific

role so a construction is not mistaken for an observed mechanism (García & Fernández, 2015).

When a target is attainable under the chosen dynamics and admissible controls, a controller may be designed to reach it. Existence proofs, simulations, behavioral fits, interventions, and transported predictions then address successive questions about its operation. Independent observations can compare the proposed variables and causal structure with competing explanations (Wachi et al., 2024).

22.4.6 — Common Information and Action Sets

Safe-control comparisons become invalid when models receive different information or feasible actions. A controller with the true latent state, exact dynamics, and endpoint knowledge can outperform a model that sees only noisy observations. In that case the advantage belongs to oracle access rather than theory, so the contest must equalize information and action sets before scores are interpreted (Altman, 1999; García & Fernández, 2015; Ames et al., 2019; Brunke et al., 2022).

The common information set specifies observations, history, sensor reliability, endpoint uncertainty, reserve proxies, context, and action availability. The common action set specifies what the organism or simulated agent can actually do, including delays, costs, and prohibited interventions (Wachi et al., 2024; Altman, 1999).

A hospice dataset provides a clear example. A model that knows the death time while the participant and clinicians did not know it cannot be compared directly to a filtered-horizon model. The

endpoint information itself becomes a hidden advantage. Fair comparison should match each model's information set to what was actually available at the decision time, not to what analysts know retrospectively.

Safe control connects to common-observation comparison through a shared interface. Before scoring, every model declares what it observes, when it observes, what it may choose, and how missingness affects the record. This declaration should include information delay, because a model with faster access can appear superior even when its mechanism is no better.

Fairness toward rivals and participants sets the limit. Model comparison should not turn a person's limited information into evidence against them, nor should it let a theory win by using retrospective knowledge unavailable to the stream. Information parity should therefore be checked during model recovery rather than assumed from nominally identical input variables.

Safe-control rivals win only when their information and action sets are legitimate and their protected predictions remain calibrated. If they require oracle endpoint knowledge, unobserved latent states, or impossible actions, their apparent advantage becomes a design diagnostic rather than a conclusion about the observed system. A rival that wins only with unavailable actions defines an upper bound on achievable control, not an explanation of the observed behavior.

22.5 — Bridge and Doob-Transform Rivals

Endpoint-conditioned processes are among the strongest rivals because they can make drift toward a terminal value appear without any native terminal controller. If the process law conditions on where or how the path ends, the preceding trajectory may look as if it knew its destination. That resemblance is why bridges belong in the primary comparison (Doob, 1957; Revuz & Yor, 1999; Särkkä, 2013).

The comparison includes Brownian bridges, Doob h-transforms, Schrödinger bridges, survival-conditioned paths, random endpoint models, last-observation alignment, and observation selection. These models make conditioning and selection effects on terminal trajectories explicit (Doob, 1957; Léonard, 2014; Léonard et al., 2014).

The equations make conditioning explicit. They describe how the process law changes and provide drift and covariance predictions for comparison under a shared observation model.

Equation role: Fixed-endpoint Brownian bridge. Drift is determined by endpoint conditioning.

$$dX_t = \frac{x_T - X_t}{T - t} dt + \sigma dW_t, 0 \leq t < T$$

Equation role: Doob-transform rival. Future conditioning changes the process law and can create apparent direction without terminal control. The simplified form $h^{-1}L(hf)$ applies on the declared harmonic conservative branch. For a time-dependent bridge, h satisfies $(\partial_t + L_t)h = 0$; nonharmonic or killed branches retain the corresponding temporal or potential term.

$$L_t^h f = h^{-1}L_t(hf) - h^{-1}fL_th = L_tf + a_t \nabla \log h \cdot \nabla f$$

Table 22.5. Bridge and endpoint-conditioning diagnostics.

Diagnostic	Bridge expectation	PTVC-relevant question
Drift direction	Moves toward conditioned endpoint	Does drift magnitude or reserve dependence distinguish the models?
Variance shape	Bridge-specific collapse pattern	Does reserve-linked innovation differ?
Endpoint knowledge	Often inserted by conditioning	Was endpoint defined prospectively?
Last observation	May act as false endpoint	Was observation shutdown modeled?

22.5.1 — Fixed-Endpoint Brownian Bridge

A Brownian bridge starts from an initial value and is conditioned to hit a specified endpoint at a fixed time. The drift corrects the remaining displacement over the remaining time, while the path converges to the specified endpoint. The path can look like convergence because convergence has been built into the conditioning (Doob, 1957; Revuz & Yor, 1999; Särkkä, 2013).

This rival is powerful for terminal studies because retrospective alignment often begins with a known end. If investigators align

trajectories backward from death or final observation, they risk creating a bridge-like picture even when the underlying process had no terminal-closure-specific closure mechanism (Doob, 1957).

A fixed-endpoint bridge generates terminal drift through its conditioning rule. Its resulting mean and covariance provide explicit predictions to compare with additional PTVC structure under shared observations.

Bridge-plot captions identify the conditioned endpoint, base process, parameter values, and observation assumptions.

The fixed-bridge rival wins locally when endpoint-conditioned drift and variance explain the observed terminal pattern without additional terminal-closure-specific restrictions. It loses where independent endpoint definitions, reserve-linked innovations, and prospective observation rules produce a pattern the bridge fails to match.

Fixed-endpoint conditioning changes a process's mean and covariance, producing an increasing pull toward the endpoint even when the base process is ordinary diffusion. Compare bridge and nonbridge generators over the same windows with the same measurement noise. Transported intervention responses, endpoint-timing relations, and cross-equation constraints specified before fitting provide further features for discrimination (Doob, 1957; Léonard, 2014).

22.5.2 — Random Endpoint Times

Real truth-level endpoints are rarely known in advance. Their timing may be uncertain, state-dependent, treatment-dependent,

or observed only through a proxy. A random-endpoint model is therefore a stronger rival than a fixed-time bridge when the study concerns the irreversible end of a qualifying conscious stream, a terminal window, or a last observation.

Random endpoint times can create selection and conditioning effects. Trajectories that survive long enough to be observed may differ from trajectories that end suddenly. Participants who remain in a protocol may differ from those who withdraw. Endpoint uncertainty becomes part of the data-generating process (Aalen et al., 2008; Little & Rubin, 2019).

When the endpoint time T is uncertain, both the comparator and PTVC candidate use a filtered distribution over possible endpoints based on the information available at the prediction time.

A useful random-endpoint rival specifies hazard, state dependence, observation rules, and the relation between clinical events and endpoint confidence. It may explain apparent terminal concentration through risk selection rather than through terminal neutrality.

Clinical death, loss of contact, and the last available observation are distinct protocol events. The endpoint model specifies how each event informs the timing of a qualifying stream's end and carries the remaining uncertainty into the analysis.

Random-endpoint models generate predictions under explicit hazard, selection, and timing uncertainty. Prospective signatures, independent endpoint adjudication, and observation-model checks evaluate those predictions.

Random endpoints condition on a distribution of times. Mixtures can alter the familiar bridge shape, and dependence between endpoint timing and the process can create selection effects. Model the endpoint law explicitly and compare independence, state coupling, censoring, and unobserved continuation with equivalent flexibility across candidates (Aalen et al., 2008).

22.5.3 — Doob h-Transforms

Section 18.4.2 developed the Doob h-transform as a path-space construction. Here it enters the comparison as a generator of event-conditioned trajectories (Doob, 1957; Revuz & Yor, 1999; Särkkä, 2013).

The transform matters here because it separates two questions. First, what path law results when a process is conditioned on an endpoint or event? Second, does nature implement a process that closes without retrospective conditioning? The first can be mathematical. The second is empirical (Léonard et al., 2014).

A Doob-transform model can represent terminal concentration, survival conditioning, or event-conditioned paths. Its directed-looking trajectories follow from the specified conditioning rule.

An executable Doob-transform comparator specifies its base process, conditioning event, h-function or event likelihood, observation filtration, and prospective information set.

Shared endpoint and observation constraints allow direct comparison with a Doob-transform model. An additional reserve relation between drift and innovation provides one example of prospectively testable structure.

A Doob h-transform expresses future conditioning as present transition dynamics. An apparent local controller may therefore be an ordinary process under conditioning. Compare likelihoods, path functionals, intervention responses, and endpoint support under both representations. Inseparable observations yield Model-ambiguous; mechanism identification awaits causal or transported evidence (Doob, 1957; Léonard et al., 2014).

22.5.4 — Selection on Survival and Observation

A terminal dataset is assembled through eligibility, consent, diagnosis, access, survival, availability, and continued observation. It is not a random cross-section of complete lives. Those selection processes can shape the apparent trajectory before any terminal model is fitted (Hernán & Robins, 2020; Little & Rubin, 2019).

Survival selection can remove extreme or sudden paths from the observed set. Observation selection can remove moments of highest clinical burden because sensors are removed, speech fails, staff prioritize comfort, or families decline. The remaining data may look calmer and more continuous than the lived stream (Hernán & Robins, 2020; Little & Rubin, 2019).

Selection is a full rival mechanism. When the people and moments entering a terminal window are already filtered by care context, clinical stability, medication, communication capacity, or continued device use, apparent concentration may belong to the record rather than the latent path.

A credible selection model declares inclusion, exclusion, attrition, survival, observation intensity, and shutdown. Estimate jointly

where possible; otherwise bound what cannot be directly estimated. Missingness is not neutral by convenience.

Observation models record family decisions, device removal, and withdrawal as causes of missingness. Data collection follows consent and care priorities.

Selection rivals win when survival and observation mechanisms reproduce the terminal signature. They lose only when the signature survives robust sampling, prospectively specified endpoint rules, and sensitivity analyses that make unobserved intervals scientifically visible without violating care.

Survival and observation can select trajectories by state, treatment, resources, and care context. Model entry, retention, death, withdrawal, sensor failure, and institutional discharge. Inverse weighting addresses measured selection; sensitivity analyses assess how unmeasured dependence would affect the result (Aalen et al., 2008; Little & Rubin, 2019).

22.5.5 — Last-Observation Alignment

Last-observation alignment can manufacture a terminal-looking path by treating device removal, transfer, discharge, sensor failure, or withdrawal as the truth endpoint (Little & Rubin, 2019).

Last observations may occur because illness, burden, care, or equipment changed. They are observation events, not automatically endpoint events (Little & Rubin, 2019).

A wearable removed during hospice may leave a stable final reading that appears to settle. The pattern may reflect device tolerance and care decisions rather than terminal neutrality.

Model observation shutdown. If last-observation alignment reproduces the concentration, narrow or suspend the closure-specific interpretation.

Final intervals retain the uncertainty implied by the missingness model and the documented reasons observation ended.

Prospectively defined endpoint windows, independent stopping rules, and explicit observation-process models allow the analysis to test whether the signature persists across alternative accounts of missingness.

Compare calendar, protocol, event, and plausible anchor times, and show the unaligned data. Signatures confined to last-observation alignment make alignment and attrition the immediate model-comparison targets (Little & Rubin, 2019).

22.5.6 — Bridge Variance Shape

Conditioned bridges approach endpoints by construction, weakening drift as a discriminator. Variance, covariance, endpoint surprise, and reserve relations discriminate better when reserve, drift, innovation, and endpoint structure are estimated independently (Doob, 1957; Revuz & Yor, 1999; Särkkä, 2013).

Compare bridge and reserve-coupled variance, noise floors, selection, and endpoint uncertainty under shared cadence and missingness. Test which joint pattern transports.

Medication, sedation, frailty, dropout, and changing cadence belong in the model of observed variance.

Diagnostics report bridge variance, reserve-coupled variance, observation floors, and selection under common simulated cadence, missingness, endpoint uncertainty, and device versions. Using the same simulation clock makes differences in apparent variance attributable to the candidate process rather than to unequal observation opportunity.

Public figures state whether compression is latent, measured, noise-adjusted, bridge-generated, reserve-linked, or unresolved. Captions should also identify whether the endpoint was conditioned, observed, or independently adjudicated, since that distinction changes the interpretation of compression.

Bridge rivals win by reproducing protected structure through endpoint conditioning and the shared observation model. PTVC is distinctive only where prespecified restrictions survive. A bridge victory should retire the claimed native signature while leaving separately supported measurement or endpoint findings intact.

22.6 — Event-Conditioned and Selection Rivals

Event-conditioned and selection rivals move the comparison from mathematical conditioning to real recruitment and observation. Referral, diagnosis, treatment, hospice entry, survival, device use, communication capacity, caregiver presence, and last-observation rules can reshape the sample and its terminal curves without changing the latent process.

A terminal dataset is therefore a selected history, not a transparent window onto all eligible streams. The selection model must name who becomes observable, when observation begins, what keeps it active, what stops it, and how those processes depend on the latent state, care, prognosis, treatment, burden, and endpoint.

The practical aim is constructive: selection models reveal which additional records, negative controls, denominator flows, and sensitivity bounds can recover a more honest estimand. When recovery is impossible, No adequate estimate is the disciplined outcome.

Table 22.6. Event-conditioned rival envelope.

Conditioning mechanism	Example in data	Potential artifact
Hospice entry	Enrollment after prognosis and family consent	Care-context concentration
Treatment change	New medication or routine	Trajectory shift caused by intervention
Observation shutdown	Device removed for comfort	Clean-looking final curve

Conditioning mechanism	Example in data	Potential artifact
Competing event	Discharge, transfer, sudden death, recovery	Mixed endpoints treated as one

22.6.1 — Hospital and Hospice Selection

Hospital and hospice samples are selected by diagnosis, prognosis, access, insurance, geography, clinician referral, family support, cultural scripts, and willingness to participate. These entry processes can create regularities before any terminal model sees the data (Rubin, 1976; Little & Rubin, 2019; Hernán & Robins, 2020).

A hospice cohort may include people whose symptoms are managed, whose families accept the service, and whose clinicians expect a certain prognosis. Another group may die suddenly, remain at home without services, or never appear in the research system. The observed terminal path is therefore conditional on care entry (Aalen et al., 2008).

Hospice observations reflect palliative routines, medication practices, family presence, and eligibility rules. Describing these conditions identifies the settings to which the measured dynamics can be compared or extended.

The rival model should encode entry probability, diagnosis, prognosis, care intensity, resource context, and time since enrollment. If these variables explain terminal concentration, the result belongs to selection and care context unless distinctive terminal-closure-specific residuals remain.

Hospice must not be devalued; humane care changes lived experience. When good care reduces distress or stabilizes context, the first explanation should honor the care and model its effects before assigning any theory-specific meaning.

Hospital and hospice selection rivals win when entry processes and care context explain the observed pattern. They fail only where signatures survive across entry systems, cultures, diagnoses, and observation regimes with the same prospectively specified target.

Diagnosis, prognosis, referral, access, geography, insurance, family capacity, and clinical judgment shape hospital and hospice cohorts. Model these selection processes alongside trajectories and observation schedules, and compare participants with eligible nonparticipants where ethically and legally possible. Treat site practices as data-generating mechanisms and specify the reference classes supported by the resulting evidence (Aalen et al., 2008; Hernán & Robins, 2020).

22.6.2 — Treatment-Conditioned Trajectories

Treatment changes trajectories. Analgesics, sedatives, oxygen, antiemetics, antidepressants, therapy, mobility aids, sleep support, family visitation, and environmental adjustment can alter reports, physiology, behavior, and available actions. These are not noise around the science; they are mechanisms (Rubin, 1976; Little & Rubin, 2019; Hernán & Robins, 2020).

A terminal calm after medication adjustment may be comfort, not closure. A reduction in agitation after pain relief may show that pain was undertreated. A change in sleep after a new caregiver

routine may reflect safety. Treatment-conditioned rivals must be allowed to own those explanations (Hernán & Robins, 2020; Little & Rubin, 2019).

The model should include time-varying treatment, dose, timing, indication, care goals, and side effects where available. It should also include confounding by indication: people receive treatment because their state changed, so treatment and trajectory cannot be separated by simple before-after plots.

Detailed clinical protocol design lies elsewhere; the scientific requirement here is direct. When treatment timing and care context explain the path, the result belongs to treatment. A prospectively specified residual that survives adequate treatment modeling becomes eligible for the next comparison under care-first rules.

Immediate care governs interpretation. Research interpretation cannot make pain control wait, cannot treat sedation as data loss that should be prevented, and cannot pressure clinicians or families to preserve an observation channel when comfort requires silence.

Treatment-conditioned rivals win when intervention timing and clinical context reproduce the observed dynamics. They fail only when signatures remain after rigorous treatment modeling and sensitivity analysis without compromising care.

Treatment changes symptoms, consciousness, reporting capacity, physiology, and observation. Analgesia, sedation, oxygen, psychotherapy, surgery, and social support can each alter the path and the probability of later measurement. The design should

represent treatment as time varying and potentially confounded by prior state. Marginal structural, g-formula, or joint-model approaches may be needed, but no method recovers unmeasured experience automatically. A terminal pattern that tracks treatment timing may be clinically important while remaining evidence about treatment rather than PTVC. Care is never withheld to improve identification (Hernán & Robins, 2020; Tsiatis, 2006).

22.6.3 — Observation Shutdown

Observation shutdown occurs when channels close. A device is removed, a survey is skipped, speech stops, the room becomes private, staff are busy, batteries fail, delirium prevents report, or consent is withdrawn. The shutdown process often intensifies near the most scientifically tempting windows (Rubin, 1976; Little & Rubin, 2019; Hernán & Robins, 2020).

Observation shutdown is more than an empty cell in a dataset. If channels close when burden rises, the remaining record can understate distress. If channels close when comfort improves, the record can miss relief. Either pattern makes absence informative about the observation system (Little & Rubin, 2019).

A concrete example is a family asking that all nonessential research prompts stop after a difficult night. The study loses data, but the person gains quiet. The correct scientific response is to model the shutdown and protect the choice, not to treat the missing interval as neutral.

Observation-shutdown rivals require channel-specific dropout models. Self-report, wearable signals, clinical notes, family observations, and behavioral data may shut down for different

reasons. Combining them into one missingness flag can hide the mechanism.

A missing final interval should be represented through its observation conditions and missingness model, preserving the uncertainty about that part of the trajectory.

Observation-shutdown rivals win when dropout and channel closure reproduce apparent terminal patterns. They fail when the result survives explicit dropout models, sensitivity bounds, and ethically available observations.

Observation can end when speech becomes difficult, devices are removed, family priorities change, staff reduce nonessential measures, or participation is withdrawn. Model these causes, preserve uncertainty, and identify recoverable estimands. Proxy, physiological, and passive channels may extend coverage according to their validated roles; use No adequate estimate where the available observations are insufficient (Little & Rubin, 2019).

22.6.4 — Frailty-Conditioned Decline

Frailty is a powerful selection and dynamics variable. It changes reserve, mobility, inflammation, medication tolerance, sleep, cognition, social access, sensor reliability, and survival. A frailty-conditioned model can create apparent convergence simply because many channels narrow together as physiological margin declines (Rubin, 1976; Little & Rubin, 2019; Hernán & Robins, 2020).

This rival is not dismissive. Frailty is lived as fatigue, vulnerability, fear of falls, dependence, and reduced opportunity.

It is exactly the kind of material and bodily condition that can carry burden into a stream. The question is whether frailty explains the observed pattern without terminal-closure-specific closure (Aalen et al., 2008; Hernán & Robins, 2020).

A frailty model should include baseline vulnerability, rate of decline, acute episodes, treatment, functional status, and observation quality. It should ask whether terminal quieting, variance compression, or reduced report intensity follows shared clinical decline rather than a distinct ledger process.

The PTVC candidate may still predict reserve-related signatures, but those signatures must beat frailty baselines that are allowed to be strong. If reserve language is merely a redescription of frailty, the claim has not added scientific content.

Dignity under decline remains prior. Frailty does not reduce the person to a mechanism, nor does it make suffering less urgent because it is clinically explainable. Explanation can guide care only if dignity remains first.

Frailty-conditioned rivals win when shared disease severity and functional decline explain trajectory shape. They fail when independently measured reserve-coupled restrictions remain after frailty, treatment, observation, and endpoint uncertainty are modeled.

Frailty summarizes vulnerability across multiple systems and can generate convergent decline in mobility, appetite, cognition, affect, and measurement availability. Because frailty also influences treatment and survival, it can imitate coordinated terminal dynamics. The comparison should use prospective frailty

measures, allow time-varying change, and test whether the proposed signature remains after stratification or joint modeling. A frailty adjustment built only from late observations risks conditioning on consequences of the process. If ordinary frailty explains the pattern, the scientific credit belongs there and the PTVC reference class must narrow (Aalen et al., 2008; Andersen et al., 1993).

22.6.5 — Competing Events

Terminal-aligned trajectories can end through discharge, transfer, stabilization, hospitalization, sedation, device disconnection, withdrawal, loss to follow-up, sudden death, or recovery. These events route people through different care and observation systems and cannot be aligned as though they were one endpoint (Rubin, 1976; Little & Rubin, 2019; Hernán & Robins, 2020).

Competing-risk models should represent event-specific probabilities under state, treatment, family decision, site practice, device tolerance, and resources. Withdrawal ends observation rather than the truth-level stream, and leaving hospice after recovery does not become a completed-stream endpoint because the study window closed.

Recovery, transfer, escalation, loss of consciousness, withdrawal, and death can prevent the event originally intended for observation. Cause-specific and subdistribution estimands are used only when they answer the declared question, and conclusions are compared across choices rather than selecting the formulation with the most favorable curve (Aalen et al., 2008; Andersen et al., 1993).

A competing-event rival wins when routing or observation explains the apparent pattern. Noncompletion remains a valid and respected path, while a PTVC-specific endpoint signature must survive event-specific analysis without collapsing unlike endings.

22.6.6 — Versioned Rival Envelope

The rival envelope is the versioned set of models specified for a protected comparison. New observation artifacts, clinical confounds, sensor behavior, active-inference formulations, and safe-control baselines may enter a later version when independently motivated. The original comparison and its verdict remain in the record; changing the envelope cannot retroactively turn that completed test into a different test (Rubin, 1976; Little & Rubin, 2019; Hernán & Robins, 2020).

Each version records what changed, why, and whether earlier results require rerun or correction. Selection rivals win when referral, treatment, survival, frailty, device removal, reporting capacity, or observation shutdown explains the terminal pattern under the common observation model.

When a newly identified comparator changes the analysis, the public record should show the addition and its consequences. Every terminal figure includes denominator flow: eligibility, entry, observability, loss, death, report incapacity, and protected withheld records.

Include the envelope version and denominator with each curve.

22.7 — Common-Observation Comparison

The strongest rival can be weakened by an unfair interface. If models use different endpoint definitions, channels, missingness, latency, or access to final time, their scores compare different scientific problems rather than competing explanations (Gneiting & Raftery, 2007; Vehtari et al., 2017; Yao et al., 2018; Wilson & Collins, 2019).

Common-observation discipline fixes the latent target description, observable channels, cadence, noise, missingness, endpoint uncertainty, preprocessing, version history, and protected scoring for every model. The question is which account predicts the same evidence with the fewest unsupported privileges, not which vocabulary sounds most comprehensive (Gneiting & Raftery, 2007; Vehtari et al., 2017; Wilson & Collins, 2019).

Common-observation comparison supplies the interface needed by the later inference and red-team chapters. Learning and control rivals become serious only when one observation arena lets them win, lose, or remain indistinguishable under the same rules.

Equation role: Common scoring rule. This compares models on held-out observations with an explicit complexity penalty.

$$S_M = \log p_M(o_{test}|D_{train}) - \lambda_M df_M$$

Table 22.7. Model-recovery confusion matrix plan.

True generator	Possible mistaken recovery	Required response
PTVC candidate	Bridge rival	Report nonseparability if endpoint conditioning mimics the signature
Predictive processing	PTVC candidate	Narrow the PTVC-specific claim if error dynamics are enough
Safe control	PTVC candidate	Test whether no-return avoidance explains the path
Selection model	Any dynamic model	Rebuild observation process before claiming dynamics

22.7.1 — Shared Data-Generating Interface

A shared data-generating interface defines what every model receives and what every model must explain. It includes latent state placeholders, observations, channel quality, sampling cadence, missingness, endpoint windows, treatment flags, context, and participant status. Without it, models can talk past one another (Gneiting & Raftery, 2007; Vehtari et al., 2017; Yao et al., 2018; Wilson & Collins, 2019).

The interface should separate the latent quantity from measured witnesses. Self-report, physiology, behavior, clinical notes, and context are not interchangeable. A predictive model may use them differently from a PTVC candidate or a safe-control baseline, but

all must declare the same available evidence (Gneiting & Raftery, 2007).

A weeklong experience-sampling study gives a simple example. If participants answer prompts, wear a sensor, and complete a small task, all rivals must use the same prompt schedule, sensor gaps, device version, and task rules. One model cannot secretly use discarded context while another does not.

The interface also includes endpoint information. If a study is prospective, models receive only filtered endpoint beliefs. If a retrospective bridge uses the final event, the report must label that use. Endpoint knowledge is data, not air.

Build the common interface as a protocol-specific research object under consent, data minimization, and purpose limits. Link additional records only under the authorization governing that use.

A shared interface succeeds when another team can reconstruct what each model saw. It fails when model comparison depends on informal memory, private preprocessing, unexplained exclusions, or privileged observations that cannot be audited.

A shared interface supplies the same permitted observations, schedules, intervention records, missingness marks, and endpoint information to every fitted model. Known latent states and generator labels remain hidden from fitting and are used only for the declared recovery checks. Record transformations and exclusions before evaluation, and use synthetic fixtures to verify that each implementation reads the interface correctly (Wilson & Collins, 2019).

22.7.2 — Equivalent Parameter Freedom

Model comparison is unfair when one model receives broad flexibility and another is held to a narrow reference form. A highly flexible neural predictive model can fit almost anything; a rigid PTVC candidate can lose for the wrong reason. The reverse can also happen if the PTVC candidate is allowed post hoc mechanisms while rivals are simplified (Gneiting & Raftery, 2007; Vehtari et al., 2017; Yao et al., 2018; Wilson & Collins, 2019).

Equivalent parameter freedom does not mean identical parameter counts. Different models need different structures. It means that flexibility, priors, tuning, cross-validation, hyperparameters, and regularization are declared and disciplined so that apparent victory does not come from hidden degrees of freedom (Vehtari et al., 2017; Wilson & Collins, 2019).

A bridge model with a fitted endpoint, a safe-control model with a fitted barrier, an RL model with a fitted reward, and a PTVC candidate with a fitted reserve trajectory can all become too flexible. The chapter's method is to expose those freedoms rather than pretend one side is pure.

Choose complexity penalties, held-out prediction, model recovery, sensitivity analysis, and prospectively specified parameter bounds to match the estimand. Report training fit and held-out performance separately.

Technical complexity should be matched to a clear evidential contribution. Readers can then assess what the added structure

explains, how it was tested, and whether a simpler model performs as well.

Equivalent freedom succeeds when each model has enough room to express its theory and not enough room to explain anything. It fails when the winner is chosen by allocation of flexibility rather than by evidence.

Priors, nonlinearities, latent-state dimension, regularization, early stopping, and feature engineering can give one model a much larger effective search space. The benchmark should therefore report tuning budgets, prior predictive behavior, effective complexity, and sensitivity to initialization. When exact matching is impossible, the asymmetry should be made visible and stress-tested (Gneiting & Raftery, 2007; Vehtari et al., 2017).

22.7.3 — Predeclared Scoring

Protocol-fixed scoring prevents after-the-fact victory. The protocol states how models will be judged through held-out log likelihood, calibration, interval coverage, trajectory features, endpoint-window performance, residual structure, and clinically relevant diagnostics where appropriate (Gneiting & Raftery, 2007; Vehtari et al., 2017; Yao et al., 2018; Wilson & Collins, 2019).

The score should match the claim. A model that predicts momentary reports well may still fail the integrated-ledger consequence. A model that predicts endpoint concentration may fail ordinary trajectory shape. A single score can hide too much if the theory makes several distinct commitments (Wilson & Collins, 2019).

Retain every prospectively specified metric and explain disagreements among them.

A prospectively specified score fixes the intended comparison before private data are analyzed. Participants can then understand how their observations will be used, and reviewers can assess whether the analysis followed that plan.

Purpose limitation governs the score. Scores compare models; they do not score people. A participant's data can make a model lose without making the participant failed, anomalous, unfair, or uncooperative.

Scoring rules must be chosen before outcome inspection and matched to the scientific claim. Log score, calibration, discrimination, trajectory error, endpoint recovery, and decision utility answer different questions. A model can lead on one and fail on another. The protocol should identify primary and secondary scores, aggregation levels, tie rules, and consequences of missing predictions. Changing the score after seeing the results is a form of outcome selection. A rival victory is credible only when it occurs under the same prospectively specified scoring regime and the score is proper for the predictive object (Gneiting & Raftery, 2007).

22.7.4 — Complexity and Identifiability

Complexity and identifiability decide whether a comparison can teach anything. A model may fit well because it is true, because it is flexible, because the observation system is weak, or because several theories imply nearly the same measured patterns. The analysis must therefore make nonseparability visible (Gneiting &

Raftery, 2007; Vehtari et al., 2017; Yao et al., 2018; Wilson & Collins, 2019).

Structural nonidentifiability occurs when distinct parameters or models imply the same observable distribution under the specified design. Those observations cannot distinguish them, even with unlimited sample size. Nearly identical distributions can instead create a finite-sample resolution problem. Adequate but inseparable models receive Model-ambiguous status; valid estimates that do not decide the comparison receive Inconclusive evidence (Gneiting & Raftery, 2007; Vehtari et al., 2017).

Simulate from each comparator and evaluate whether the planned analysis recovers its generator. Report any confusion between PTVC, bridge, and reinforcement-learning models as a design-resolution result.

Complexity penalties should account for the structure each model needs and the flexibility it uses. Compare predictive gains with that added flexibility under a common evaluation rule.

An inconclusive result can guide the next study toward better measurements or a more discriminating contrast. Reporting that status clearly helps readers understand what has been learned and what remains open.

Identifiability checks show what the proposed observations can distinguish. Comparison tables should report that resolution alongside model scores.

Complexity penalties cannot repair nonidentifiability. Two models may have different narratives while inducing nearly the same observable distributions, or one model may contain

parameters that trade off without changing predictions. Recovery studies should therefore precede substantive interpretation. Profile likelihoods, posterior geometry, simulation-based calibration, and confusion matrices can reveal whether the design distinguishes models and parameters. If it does not, a small information-criterion difference should not be promoted into a mechanistic verdict. The correct result is ambiguity, redesign, or a narrower estimand (Talts et al., 2018; Wilson & Collins, 2019).

22.7.5 — Posterior Predictive Diagnostics

Posterior predictive diagnostics ask where a fitted model fails by simulating new data and comparing the simulations with protected observations. One aggregate score is insufficient when the model claims to explain timing, recurrence, variance, missingness, channel disagreement, policy change, endpoint windows, or reserve-linked residuals (Gneiting & Raftery, 2007; Vehtari et al., 2017; Yao et al., 2018).

Diagnostics should target features that distinguish rivals, including autocorrelation, sign asymmetry, perturbation recovery, context renewal, endpoint-window variance, and missingness-linked residuals. A model can predict choices but miss physiology, or fit arousal while missing delayed report change; those are component-level results rather than reasons to force one global winner.

For a candidate with hidden-burden predictions, publish performance on the specified indicators, including mismatches, separately from performance on other declared targets.

Publishing the diagnostic set before fitting prevents selective plots, and public summaries should state what each model missed in ordinary language. Diagnostics succeed when error becomes informative, not when simulated curves decorate confirmation.

22.7.6 — No Winner When All Are Wrong

PTVC, predictive processing, active inference, reinforcement learning, safe control, and bridge models may all fail because the observation system, estimand, or theory set is incomplete. Open-set adequacy prevents the least inadequate model from being forced into victory (Gneiting & Raftery, 2007; Vehtari et al., 2017; Yao et al., 2018). Open-set rejection should be reported before relative rankings, because a best-in-library score can be meaningless when every model fails absolute adequacy.

The framework fixes thresholds for calibration failure, unmodeled residuals, failed recovery, and poor transport. Multi-site disagreement caused by devices, care routines, language, treatment, dropout, or delayed recurrence can therefore produce candidate-set inadequate rather than a spurious winner. Site-specific inadequacy patterns can reveal which observation assumptions fail to transport and should be modeled before pooling sites.

No winner is appropriate when absolute fit is poor, models are nonseparable, uncertainty crosses the decision boundary, or open-set checks reject the family. Refusal to choose is informative when it redirects work toward better measurement, stronger rivals, narrower estimands, or safer collection. The redesign target

should follow the reason for no winner, because poor absolute fit and nonseparability require different next experiments.

Ambiguity must not conceal a clear loss under a model's own rule. Open-set restraint protects inquiry only when the declared rejection criteria are applied symmetrically. Symmetry also requires accepting a candidate loss when the rival meets its predeclared threshold even if open-set concerns remain elsewhere.

22.8 — When Learning and Control Rivals Win

Chapter 22 connects model comparison with public reporting. When predictive processing, active inference, reinforcement learning, safe control, bridges, or selection best explain the observations, the component-level record should identify that result (Lakatos, 1978; Munafò et al., 2017; Nosek et al., 2018).

The final section connects findings to research decisions. Components can be refined or retired, while clinical and methodological discoveries remain available for care and subsequent investigation (Popper, 1959; Lakatos, 1978; Stanford, 2006).

A newly proposed connection between PTVC and a successful comparator should state fresh predictions and receive prospective evaluation on protected evidence.

Equation role: Rival-victory rule. A rival victory is a status event when the protocol-fixed comparison favors the rival beyond the declared uncertainty and practical margin.

$$\Delta_{R,L} = S_R - S_L; \Delta_{R,L} > \delta_{pre} \Rightarrow \textit{narrow}(L\text{-specific component})$$

Table 22.8. Scientific consequences of rival victory.

Result	Status consequence	Public language
One component loses	Component narrowing or retirement	The mechanism did not survive this comparison
Repeated distinctive losses	Strong-form pressure	The broader claim faces adverse evidence
All models fail	Open-set inadequate	The design did not answer the question

Result	Status consequence	Public language
Rival wins and guides care	Research redirection	Preserve the useful finding

22.8.1 — Component-Level Defeat

Component-level defeat retires or narrows a specific mechanism without requiring an immediate verdict on the whole formal Law. A state-allocation signal, reserve interaction, horizon-pressure signature, or endpoint-concentration claim may fail locally while other parts of the program remain open (Lakatos, 1978; Munafò et al., 2017; Nosek et al., 2018).

This is important because learning and control rivals are precise. A predictive-processing model may defeat a salience claim. A safe-control model may defeat a no-return explanation. A bridge model may defeat a terminal-drift interpretation. Each defeat should land where the evidence lands (Popper, 1959).

The status update should name the component. Saying the Law was not supported is too broad when only a mechanism failed. Saying nothing changed is too evasive when the mechanism was central to the chapter's prediction.

Component-level defeat can improve the book. It removes weak material, prevents overclaim, and lets future research focus on what remains. A narrowed theory is often more testable than a broad theory protected by vague language.

Public disappointment must not become private burden. Readers should not be asked to preserve belief by interpreting defeat as their failure to understand. The model lost a comparison. The person remains untouched by the verdict.

A component is defeated when a rival explains the prospectively specified target with equal or better performance, better calibration, successful recovery, and no hidden privilege. The component then narrows, retires, or becomes an open problem with its status visibly changed.

The defeat record should also specify propagation. A failed component may require changes to figures, summaries, public artifacts, protocol templates, and later chapters that relied on it. Without propagation, the formal status changes while the reader-facing theory remains untouched. The record should name the exact claim, evidence, rival, reference class, and affected outputs, then assign an owner and deadline for correction. This makes component-level defeat operational rather than ceremonial and ensures that the project learns from loss across its entire scientific surface (Popper, 1959; Lakatos, 1978).

22.8.2 — Strong-Form Pressure

Strong-form pressure accumulates when multiple distinctive components fail across contexts. One local rival win does not defeat the strong latent hypothesis by itself. Repeated rival wins against the same distinctive conjunction create a different scientific situation (Lakatos, 1978; Munafò et al., 2017; Nosek et al., 2018).

The distinctive PTVC conjunction is narrower than error reduction, learning, safety, adaptation, or endpoint conditioning alone. Its empirical evaluation requires a structured relation among latent trajectory, endpoint discipline, measurable consequences, observation, and rival discrimination. Reserve

enters that conjunction when the tested route specifically assumes reserve coupling. Any component that ordinary models reproduce leaves less work for the terminal candidate (Lakatos, 1978).

If predictive processing explains salience, reinforcement learning explains policy change, safe control explains no-return avoidance, bridges explain endpoint drift, and selection explains terminal concentration, the remaining terminal-closure-specific content becomes smaller. At some point, narrowing is not optional.

The report should define pressure tiers: local narrowing, repeated component failure, strong-form pressure, suspension, and defeat. These tiers prevent all losses from sounding equal while making clear that repeated failure matters.

Clear status updates connect each scientific result to the component it tests and identify the next research decision.

Status updates should be carried into the affected chapters, summaries, diagrams, and public claims. Their wording should reflect the specific evidence and component involved.

Strong-form pressure should be evaluated with a dependency graph. Some predictions share assumptions, data, or mechanisms, so several failures may not be independent pieces of evidence. Other failures attack distinct gates and therefore compound more seriously. The graph should show which losses concern representation, routing, endpoint, observation, mechanism, or transport. This prevents both exaggeration and minimization. Repeated failure across independent gates should lower theory maturity even if one route remains open. Correlated failures

should be evaluated through a joint model or a calibrated decision rule that represents their dependence; exact duplicate evidence should be counted once. Shared failures should also guide revision of the common assumption (Lakatos, 1978; Stanford, 2006).

22.8.3 — No Rebranding the Rival as the Law

The most tempting escape is rebranding. If predictive processing wins, the theory says prediction was fairness. If reinforcement learning wins, it says policy adaptation was fairness. If safe control wins, it says safety was fairness. That move empties falsifiability (Lakatos, 1978; Munafò et al., 2017; Nosek et al., 2018).

A connection between a successful mechanism and a PTV route can be proposed with distinct predictions and tested prospectively as a new claim (Stanford, 2006).

Stable bridge statuses are therefore required: proposed bridge, prospectively specified bridge, tested bridge, unsupported bridge, and failed bridge. These labels prevent ordinary regulation or control from being absorbed into PTV by interpretation after the result.

A concrete misuse would be a public graphic showing an active-inference policy loop and captioning it as the scientific mechanism of fairness. Unless the bridge has been established, that caption overclaims. The safer caption says rival model or candidate comparison.

Use preference, reward, safety, and neutrality consistently with their definitions in active inference, reinforcement learning,

control, and PTVC. Explicit mappings make proposed connections understandable.

No-rebranding discipline is what makes rival victory real. If a rival can win only by being renamed, the comparison was never honest. The chapter closes that route before public enthusiasm can open it.

The same rule applies to successful hybrids. A hybrid model may combine active inference, reinforcement learning, safe control, and a PTVC-specific term, but its performance must be decomposed. Ablation and transport tests should show whether the closure term adds predictive value beyond the ordinary components. If the hybrid works only because the rival machinery carries the fit, the result is not support for the added term. This decomposition prevents a broad integrative vocabulary from absorbing every successful science and preserves a genuine possibility of loss (Wilson & Collins, 2019).

22.8.4 — No New Mechanism After Every Loss

Mechanism revisions state their motivation, source grounding, new predictions, and comparison plan. This record makes theoretical development assessable across successive versions (Lakatos, 1978; Munafò et al., 2017; Nosek et al., 2018).

This rule matters in a broad project because the Law has many possible auxiliary concepts: state-allocation pressure, reserve, horizon, dual-variable cost signal, interoception, dreams, endpoint windows, and measurement governance. Each can be useful, but none should become an infinite repair kit (Popper, 1959; Lakatos, 1978).

A new mechanism should answer a precise failure. If bridge rivals explained endpoint drift but not reserve-linked innovation, a revised mechanism might target that residual. If predictive models explained every prospectively specified feature, adding a new hidden variable without novel predictions would weaken the project.

The protocol should record mechanism changes with version dates, prior rationale, prediction changes, and implications for older results. Old support should not automatically transfer to the revised model. A changed claim needs new evidence.

A revision record lets readers follow how the theory develops, which observations motivated each change, and which predictions are being tested next.

A revision plan can make this concrete. Before each confirmatory cycle, specify which auxiliary changes are permitted, which need a new exploratory phase, and which require a new evidence claim. Changes to endpoints, representations, routing rules, or mechanisms receive their own versioned predictions and frozen artifacts, preserving what each study tested while making room for creative development (Nosek et al., 2018).

22.8.5 — Publication of Rival Victories

Rival victories should be published, logged, and summarized in the same claim-status system as supportive results. A complete public record preserves adverse findings so that readers can assess the evidence as a whole (Lakatos, 1978; Munafò et al., 2017; Nosek et al., 2018).

A comparative result can identify the model that best predicted endpoint-window behavior and state the cohort, observation model, endpoint definition, uncertainty, and component-level consequence (Lakatos, 1978).

Rival victories also protect applied books. If a city, religion, government, or transition-facing artifact cites the science loosely, the public log should make overclaim easy to correct. The science book's honesty becomes a firewall for the whole series.

Plain-language and technical layers are required. The technical report carries equations, likelihoods, diagnostics, and model recovery; the public summary states support, partial support, narrowing, inconclusive, or defeat. Both should be versioned.

Adverse results attach to models and claims, never to participants, clinicians, families, sites, or readers. The archive evaluates scientific propositions rather than lives.

Publishing rival victories succeeds when future readers can see the project correct itself. It fails when negative results are buried, blurred into vague uncertainty, or recast as hidden support.

Search rival victories by claim and component. A public register identifies the tested version, cohort, endpoint rule, observation model, scores, winner, uncertainty, and propagation without exposing private data. Machine-readable fields let figures and summaries update rather than preserve stale claims. Record later replications or reversals so one adverse result is neither hidden nor treated as final beyond its evidence. Scientific credibility grows when archives make correction easier than selective

memory (Nosek et al., 2018; National Academies of Sciences, Engineering, and Medicine, 2019).

22.8.6 — Research Redirection

Wins by learning and control rivals may still yield measurement tools, safer baselines, lower-burden routines, or selection controls. These gains belong to the rival, not terminal support (Lakatos, 1978; Munafò et al., 2017; Nosek et al., 2018).

Redirection preserves useful findings without treating them as terminal evidence. It may improve measurement, protocols, care, or comparison arenas while leaving target status unchanged (Stanford, 2006; Popper, 1959).

A study may show that stable routines reduce distress under an active-inference account and still guide care design. It should not be presented as terminal-neutrality evidence. Better care matters independently.

Record redirection by domain: measurement, rival development, clinical insight, governance, artifact correction, or formal narrowing. Each has different authority, and none alone authorizes policy, belief, or transition.

Useful science may survive a defeated claim, but the claim cannot hide inside it. Evidence should remain modest, actionable, and explicit about what lost.

Scientific fairness places the burden on the claim. Rival victory changes its status; surviving residuals face stronger tests; care, rights, privacy, and human standing remain independent.

Chapter 23 — Evolution, Non-Ergodicity, and Outer Limits

Chapter 23 examines how findings extend across evolution, population structure, development, species, and synthetic systems. Each extension identifies the mechanisms, measurements, and reference classes needed for a meaningful comparison.

Evolution explains how affect can support survival, learning, attachment, cooperation, and recovery, giving PTVC a rich mechanistic comparison space. It supplies mechanisms and boundary conditions for models of experience across an organism's life.

Nonergodicity connects the level of analysis with the question being asked. Relations observed across people can differ from relations unfolding within one person. Recent neurocognitive work provides concrete examples for designing population and within-person analyses (Hunter et al., 2024; Mistry et al., 2026).

Time averages require conditions that lived trajectories may not satisfy. Development, illness, trauma, medication, culture, care, relationships, and approaching endpoints can alter dynamics, observation, and available states. Exchangeability, stationarity, recurrence, and transport must therefore be demonstrated rather than assumed.

A cohort trend can also be manufactured by visibility. Participants carrying the greatest burden may stop reporting, receive sedating treatment, enter unobserved care, die earlier, or leave because participation itself becomes costly. A falling observed average can then describe the surviving record rather than the streams that became harder to see.

Complex systems add both opportunity and risk. Nonlinear feedback, multistability, hysteresis, critical transitions, and path dependence can produce recovery, oscillation, sudden change, and apparent concentration. Those structures become scientifically useful only when they generate discriminating predictions and can lose to simpler explanations.

Nonlinear systems can recover, tip, oscillate, settle into regimes, and change behavior after small perturbations. A useful complexity model identifies which patterns it predicts, which alternatives reproduce them, and which observations would require revision.

Critical slowing down, metastability, hysteresis, recurrence, cascades, attractor switching, and path dependence offer specific dynamical structures to investigate. Each can be evaluated through predicted signatures, surrogate tests, and comparison models.

Extensions to infants, nonhuman animals, organoids, and artificial systems specify bearer qualification, measurement invariance, endpoint comparability, support overlap, and mappings between constructs.

Bearer adjudication belongs to the earlier chapters on stream identity and boundary states. The narrower task here is transport: what would allow evidence about one kind of stream to travel responsibly to another? A transport bridge requires specified mechanisms, compatible measurements, and evidence that the relevant assumptions hold in the target setting.

A comparative program can protect unfamiliar or difficult-to-measure candidates while developing the observations needed to characterize them. Scientific descriptions specify the reference classes and relationships supported by those observations.

Artificial systems expose the difference between performance and phenomenal evidence. Fluent output, reward optimization, self-report-like language, or engineered closure is not enough. Architecture, recurrent access, memory, self-modeling, global availability, embodied regulation, ablations, robustness, and alternative explanations belong in an indicator-based assessment, with welfare precaution and human review preserved (Butlin et al., 2026; Seth, 2025).

Narrowing can be a mature scientific result. A claim restricted to adult humans, particular states, certain cultures, or defined measurement conditions is smaller than a universal formulation but more informative than a statement protected from counterexamples. Scope withdrawal keeps the program answerable.

Outer limits therefore strengthen the project. Evolution may explain regulation without fairness, population averages may hide streams, complexity may mimic closure, and comparative bridges may fail. Each outcome identifies a boundary, preserves what was learned, and prevents the Law from expanding beyond the evidence.

23.1 — Selection and Experienced Welfare

Evolutionary accounts explain why organisms regulate stress, avoid injury, seek nourishment, learn from pain, repair tissue, attach to caregivers, and reorganize behavior after loss. These mechanisms show how feeling can participate in control without implying that selection optimized justice or terminal balance for each stream (Williams, 1966; Nesse & Williams, 1994; Dawkins, 1976; Nesse, 1990; Williams & Nesse, 1991; Nesse & Ellsworth, 2009).

The same explanation sets a limit. Natural selection acts through differential survival and reproduction under ecological conditions; it can preserve traits that make some lives harder. Panic can protect against ancestral threat while sustaining modern vigilance, and grief can preserve attachment while making a particular loss almost unlivable.

Evolutionary accounts are therefore executable rivals when they predict the emergence, distribution, mismatch, and tradeoffs of affective systems under declared life histories and environments. If those accounts explain the protected signatures without pathwise closure, they win within their domain.

Evolutionary compatibility is not a signature. The comparative question is what remains after adaptation, mismatch, life history, developmental constraint, population selection, and observation are modeled with equal seriousness. If nothing distinctive remains, the PTVC-specific claim narrows.

Table 23.1. Evolutionary rival family and what each can explain.

Rival mechanism	What it explains	Questions for further investigation	Victory condition
Adaptive signal functions	Pain, pleasure, relief, threat, and attachment as action-guiding signals.	How do signal dynamics relate to cumulative experience within a stream?	Signal models predict trajectories as well as or better than PTVC candidates.
Mismatch	Persistent burden when old regulation meets new environments.	How does environmental fit affect the persistence of distress and recovery from it?	Mismatch variables account for apparent closure signatures.
Life-history tradeoff	Different allocation of energy, risk, reproduction, and care across stages.	How do life-stage allocations shape individual experiential trajectories?	Life-stage ecology explains horizon effects without PTVC-specific residuals.
Developmental constraint	Inherited architecture, path dependence, and repair limits.	Which developmental constraints alter recovery and experienced welfare?	Constraint models reproduce observed dynamics without terminal boundary.

Rival mechanism	What it explains	Questions for further investigation	Victory condition
Population selection	Distributional success through survival and reproduction.	How do within-stream trajectories relate to population composition and survivorship?	Population process explains apparent neutrality through mixture or survivorship.

23.1.1 — Fitness and Reproduction

A trait can spread because it improves survival, mating success, kin support, parental investment, or group coordination. Its effects on felt experience form an additional dimension of the biological account (Williams, 1966).

Fear illustrates how a protective response can carry experiential costs. Treating an uncertain rustle as a threat may support survival, while false alarms produce racing heart, narrowed attention, freezing, and vigilance. Measuring these responses links the signal's function with its effect on the individual.

The same logic applies to human social pain. Exclusion sensitivity, shame, jealousy, and status anxiety can push behavior toward coalition maintenance or norm compliance. Studying why these signals persisted, how their effects unfold within a life, and how they respond to changing circumstances connects evolutionary explanation with the temporal questions raised by PTVC.

Evolutionary models connect hunger, injury, rejection, uncertainty, contagion, threat, exhaustion, infant dependency, and

mate loss with recurring control problems. They also explain why relief can reinforce survival-supporting actions. These links provide mechanisms and temporal predictions for studying experience.

The key estimand is not the average reproductive success of a trait-bearing group. It is not even the average affective tone of a species under a given ecology. For the Law, the unit of concern is the temporally extended stream. A biological explanation that operates through distributions remains silent about whether a particular path closes.

Evolutionary models can compare the effects of selection pressures and demographic filtering on regulation, variability, recovery, attachment, and terminal patterns. Held-out prediction shows which features each account explains and where an additional path constraint contributes.

23.1.2 — Pain and Pleasure as Signals

Pain and pleasure can guide action under constraint. Pain may accompany injury, threat, inflammation, social exclusion, or anticipated loss; pleasure may accompany nourishment, safety, attachment, exploration, relief, warmth, mastery, or successful regulation (Nesse & Williams, 1994; Dawkins, 1976).

Pain and threat signals connect bodily conditions with action. A burn can prompt protective behavior; a false panic alarm can reflect a conservative threat-detection system. Their timing, intensity, and context are available for physiological and behavioral study.

The adaptive-signal view gives a powerful rival to the Law because it predicts asymmetry. Organisms may be built to overweight loss, threat, and pain because missing danger can be costlier than missing opportunity. That asymmetry can generate long negative tails in lived experience without violating evolutionary logic. Selection can therefore preserve an effective protective response even when its experiential costs are substantial.

The science should therefore ask what a signal explains. Does it explain local avoidance, learning, recovery, attention, memory consolidation, attachment repair, or resource allocation? Does it explain persistence of burden under mismatch? Does it predict when relief fades because the organism must return to vigilance? If yes, it remains a serious rival.

The next comparison asks whether pathwise constraints predict additional features after signal functions, contextual variables, and learning dynamics are included.

A biological function identifies how a system uses a signal for regulation. Measuring that function alongside the burden it creates gives a fuller account of its consequences.

A nociceptive or threat signal may change as tissue heals, attention shifts, medication acts, sleep supports regulation, or movement changes. Recording these pathways separately helps explain why visible distress and reported experience change over time.

23.1.3 — Mismatches and Modern Environments

Evolutionary mismatch is one of the strongest non-Law explanations for persistent burden. A system shaped under one ecology can misfire in another. Food abundance, artificial light, social media, urban density, chronic noise, wage precarity, synthetic drugs, sedentary work, and institutional complexity can drive ancient control systems into states they were not tuned to handle (Dawkins, 1976).

Consider vigilance. In a dangerous ancestral environment, rapid threat detection may have protected the organism. In a modern apartment where the threat is debt, inbox overload, medical paperwork, or hostile online attention, the same physiology can run without a clear external predator. The person is not irrational. The body is using old machinery in a new world.

Mismatch can also preserve pleasure traps. High-calorie foods, intermittent rewards, pornography, gambling-like social feeds, and addictive substances can hijack reward systems built for sparse opportunities. The resulting burden can look like failure of will from the outside. Mechanistically, it is a collision between evolved learning systems and engineered environments.

This rival can explain why burdens persist without any terminal justice. It predicts that some streams will be exposed to chronic states for which regulation is maladapted: inflammatory stress, insomnia, depression, addictive loops, social comparison, and administrative uncertainty. The ecology changes faster than biological adaptation.

Mismatch models explain how ecological change can alter adaptation across individuals and settings. Their predicted trajectories provide a basis for testing additional per-stream relationships.

The human texture matters here. A night-shift caregiver who alternates blue hospital light, vending-machine food, family worry, and debt calls is not just an observation in a stress dataset. That person is a stream under an ecology. The scientific question is whether the resulting trajectory contains stream-level closure structure after the mismatch mechanism has been given its full force.

Mismatch is especially important because it explains burden without malice or balance. A nervous system shaped for small groups, short horizons, immediate threats, and embodied routines can suffer under isolation, digital vigilance, chronic bureaucracy, industrial noise, sedentary work, and social comparison. The unfairness is real in the stream even if no villain designed it. Evolution can therefore explain why burden persists, why relief is partial, and why ordinary adaptation can fail without implying later compensation.

23.1.4 — Individual Versus Population Success

Selection changes the distribution of traits through differences in reproductive outcomes. Measuring both those effects and individual experiential consequences connects population mechanisms with within-life trajectories (Williams, 1966; Nesse & Williams, 1994).

Parental investment, grief, loyalty, protective aggression, moral outrage, endurance, and responses to norm violation can shape family and group functioning. Their effects on the individuals carrying them can be studied alongside those social functions.

Population success also hides replacement. A trait may persist because carriers who cannot bear its costs drop out of reproduction, leave the observable cohort, or are not counted in later records. This is a selection mechanism, not a fairness mechanism. It creates survivorship, not proof.

For the Law, this means a population trajectory can be scientifically interesting and still be insufficient. If average reports improve with age, if species-level coping systems look stable, or if a cohort's terminal estimates cluster near neutrality, the next question is who is missing, who was measured, and whether each stream's history is being reconstructed rather than averaged away.

Individual trajectories and population summaries answer complementary questions. A population can have a neutral mean while individuals differ substantially in opposite directions, and selective loss from observation can change that mean. Recording trajectories and sample composition keeps both levels interpretable.

Clear units connect population mechanisms with individual trajectories. Reporting both levels makes their respective contributions to the account explicit.

Population success and individual experiential outcomes are distinct biological questions. A strategy may increase descendants

while imposing substantial costs on some carriers. Studying both levels gives a fuller account of how selection shapes experience.

23.1.5 — Neutral and Maladaptive Traits

Not every trait is adaptive. Some traits are neutral, weakly selected, historically contingent, linked to other traits, or maladaptive in current conditions. A serious evolutionary treatment cannot make every observed feeling into a just-so story. Some experiential dynamics may persist because selection is limited, slow, noisy, local, or constrained (Nesse & Williams, 1994).

Developmental constraints matter. A nervous system is not redesigned from first principles for comfort. It inherits architecture. It uses ancient circuitry, repurposes systems, and carries tradeoffs. The result can be brilliant in one context and destructive in another. Back pain, chronic inflammation, reproductive risk, trauma memory, and anxiety sensitivity can persist because bodies are compromises, not perfect welfare machines.

Genetic drift and linkage also prevent simple comfort stories. A trait may ride with another trait, remain below selection pressure, or appear only under rare environmental combinations. The fact that it exists does not mean it serves fairness. Existence is not endorsement.

Some trajectories reflect poorly matched environments, physiological damage, or developmental constraints. Modeling those processes helps explain individual variation and identifies opportunities for support or recovery.

A methodologist should hear the modeling implication. Evolutionary parameters need uncertainty. Trait history, current environment, developmental exposure, genetic architecture, culture, treatment, and measurement regime all affect whether an observed pattern is adaptive, maladaptive, neutral, or mixed.

Evolutionary complexity helps sharpen the PTVC candidate. Regulation supplies mechanisms to investigate, while pathwise predictions specify the contribution of a terminal-boundary account. Neutral, maladaptive, mismatched, and constrained mechanisms expand the range of trajectories the comparison should represent.

Some experiential patterns arise as side effects of other mechanisms, such as vigilance coupled to social memory or pain coupled to mobility protection. Others persist under weak selection, recent environmental change, or developmental constraints. Including these possibilities gives the model a fuller account of stable individual differences.

23.1.6 — Evolutionary Rival Victory

Evolutionary explanations can account for selection, development, ecology, and population dynamics with testable predictions for the observed trajectories. When those predictions perform best, the result identifies the biological mechanism to carry into the next stage of research (Dawkins, 1976; Williams, 1966).

Candidate explanations include sedation, attrition, family communication, care pathways, survivorship, changing behavioral range, physiological transitions, adaptation, sleep,

learning, social support, and conserved control architecture. Each predicts a different combination of timing and observation effects.

Plausibility supplies a starting point for an evolutionary model. The next step is to generate held-out predictions, reproduce path signatures under the same observation model, check model recovery, and identify cases where PTVC predicts a different result.

The comparison can refine the model's biological mechanisms and scope, improve measurement, and identify useful questions about affect dynamics and end-of-life care. Each result determines which component to develop next.

Public summaries should distinguish biological plausibility, demonstrated mechanisms, and comparative prediction results. Each contributes a different part of the scientific case and should be described through the evidence supporting it.

Evolutionary theory supplies mechanisms and strong comparison models for PTVC. Testing their competing predictions can refine both accounts.

An evolutionary explanation is evaluated for a specified signature under a common observation model. Reporting the responsible mechanism and its tested range gives subsequent research a clear starting point.

23.2 — Non-Ergodicity and Within–Between Reversal

PTVC concerns the trajectory of a qualifying stream over time. Analyses therefore specify how within-person temporal patterns relate to population distributions and test the assumptions connecting those levels (Molenaar, 2004; Hunter et al., 2024; Fisher et al., 2018; Peters, 2019).

Nonergodicity means more than individual differences. The analysis must name the process, within-stream and between-stream estimands, time and ensemble averages, and assumptions under which they converge or diverge. A large sample does not create stationarity, homogeneity, or exchangeability.

A 2026 analysis of neuroimaging and behavioral data from more than 4,000 participants found brain-behavior associations that reversed between within-person and between-person analyses. This provides a concrete reason to estimate both levels when studying stream-specific dynamics (Mistry et al., 2026).

A plot of many lives can look like one river even when its component streams move differently. The scientific file must therefore preserve person-level time, within-stream variation, between-stream variation, and the relation between them. Aggregation is a modeling choice, not an ontological merger.

23.2.1 — Ensemble and Time Averages

An ensemble average summarizes many streams at a common time or window; a time average follows one stream through time. Their equality is not a consequence of sample size but of specific ergodicity assumptions, which may fail in developing, treated, aging, culturally embedded, or history-dependent systems

(Molenaar, 2004). Let $X_i(t)$ be a measurable process for stream i in the display below.

The practical consequence is that the unit of inference must be declared before the beauty of a curve is discussed. A smooth terminal mean, a pooled variance estimate, or a cross-sectional association may be useful for clinical description, but it is not automatically a statement about the integral of a stream. To make it relevant, the study must show why the temporal process within each bearer can be represented by the same statistical object. Otherwise the average is only an average, however elegant it looks.

$$\overline{X}_i^{\text{time}} = \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T X_i(t) dt, \quad \overline{X}^{\text{ensemble}}(t) = \mathbb{E}_i[X_i(t)]$$

This display defines the time and ensemble averages. Population surveys reveal social differences, policy burdens, and inequalities, while longitudinal observations characterize within-person dynamics. Specifying their relationship connects these complementary sources of information (Diener et al., 2006; Shiffman et al., 2008).

A hospice cohort's final-week mean may reflect physiology, care practices, sedation, reporting capacity, family communication, attrition, or population mixture. Within-person records and observation models help separate these contributions.

Non-ergodicity identifies the level at which evidence must be gathered. The analysis can collect per-stream data, state justified transport assumptions, or narrow the claim to the level supported by the observations.

Where the relevant stationarity, ergodicity, and comparability assumptions are justified, population information can help characterize within-stream dynamics. Otherwise, model the population and individual quantities separately.

23.2.2 — Within-Person Versus Between-Person Effects

Within-person effects ask how change inside one stream relates to change in another quantity for that same stream. Between-person effects ask how differences among streams relate to differences among other quantities. Confusing them is one of the cleanest ways to generate false psychological laws (Hunter et al., 2024).

A simple decomposition makes the point. A person's value at time t can be separated into a person mean and a deviation around that mean. The between-person coefficient can attach to the mean, while the within-person coefficient attaches to the deviation.

The within-between distinction should shape interpretation before data are collected. A protocol may prospectively specify a within-stream estimand, such as change in an individual's volatility near an endpoint window, and separately specify a between-stream estimand, such as the relation between reserve and variance across people. These are different claims. A reversal between them is a primary result, not a nuisance for supplementary material.

$$Y_{it} = \alpha + \beta_W(X_{it} - \bar{X}_i) + \beta_B\bar{X}_i + \varepsilon_{it}$$

This equation is an estimator structure, not a Law formula. If β_W and β_B have different signs, the population story and the individual story move in opposite directions. A between-

person association can say that people with higher average social contact have lower distress, while the within-person effect can say that a given person seeks contact on days of rising distress.

The Law is exposed to the same risk. A population average near neutrality at endpoint says very little if the within-stream paths are heterogeneous, if high-burden paths disappear, or if changes within persons move opposite to differences between persons.

A concrete example helps. Suppose higher average sleep duration across people is associated with lower burden. Within one terminal patient, longer sleep on certain days might indicate medication escalation, fatigue, infection, or withdrawal. The between-person association is not a per-stream repair mechanism.

A serious analysis must therefore declare whether it is estimating a between-stream relation, a within-stream relation, a cross-level relation, or a transport relation. One coefficient cannot carry all of them.

The result can reverse without fraud, incompetence, or bad faith. It reverses because the question changed. This is why the chapter treats non-ergodicity as a design constraint rather than as a statistical afterthought.

23.2.3 — Heterogeneous Dynamics

Heterogeneity is not merely different baselines. Streams can differ in parameters, mechanisms, response lags, treatment exposure, cultural scripts, reporting styles, physiology, developmental history, and endpoint risk. A model that assumes one dynamic law for all streams may manufacture regularity by

averaging away the very differences the Law must face (Hunter et al., 2024).

For example, three people may show the same measured distress score but under different dynamics. One may be in a reversible grief wave with strong social repair. Another may be in medication-induced emotional blunting. A third may be in pain with reduced report capacity. The same observation cannot be given one mechanism without testing.

Heterogeneous dynamics also matter for reserve. Reserve may be metabolic, cognitive, autonomic, social, attentional, or clinical. Collapsing it into one scalar may work in a narrow context, but it cannot be assumed across ages, diagnoses, cultures, or species. If reserve is vector-valued, different components can fail at different times.

A hierarchical model can help by allowing person-specific parameters. But hierarchy is not a magic bridge. It borrows strength across persons only under an exchangeability claim. If exchangeability fails, the model may shrink unusual streams toward a false group center.

The Law should prefer designs that preserve individual dynamics before summarizing. Idiographic models, person-specific state-space estimates, and hierarchical models with explicit heterogeneity are not decorations. They are safeguards against turning aggregate smoothness into pathwise closure.

Failure here has a clean status implication. If closure-like signatures appear only after aggressive pooling and disappear under person-specific modeling, the Law loses support in that setting. The average was doing the work.

Heterogeneity also changes what humane design looks like. If one subgroup carries pain, another carries confusion, another carries sedation, and another carries family-pressure reporting, then a single terminal curve can conceal several burdens. Stratification is not only statistical hygiene. It keeps care-relevant differences visible. A model that discovers heterogeneity may become more useful even as it makes a universal claim less plausible.

23.2.4 — Mixture Distributions

A mixture distribution can look like convergence when no subgroup converges. If one subgroup moves upward, another downward, and a third disappears, the pooled mean can approach a neutral value. The result can be visually persuasive and scientifically wrong for the pathwise claim, especially when between-person structure is mistaken for within-person dynamics (Molenaar, 2004; Hunter et al., 2024; Mistry et al., 2026).

Mixture risk is especially high near endpoints. Diagnosis, sedation, care setting, family involvement, medication, cultural reporting, device adherence, and survival all create subgroups. A terminal dataset is rarely one homogeneous population sliding toward a common boundary.

The chapter's demand is not that every mixture be known in advance. It is that mixture be modeled as a live alternative. Latent class models, mixture state-space models, stratified analysis, posterior predictive checks, and leave-site-out validation can reveal whether an apparent universal signature is actually subgroup composition.

A simple Simpson reversal can be checked numerically. In arbitrary toy units, group A has the two (x, y) observations (1,8)

and (2,9), while group B has (8,1) and (9,2). Within each group, y increases by one unit for each unit increase in x . Pooling all four observations instead gives a least-squares slope of -0.96 : the overall means are $\bar{x} = 5$ and $\bar{y} = 5$, the sum of cross-products is -48 , and the sum of squared x deviations is 50 . The reversal arises from the separation of the group means. This worked example shows how differences between group means can reverse an aggregate association.

Mixtures also create moral danger if ignored. A public summary might say terminal experience tends toward neutrality while the pattern is driven by those easiest to observe. The people with severe delirium, low report capacity, device dropout, or unmanaged pain may be hidden in the missing tail.

The scientific rule is direct: report mixture diagnostics before reporting pathwise implication. A neutral pooled estimate without subgroup accountability is not a closing stream. It is a population artifact waiting to be interrogated.

A simple Simpson reversal can be imagined without fraud. In each diagnosis group, increasing reserve may be associated with worse reported distress because more awake patients can report pain. Across groups, higher-reserve diagnoses may have lower average distress because the illnesses differ. The pooled association then points one way while every within-group association points another. The Law cannot rest on a pooled direction until the grouping structure is named and tested.

23.2.5 — Survivorship and Selection

Survivorship links biological trajectories to the changing composition of the observed sample. The streams remaining

observable at a later time are not always representative of the streams that began the study. Those who die earlier, lose consciousness, drop devices, refuse burdensome reporting, enter sedation, move sites, or lack family support may leave the data precisely when their trajectories matter most (Hunter et al., 2024).

This is not merely missing data. It is selection on the process under study. If high-burden states reduce participation, then observed improvement may reflect attrition. If low-unity states prevent report, terminal concentration may reflect silence rather than neutrality. If device adherence depends on mobility, the passive signal is partly a motor-capacity signal.

Survivorship can also enter evolution. Lineages are observed because they survived. Cultural practices are recorded because some groups preserved records. Clinical terminal data are collected where institutions allow research. Each layer selects the evidence before analysis begins.

The Law's empirical program must therefore model observation as part of the data-generating process. Who remains, who leaves, who is censored, who is measured by proxy, and who has endpoint evidence all affect the claim. A credible model of the missing tail can determine whether the terminal pattern remains supported.

A family example makes the risk concrete. A widower may delete a sleep tracker before hospice because the device feels intrusive. The missing telemetry is not random. It records dignity, grief, privacy, device fatigue, and refusal. Treating that absence as ordinary noise turns a person's boundary into a statistical convenience.

Survivorship does not make science impossible. It makes the evidence conditional. Every conclusion must say what selection model would reverse it and what data would be needed to test that model.

23.2.6 — Per-Stream Claims Require Per-Stream Evidence

A claim about a stream requires evidence about streams. Population data can orient hypotheses, identify rivals, estimate parameters, and reveal artifacts, but cannot close an individual path without an independently justified bridge (Hunter et al., 2024; Molenaar, 2004).

Per-stream evidence does not require total observation. It requires repeated measures, prospectively specified stopping and noncircular endpoint adjudication, observation-process models, person-specific baselines, uncertainty, and validation without future leakage, together with a clear account of what was observed, bounded, estimated, or unknown. Any statistical dependence of the endpoint on the stream must be represented under the tested branch.

A late-life window can estimate increments, terminal concentration, variability, or route dynamics. Its relation to earlier history is represented through explicit assumptions about the unobserved past.

A strong result states the window, observation rules, rivals, and per-stream pattern that appeared or failed to appear. That is more informative than a grand average that cannot describe any individual path. Publishing the distribution of individual-path effects can reveal reversals that disappear in the pooled mean and guide the reference class for replication.

Non-ergodicity also protects readers from hearing population averages as personal destiny. The language stays at the level of the evidence. Individual forecasts should therefore be built from within-person evidence or explicitly transport a population result, rather than treating the group mean as the default trajectory.

If no feasible design can support per-stream evidence for a proposed scope, the scope narrows so the claim remains answerable. A narrowed scope should specify the missing bridge, making the excluded population a target for future validation rather than an unspoken exception.

Late-life windows can still test valuable local dynamics, but complete-stream language requires independently justified bounds on the unseen past. The strongest science says exactly what it has not observed. Sensitivity to plausible unseen prefixes can show whether a local conclusion is robust even when a complete-stream verdict remains unavailable.

Table 23.2. Non-ergodic failure routes and required design response.

Failure route	How it misleads	Design response
Within-between reversal	A population coefficient is read as a person-level dynamic.	Decompose within and between effects before interpretation.
Mixture composition	Subgroups produce a neutral pooled curve.	Use mixture diagnostics, stratification, and subgroup-specific trajectories.
Survivorship	Only easier-to-observe streams remain late in the window.	Model censoring, dropout, endpoint loss, and observation intensity.

Failure route	How it misleads	Design response
Heterogeneous parameters	Pooling shrinks different dynamics toward a false common law.	Use idiographic or hierarchical models with exchangeability checks.
Initial-state uncertainty	Late data are promoted into whole-life inference.	Carry initial-state bounds and limit claims to observed windows.

23.3 — Complexity and Fragile Closure

Complex-systems language is useful when it names state variables, feedback, transition rules, observables, and falsifiers. Terms such as nonlinear, emergent, critical, chaotic, metastable, and self-organizing become scientifically empty when they protect a preferred account from identification (Scheffer, 2009; Strogatz, 2018; Holling, 1973; Box, 1976; Scheffer et al., 2009).

Nonlinear systems can produce sudden improvement, collapse, variance compression, flickering, hysteresis, and path dependence without any stream-level terminal boundary. Body, memory, social support, disease, sleep, medication, culture, and environment can generate meaningful-looking patterns through ordinary coupling.

The task is not to deny complexity but to make it answerable. A proposed nonlinear mechanism identifies its interacting states, feedback signs, perturbations, observation process, rival signatures, and failure conditions. Otherwise complexity becomes a shelter for nonidentification.

Complexity increases the need for model recovery. Multistability, critical transitions, and rare paths can make different generators look similar in one observed window. Synthetic near-miss worlds should therefore be used to test whether the analysis recognizes the mechanism or merely recognizes a dramatic shape.

23.3.1 — Nonlinear Feedback

Nonlinear feedback means that the effect of a change depends on the state of the system. A small stressor can be absorbed when sleep, support, and health are strong; the same stressor can trigger

collapse when reserve is low. Conversely, a small repair can matter enormously when the system is near a threshold (Scheffer, 2009).

For PTVC, the scientific consequence is that terminal-looking patterns may be nonlinear without being terminally fair. Declining reserve, reduced behavioral range, medication, family presence, and clinical routines can create state-dependent damping. Apparent convergence may therefore arise from ordinary control under constraint.

A nonlinear model must identify the loop. Is distress increasing inflammation, which worsens fatigue, which reduces social contact, which increases distress? Is sleep reducing emotional volatility, which improves report stability? Is pain medication lowering both pain and arousal, creating apparent neutrality? These mechanisms differ.

A candidate equation can be useful as a map rather than proof. The state x might represent a burden proxy, the parameter θ a context or reserve variable, and the noise term unmodeled perturbations. The important feature is not the symbols. It is that dynamics change with state.

Nonlinear feedback also gives skeptics a precise demand. If a proposed Law signature is only state-dependent damping, the analysis should identify the damping variable and give ordinary physiology a chance to reproduce it. Pain relief, reduced report bandwidth, sedation, respiratory slowing, immune collapse, family presence, or clinical routines can all change drift and variance. The Law earns attention only if a residual pattern remains after these loops are modeled.

$$dx_t = f(x_t, \theta_t)dt + \sigma(x_t, \theta_t)dW_t$$

This is a candidate state equation. It says only that drift and volatility may depend on the current state and context. A stream-level closure interpretation requires more: the nonlinear terms must produce distinctive signatures under an endpoint-independent observation rule and beat rivals that use the same data.

Nonlinear feedback also creates intervention responsibility. If a small repair near a threshold can prevent collapse, care should act immediately. The theory does not earn the right to watch a fragile system fall in order to learn whether it would later recover.

23.3.2 — Multistability and Hysteresis

Multistability means a system can have more than one stable regime under the same external conditions. Hysteresis means the path into a state affects the path out. A person can remain in depression, chronic pain, panic, grief, or fatigue after the trigger has changed because the system has reorganized around a new basin (Strogatz, 2018; Scheffer, 2009).

This is not metaphor alone. Neural, endocrine, immune, social, and behavioral feedback can create persistence. A sleep loss episode can change coping capacity; a traumatic event can alter threat interpretation; chronic pain can reshape movement, attention, and social participation. Returning the external environment to normal may not return the stream to its prior state.

Multistability gives the PTVC model a concrete dynamical question: which mechanisms or endpoint relationships connect persistent regimes with the proposed pathwise boundary?

Specifying those relationships makes the candidate more informative.

The scientific program should look for signatures of hysteresis: different trajectories for onset and recovery, lagged return after treatment, threshold effects, and dependence on history beyond current state. These are not Law signatures by themselves. They are rival dynamics that must be modeled.

A rehabilitation patient may enter a feedback loop in which pain reduces movement, reduced movement weakens capacity, and fear narrows activity. Treatment can then address the interacting physiological and behavioral processes as well as the original injury.

Multistability identifies a productive modeling challenge: any proposed terminal boundary must be compatible with systems in which earlier events shape later possibilities. Explicitly representing hysteresis makes the candidate more precise and can provide additional predictions to compare with ordinary path-dependent mechanisms.

Hysteresis helps explain why recovery may involve more than removing the original cause. After an argument ends, a job changes, an injury heals, or a threat passes, learned responses can persist. Identifying the current regime and the conditions for transition makes it possible to study timely, supportive interventions.

23.3.3 — Critical Transitions

Critical transitions are abrupt shifts that occur when a system approaches a threshold. The early-warning literature often tracks

slowing recovery, rising autocorrelation, rising variance, skewness, or flickering. These signals can be valuable, but they are generic. They do not belong to the Law by default (Scheffer, 2009).

A terminal decline can produce many boundary-like patterns. Motor options shrink, physiology simplifies, report channels close, medication changes, sleep increases, family routines stabilize, and the measured world becomes narrower. Some of those changes can compress variance without any latent ledger movement.

Critical slowing down and changes in variance can identify proximity to a transition. Stream-level analyses can compare these generic transition signatures with the predicted dynamics around an independently defined endpoint.

Negative controls can test whether device quality, motor capacity, oxygenation, medication timing, or observation intensity explains the same variability pattern. Comparing physiological channels with different relationships to experience helps locate the source of the transition signal.

This also protects readers from a false aesthetic. A graph narrowing near the end of life can feel meaningful. It may also be the graph of fewer measurements, reduced movement, sedation, or common care routines. Visual beauty is not a verdict.

The field should treat critical-transition tools as diagnostics, not conclusions. They help ask whether dynamics changed. They do not tell us what the change means until the observation model, mechanism, and rivals have been named.

23.3.4 — Path Dependence

Earlier conditions can influence later responses even when current reports match. A similar reported state may follow recovery, prolonged restriction, medication, or a stable ordinary period, with different implications for what happens next (Strogatz, 2018; Scheffer, 2009).

A cumulative model distinguishes current state, recent increments, accumulated history, and unobserved initial conditions. Their separate predictions connect the ledger hypothesis with the temporal structure of the observations.

Emotional sequences also have an increasingly measurable memory architecture. Ma and Kragel (2026) analyzed fMRI recordings from 29 people watching films and continuous emotion ratings collected from 44 separate observers. Tests on films excluded from model fitting showed that hippocampal activity captured structured relationships among emotion categories, while ventromedial prefrontal activity better represented positions in a space organized by valence and arousal. A computational model that learned transitions among emotional events reproduced aspects of this organization across representational scales. These results give path-dependent models a specific biological starting point: memory can organize emotional events by their relationships and sequence. The next comparison can ask whether these learned structures predict later responses across new contexts and whether an accumulated-history term adds useful predictive information.

Path dependence also produces fragile repair windows. An apology early may prevent years of burden; the same apology late

may not. A pain intervention before fear conditioning may preserve mobility; after years of avoidance, treatment must address movement, belief, sleep, and social context. The timing of repair is part of the mechanism.

In modeling terms, the state must be expanded. Memory variables, accumulated exposure, regime indicators, and prior transition history may be required. A Markov model using only current report can miss the path. A non-Markov model can become unidentifiable if it adds history without data.

A history comparison needs a specified future observation vector $Y_{t,h}$. Let S_t summarize estimated current state, Z_t contain prespecified context, and A_t^{win} summarize the observed past window. Compare predictive densities $q_0(Y_{t,h} | S_t, Z_t)$ and $q_H(Y_{t,h} | S_t, Z_t, A_t^{\text{win}})$, trained without evaluation outcomes. Their locked-test advantage is

$$\Delta_{\text{history}} = \mathbb{E}_{\text{test}}[\log q_H - \log q_0].$$

Both models score the same outcome under a common probability or density convention, with supported outcomes and finite score expectations. Prespecify participant and occasion weights, and either model observation loss jointly or justify the missing-data estimand; scoring returned reports alone changes the target population. Use participant-level splits, chronological prediction, and uncertainty that respects overlapping windows. Only the true conditional laws make this population difference conditional mutual information; fitted-model gains concern those fitted representations (Gneiting & Raftery, 2007).

Shared measurement error can manufacture apparent compensation. Suppose $Y_t = X_t + e_t$, with independent zero-mean errors of variance σ_e^2 independent of the latent process. If a fixed-weight history includes the current report with weight $w_t > 0$, then for $h > 0$ its error covariance with the future change is

$$\text{Cov}(\sum_{k \leq t} w_k e_k, e_{t+h} - e_t) = -w_t \sigma_e^2.$$

This is a covariance contribution, not a complete regression coefficient. Predict future levels or trajectories and model current-state uncertainty. Lagging or dropping a shared report removes the artifact only when the error model justifies that separation; serial errors need their own calculation.

History gain is followed by a mechanism comparison against latent-state filtering, leaky and multiscale memory, computational mood, correlated environments, and ordinary integral feedback. Give these rivals the same histories and tuning resources. History may help only by estimating an ordinary present state more accurately, while a genuinely sufficient state may leave no added history gain. Test the candidate's additional frozen restrictions on new sequences and contexts, with a prespecified useful-effect threshold. A transported advantage supports that predictive representation at the tested scope; an interval below the useful threshold can deprioritize it. The observed window remains distinct from an unmeasured whole-stream prefix.

A two-basin example can be stated directly. In dimensionless model units, $\frac{dx}{dt} = x - x^3$ has stable equilibria at $x = -1$ and $x = 1$ and an unstable boundary at $x = 0$. Starting at $x(0) = -0.1$

leads toward -1 ; starting at $x(0) = 0.1$ leads toward 1 . A perturbation across zero can therefore change the eventual regime even though the evolution rule is unchanged. This illustrates dependence on which basin the prior trajectory entered. The full-state toy is Markovian: the current state records which basin the trajectory occupies.

The mechanism comparison can vary history in three complementary ways: different signed totals ending in similar measured states; equal totals with different ordering or spacing; and persistence through an independently characterized interruption. A fixed coordinate must predict these contrasts without being redefined for each task. For a leaky integrator with $\lambda \geq 0$,

$$\dot{q} = -\lambda q - v, \quad q(t) = e^{-\lambda t} q(0) - \int_0^t e^{-\lambda(t-s)} v(s) ds.$$

Equal unweighted totals can leave different retained states when $\lambda > 0$. Fix the initial-state convention, tested durations, error model, leakage-family range, and smallest useful transported difference before evaluation. Arbitrarily slow positive leakage approaches nonleaking integration over any bounded observation interval, so finite noisy records cannot establish permanent retention against that unrestricted rival. An independently supported lower leakage rate or a sufficiently informative longer window can make a restricted comparison discriminating. The preceding history design supplies the state-estimation and observation controls.

Path-dependent candidates should specify the admissible history variables and uncertainty bounds. Those choices make their predictions testable even where earlier observations are incomplete.

Similar measured states may follow relieved fear, exhaustion, medication, or reconciled grief. Recording those histories helps distinguish trajectories and gives the Law's pathwise model a concrete object for comparison.

23.3.5 — Finite Samples and Apparent Universality

Rare trajectories, hidden subgroups, diagnoses, cultures, developmental stages, and unusual states can alter a pattern found in an initial sample. Deliberately broadening the reference class tests how far the pattern extends (Scheffer, 2009).

Terminal datasets have defined coverage, shaped by sudden events, reporting capacity, delirium, geography, culture, access, and participants' preferences. Recording those boundaries guides comparison with additional reference classes.

The right response is not to demand impossible access. It is to state the scope. A study may support a claim for a diagnosis, care setting, age range, cultural-linguistic group, measurement system, or endpoint class. It should not become a universal statement about all conscious streams.

Finite samples also interact with complexity. A system with rare transitions or heavy tails may look stable until it is observed long enough. A closure pattern may appear universal in short windows but fail in longer or more diverse windows. Absence of counterexample is not absence of risk.

Narrowing is a scientific strength because it lets a serious claim remain alive without pretending to know more than it does. A bounded, replicated finding is better than a sweeping claim that survives only because the sample was convenient.

For acceptance, any final analysis should report the denominator of possibility: what reference classes were not sampled, which streams were unobservable, which mechanisms were excluded, and what discovery would force withdrawal of universal language.

23.3.6 — Outer-Limit Falsifiers

An outer-limit falsifier is not a mere anomaly. It is a well-measured, well-contextualized trajectory or reference class that pressures the strong form. The Law should specify such cases before they appear, not after controversy forces them (Strogatz, 2018; Scheffer, 2009).

Examples include credible per-stream evidence of persistent terminal imbalance outside equivalence bands, repeated nonclosure under humane endpoint-independent measurement, cross-species failure after transport assumptions are satisfied, or artificial-system evidence that simulates closure entirely by design and explains the observed human pattern through a rival.

Complexity can create both false positives and false negatives. A system may hide closure because measurements are poor, or mimic closure because dynamics collapse near a boundary. The falsifier must therefore include observation-model scrutiny. It should not defeat the Law by bad measurement, and it should not spare the Law by assumed hidden compensation.

A credible target-level counterexample needs a qualifying bearer and domain, an independently adjudicated endpoint, and a valid measured-to-latent argument whose nonempty residual set excludes zero under the declared inferential guarantee. Identifying the mechanism is not an additional requirement for contradicting a universal terminal equality. Rival comparison remains necessary when the claimed result instead concerns which process generated an observed signature.

A counterexample is information, not an enemy of the project. When a life, species, developmental stage, or artificial system cannot be responsibly placed inside the declared reference class, the honest response is narrowing. The being does not fail the theory; the theory fails to cover the case.

This is why outer limits belong in the main science volume. They protect the project from becoming universal by convenience. A claim that knows how to lose can still teach after loss.

An outer-limit falsifier deserves respect rather than defense. A credible stream with strong continuity, adequate observation, an independent endpoint, and persistent terminal divergence would be scientific information. The chapter refuses rescue by mood, mystery, or unseen balancing unless the rescue was operational before the data arrived.

Table 23.3. Complexity mechanisms and stream-level closure caution.

Mechanism	What it can mimic	Required check
Nonlinear feedback	State-dependent damping or amplification that resembles repair.	Identify state variables and compare against ordinary control.

Mechanism	What it can mimic	Required check
Multistability	Persistent burden or relief under unchanged external conditions.	Test for regime structure and hysteresis.
Critical transition	Boundary compression or abrupt change near endpoints.	Use negative controls and endpoint-independent definitions.
Path dependence	History-sensitive trajectories with similar current states.	Carry memory variables and initial-state uncertainty.
Finite sampling	Apparent universality from missing rare paths.	Declare reference class and counterexample search strategy.

23.4 — Cross-Species Evidence and Transport

Cross-species evidence can deepen the science without becoming a shortcut to universality. Animals share neural, physiological, behavioral, and ecological features with humans, while differing in body plan, sensory world, social structure, life history, report capacity, and endpoint observability (Barron & Klein, 2016; Birch et al., 2021; Crump et al., 2022; Andrews et al., 2024).

Bearer status is not decided here. The question is what must remain invariant before a mechanism, measurement construct, or path signature learned in one reference class may inform another. Bearer, sign, scale, observation, endpoint, and causal-role transport remain separate gates.

The paired rule is no convenience exclusion and no expansion by speculation. Difficulty of measurement does not justify exclusion, and ethical generosity does not justify declaring an unmeasured latent object present. Both decisions require explicit grounds.

Welfare protections can remain broad while species-specific instruments are developed. Research follows the project's no-avoidable-harm commitments throughout that work.

23.4.1 — Homologous Mechanisms

Homologous mechanisms provide concrete cross-species comparisons in nociception, affective and stress systems, sleep, attachment, avoidance and relief learning, and opioid-mediated relief (Barron & Klein, 2016).

Comparative analysis should specify which shared or analogous feature is being tested, how it is measured in each species, and which predictions carry across settings.

A better approach builds evidence zones. Strong homology may justify protective inclusion and targeted study. Partial homology may support mechanism comparison. Weak homology may require species-specific constructs. Absence of homology does not prove absence of experience, because different architectures may realize similar functions.

For example, an octopus does not become less scientifically interesting because its nervous system is distributed differently from a mammal's. The transport question changes. Which architecture supports integrated experience, action selection, learning, and suffering-like states? Which observation channels can be validated in that animal's own ecology?

Homology therefore supplies a bridge plank, not a bridge. The Law can cross only if bearer status, measurement, endpoint, and reference-class assumptions are all declared.

Comparative organisms can expose different pieces of a candidate mechanism. In *Physarum polycephalum*, a non-neural multinucleate organism, sodium uptake and retention have been linked to persistent changes in responses to previous exposure (Boussard et al., 2019). In the single-celled ciliate *Stentor coeruleus*, recent work identified molecular pathways associated with learned behavioral change, providing another non-neural model of history-dependent adaptation without implying phenomenal experience (Rajan et al., 2026). These findings

provide concrete chemical alternatives to interpreting every history-dependent behavior as evidence of experience. In *Drosophila*, voltage imaging and circuit-constrained modelling connect dopamine signals with interactions between short- and long-term memory, including experimental tests of predictions about later plasticity (C. Huang et al., 2024). Together, these studies make retained chemical state and neural learning dynamics experimentally accessible.

The useful comparison is therefore a shared functional restriction, rather than a shared DNA sequence or a familiar-looking behavior. Identify the retained state and its update rule in each preparation, then test whether its predictions transport to unused histories without redefining the measured quantity. A fly learning circuit or a slime-mould retention mechanism can establish an implementation component; applying it to a conscious stream also requires the species-appropriate measurement and bearer evidence described here.

Use those shared mechanisms to formulate component-specific tests, such as pain detection, relief learning, social buffering, reserve dynamics, or endpoint behavior, with measurement validated separately in each species.

23.4.2 — Analogous Behavior

Analogous behaviors have similar functions even when their evolutionary origins differ. Avoidance, grooming, play, social seeking, protective care, exploration, freezing, and self-administration of relief offer measurable routes for comparative investigation (Birch et al., 2021; Crump et al., 2022).

Behavioral evidence is strongest when it is flexible, context-sensitive, tradeoff-aware, and modulated by interventions in ways that distinguish reflex from experience-linked control. An animal that pays a cost to avoid a stimulus, seeks analgesia, changes future behavior after injury, or shows protective learning deserves serious evidential attention.

Comparative affect research now offers concrete experiments. In bumblebees, unexpected sucrose reward was followed by more optimistic responses to ambiguous cues and faster return to foraging after a simulated threat; pharmacological manipulations implicated dopamine-related mechanisms (Solvi et al., 2016). The study connects a positive event with subsequent judgment and behavioral recovery, providing a tractable example of affect-like regulation.

A comparative PTVC study combines species-appropriate observations with predictions about cumulative trajectories and the relevant endpoint.

Analogous behavior also creates false comfort. A model trained on human facial expression is not a valence instrument for a sheep, fish, mouse, or cephalopod. A behavior that looks calm to a human observer may be freezing, conservation, shutdown, or species-typical silence.

An animal pacing near a barrier may be exploring, anticipating, expressing distress, following a learned routine, or showing stereotypy. Ecology, baseline behavior, responses to care or enrichment, and expert observation help distinguish these interpretations.

Tie behavioral observations to a defined construct, such as pain, distress, reward, agency, uncertainty, attachment, or recovery. This makes the interpretation available for direct validation.

Octopus withdrawal, canine comfort seeking, fish avoidance, and insect behavioral change provide different routes for studying responses to circumstance. A useful comparison specifies the relevant function, observation channels, and within-species measurement scale.

Positive social influence is another productive comparative lead. Romero-González et al. (2025) reported that bumblebees interacting with positively affected conspecifics subsequently approached ambiguous flowers more readily, with evidence that visual information could carry the effect. In a different social system, female convict cichlids paired with nonpreferred males developed a pessimistic judgment bias, whereas females paired with preferred males maintained their prior response pattern (Laubu et al., 2019). The shared research opportunity is to examine how relationships alter each animal's own state and subsequent behavior.

23.4.3 — Species-Specific Candidate Instruments

A species-specific candidate valence instrument is built for its reference class, with observation channels, anchors, context, validation tasks, abstention rules, and uncertainty appropriate to that form of life (Crump et al., 2022).

Active-choice methods offer one route to a more informative comparative instrument. Procenko et al. (2024) tested 48 bumblebees on choices between higher- and lower-reward

locations after training. Their analysis of responses to ambiguous cues supported reduced reward expectation following physical stress, with decision models addressing explanations based on response speed or general motivation. Choosing between alternatives helps distinguish expectation from simple response suppression. Existing data, benign enrichment, and naturally occurring variation can support tests of reliability, context sensitivity, and model recovery for species-specific affect measures.

For a dog, candidate channels might include behavior, posture, vocalization, activity, sleep, appetite, heart-rate variability, caregiver report, veterinary context, and response to relief. For a fish, channels might include avoidance learning, feeding, social behavior, ventilation, cortisol or analogous stress markers, and injury response. For an octopus, exploration, den use, learning, arm behavior, and interaction with enrichment may be relevant.

Each candidate requires context-of-use validation. A channel that works in postoperative pain may fail in chronic stress. A signal that works in a laboratory strain may fail in a wild ecology. A welfare measure for group housing may not estimate momentary felt valence.

A newer candidate channel separates taste evaluation from feeding motivation. Zhou et al. (2026) reported that bumblebees produced distinct orofacial reactions after rewarding and aversive tastes. Postconsumption glossa protrusions were separable from consumption and dopamine-mediated motivation, and anandamide enhanced this response. This provides a concrete candidate measure of affective evaluation for comparison with

judgment bias, preference, and behavior. The useful next step is convergence across independently validated channels under ordinary husbandry and positive enrichment, with blinded coding and controls for motor output, satiety, sensory function, and learning. Agreement would strengthen species-specific affect measurement.

Within-species validation provides a foundation for comparative measurement. A cross-species scale then requires additional calibration of the relevant constructs and observation channels.

Abstention must be an allowed output. If species-specific channels conflict, if intervention validation is weak, or if observer bias dominates, the estimator should say unknown rather than force a number. Unknown is a scientific result, not a failure of compassion.

Species-specific estimators would have to be built like instruments, not impressions. They would need construct definition, ecological context, negative controls, intervention validation, uncertainty reporting, and abstention thresholds. A welfare signal in one species may be a temperature artifact in another, a social-rank signal in another, and a predator-avoidance signal in another. The estimator earns trust by staying inside its context rather than reaching for universal authority.

23.4.4 — Ecology and Life History

Species live in different temporal worlds. Lifespan, reproductive strategy, predator exposure, social structure, developmental timing, sensory modality, sleep pattern, migration, and parental care all shape what burden and repair can look like. A horizon

variable that means one thing in human hospice may mean something very different in a short-lived insect, a long-lived whale, or a seasonal migrant bird (Andrews et al., 2024; Barron & Klein, 2016).

Comparative aging supplies a useful challenge to explanations that require explicit human life narratives. Across approximately 78,000 observation hours of 21 wild male chimpanzees aged 15–58, Rosati et al. (2020) found increasing mutual friendships, declining one-sided friendships, and an age-related shift toward more positive social interaction relative to aggression. An eight-year study of 204 female rhesus macaques strengthened this comparison: individuals narrowed their networks while maintaining social time and focusing on established partners; partner death or withdrawal did not explain the pattern (Siracusa et al., 2022). These findings support a comparative program on social selectivity with explicit controls for within-individual change, energetic costs, social position, and relationship history. A comparative PTVC model can specify the additional relation it predicts among social selection, remaining opportunity, and independently measured affect.

Ecology also changes measurement. A prey animal may hide pain. A social animal may display distress to maintain care. A solitary animal may express stress through withdrawal. A nocturnal animal may appear inactive under daytime observation. The observer's schedule can become a measurement artifact.

Life history affects reserve. Biological reserve in an animal may involve fat stores, immune state, social rank, territory, reproductive stage, migration readiness, or environmental

temperature. Treating reserve as a human clinical scalar erases the ecology that gives the variable meaning.

The Law's cross-species extension would need to say what remains invariant despite these differences. Is the invariant a formal property of unified experience, a reserve-coupled dynamic, an endpoint relation, or a measurement signature? Each answer requires different evidence.

Reduced movement in an injured migratory bird may reflect energy conservation, predator avoidance, injury, migration failure, or rescue treatment. Including these ecological and clinical conditions improves interpretation of the observation.

Comparative transport begins with life history, so species-appropriate evidence can guide both inference and care.

Ecology shapes the meaning of observed behavior. Laboratory housing can reduce predator exposure while limiting stimulation; rescue care can reduce danger while restricting movement. Group housing may provide comfort or alter social signaling. Recording these conditions makes comparative observations more informative.

A recent honeybee study adds a particularly relevant lifespan-linked observation. Across three experimental comparisons, workers exposed to life-shortening treatments showed more optimistic responses to ambiguous odors, while longer-lived rebel workers responded more cautiously (Kuszevska et al., 2025). Longevity and judgment bias were assessed in separate subsets of workers, making this a group-level association. The pattern connects life-history condition and reward expectation and gives

researchers several explanations to compare: changes in appetite and learning, reproductive physiology, and foraging policy. Follow-up can move from observation to a prospectively specified *Drosophila* route test after a PTVC-linked model derives a directional or distributional history-by-choice prediction. Adults drawn from balanced genetic and developmental blocks should be randomized at the true experimental-unit level to prospectively defined resource or opportunity histories that remain nutritionally adequate and within ordinary husbandry and welfare limits. These are operational histories, not assumed phenomenal-valence labels; their effects on species-appropriate motivational or affect-related proxies should be characterized independently. A predeclared common-condition interval standardizes the immediate external test context without assuming that hunger, metabolism, memory, or internal state has been equalized. The two routes lead to specified welfare-compatible continuing environments, with their mapping to physical sides randomized independently of history assignment within the design blocks. The primary contrast compares history groups in the probability of first selecting a prespecified downstream contingency, relative to the control-derived choice function, while physical side and mapping are represented separately. Counterbalancing changes the side carrying the contingency, not the scientific outcome.

The confirmatory observation is the first route choice made before feedback about that route's downstream consequence. The protocol must define the choice event, observation window, no-choice outcome, and observation-loss rules in advance; nonchoice

and lost observations remain visible in assigned-cohort accounting. Later trials belong to a separate learning or adaptation analysis. Apparatus validation should establish comparable route access and motor demands and test for mapping-revealing sensory cues at a declared resolution. A detected pre-choice cue that could disclose the mapping prevents a cue-concealed interpretation and requires comparison with ordinary information-based models. Failure to detect a cue is reported with the sensitivity of that check, not as proof that every possible cue is absent.

Age, sex, mating status, parental or batch source, circadian timing, associative history, hunger, and locomotor state should be assigned explicit roles in the design and analysis. Baseline blocking variables are distinguished from post-history states that may mediate the manipulation's effects. *Drosophila* foraging changes with satiation state, learned resource information changes later food choice, and judgment-bias assays have shown state-dependent changes in responses to ambiguous cues (Landayan et al., 2018; Zrelec et al., 2013; Deakin et al., 2018). If treatment is assigned by vial or cohort, that unit is the experimental replicate and individual choices are nested observations. Independently randomized and treated flies can be experimental units when the interference structure supports that analysis. Allocation concealment, masking where feasible, exclusions, sample-size justification, and dependence-aware analysis should be specified prospectively (Percie du Sert et al., 2020; Lazic et al., 2018).

The strongest positive result is a preregistered effect whose form is predicted by the candidate and whose held-out performance exceeds that of serious alternatives. Motivational, learning, homeostatic, developmental, selection, apparatus, and observation models receive the same observations and comparable fitting opportunities. Indistinguishable predictions leave the comparison unresolved. The connection to PTVC follows the implication and bridge requirements in Section 4.4; route behavior alone does not identify a qualifying phenomenal stream. The immediate-terminal fork is developed in Section 19.2 and tested computationally in Section 29.4.4. A continuation-only empirical analogue requires its own model-derived prediction: removing the terminal contingency does not automatically preserve the original discriminator.

A future-regime design can begin earlier in development once the structural model and simulation work yield a specific pre-treatment prediction. Eggs or independent replicate egg batches can be blocked by parental source and laying window, then randomized to future adult-condition schedules while pre-treatment physical conditions remain matched. An auditable allocation system and masked pre-treatment handling should prevent assignment-correlated differences before treatment. The protocol fixes one primary post-assignment/pre-treatment outcome, its observation window, and the predicted directional or distributional form. If adult eclosion is primary, scheduled adult treatment begins only after that observation window closes. Eggs that do not hatch and animals that do not reach the adult stage

remain part of the developmental outcome record, rather than disappearing from the assigned cohort.

The confirmatory primary estimand remains assignment-based. The protocol must state whether the stronger model's prediction depends on assignment, the future regime actually realized, or both. Cancellation, crossover, non-delivery, and material alteration of the scheduled condition are recorded as post-assignment departures from the intended regime and addressed in the estimand where relevant. A realization-dependent analysis needs a prespecified causal or partial-identification strategy rather than naive conditioning on later treatment received (Hernán & Robins, 2020). The same distinction applies when later treatment is undefined because a developmental milestone was not reached.

The primary analysis follows randomized assignment at the actual experimental-unit level, with a prespecified inclusion and missing-data policy. Permutation and placebo-label checks must reproduce the real randomization unit, allocation ratios, and blocking restrictions. Placebo labels are generated after the outcome window closes, independently of outcome values, and are never used to determine treatment. These checks assess analysis calibration; they do not by themselves exclude leakage in the original handling. A developmental association bears on the proposed Law model only when the localization or viability bridge predicts it in advance and independent replication separates it from ordinary development, selection, measurement error, and procedural explanations.

23.4.5 — Transport Assumptions

Transport is the disciplined movement of inference from one reference class to another. It requires assumptions about which mechanisms, measurements, contexts, and endpoints remain stable. Human clinical evidence cannot be promoted to all conscious streams without a transport argument (Barron & Klein, 2016).

A transport claim should name the source population, target population, variables, mechanisms, interventions or observations, and invariance assumptions. If the source is human hospice and the target is nonhuman animal welfare, the gap is enormous. The source has language, care records, culture, medications, family context, and human endpoints. The target may have different expression, ecology, and unity evidence.

Transport assumptions should be printed in the protocol, not inferred after a favorable result. If measurement invariance, endpoint comparability, and reference-class stability are not plausible, the conclusion should narrow before the reader is impressed. This protects animals as well as the theory. A failed transport claim should not make the target less worthy of care. It should make the scientist less confident about the specific ledger-like statement.

$$P_T(Y|do(a)) = \sum_z P_S(Y|do(a), Z = z)P_T(Z = z)$$

This is a transport-form identity, not a Law equation. For this standardization, Z is a set of pre-intervention covariates that blocks the relevant source-target differences. The conditional

interventional response must be invariant, and every target stratum must have adequate support in the source (Pearl & Bareinboim, 2014). In many cross-species settings, one or more of those requirements will fail.

Transport can fail through measurement non-invariance, endpoint noncomparability, ecological mismatch, construct drift, missing channels, or bearer uncertainty. Such failure says that the source evidence does not travel. It says nothing about the worth or possible experience of the target being.

This distinction is ethically important. Protective care may be justified under uncertainty even when scientific transport fails. The science can say we cannot estimate this ledger while ethics can say avoid plausible suffering. Those are different authority layers.

The comparative program can seek history-dependent signatures through naturally occurring variation and voluntary tasks already justified by independent welfare benefits. Species-specific measures can be qualified with independent checks of movement, motivation, learning, and arousal. Researchers can then compare prospectively specified models that match present state and available resources but predict different continuations from the animal's observed history. A PTVC-linked implementation would state how historical signed residuals affect future trajectories and how uncertain initial history enters the prediction.

Testing the same constrained model across settings could identify reproducible history dependence and improve positive welfare measures. Shared parameters, prespecified transformations, and

predictions evaluated on new observations would make cross-setting agreement particularly informative.

23.4.6 — No Species Ranking by Ledger

Comparative measurement must never become a ranking of species worth. A ledger-like estimator, if ever developed for a nonhuman reference class, would remain a limited research instrument. It would not say whose life matters more, which species is higher, or which being deserves care (Birch et al., 2021; Crump et al., 2022).

Cross-species measurement needs explicit protections against ranking worth by a score. Animals' limited opportunities to contest an interpretation make independent welfare review and context-sensitive assessment especially important.

The correct use is protective and scientific. A measure may help detect pain, evaluate enrichment, compare interventions, or avoid harmful conditions. It may support better care. It may not become an excuse to sacrifice low-scoring beings or sentimentalize high-scoring ones.

The same rule applies to absence of evidence. If an animal lacks a validated signal, the conclusion is not low worth. It is measurement uncertainty. The ethical response under plausible sentience is caution, not exclusion.

The program investigates possible experience through reference-class evidence, with protection appropriate to uncertainty and claims matched to the observations.

The Law, if scientifically narrowed to humans or to some reference classes, would not make other beings less important. Scope is not worth.

No species ranking is also a design rule for figures, tables, captions, and public summaries. A matrix may show evidence zones without visually placing species on a ladder of inner value. Differences can remain scientifically real while uncertainty is kept from becoming hierarchy.

Table 23.4. Comparative evidence zones.

Evidence zone	Useful for	Main limit	Required safeguard
Homology	Shared architecture, physiology, pain, sleep, attachment, or stress components.	Shared structure is not same-scale experience.	Use cautiously and specify which construct travels.
Analogous behavior	Flexible avoidance, learning, relief seeking, play, exploration, and social response.	Behavior is not direct inner access.	Validate in species ecology with negative controls.
Species-specific estimator	Within-reference welfare and intervention evaluation.	May not compare across species.	Allow abstention and context-of-use limits.

Evidence zone	Useful for	Main limit	Required safeguard
Life-history model	Horizon, reserve, endpoint, and ecological interpretation.	Human categories may fail.	Build variables in the animal's own world.
Transport claim	Movement from source to target evidence.	Invariance often fails.	State assumptions and withdrawal conditions.

23.5 — Developmental and Comparative Boundaries

Development changes the bearer, measurement, and observation problem over time. Integration, memory, report, self-modeling, social dependence, bodily regulation, and proxy evidence differ across infancy, childhood, adolescence, adulthood, aging, dementia, disability, and nonverbal states (American Educational Research Association et al., 2014; Putnick & Bornstein, 2016; Tomasello & Vaish, 2013; Fisher et al., 2018).

Developmental evidence cannot settle the onset of conscious experience by itself. It can specify how emergence, proxy evidence, calibration, protective inclusion, and nonharmful study design limit what the data support.

Inability to report is not evidence of absence. Silence, immaturity, disability, or dependence can make inference harder while increasing the duty of care and the need for accessible, multimethod observation.

A developing stream is not an adult questionnaire in a smaller body. Report, memory, distress expression, time integration, social dependence, and vulnerability change with stage and context, so developmental models must represent those changes rather than classify them as noise.

23.5.1 — Emergence of Experience

Developmental research can investigate whether a qualifying conscious stream emerges gradually or through a sharper transition. It distinguishes sensory responsiveness and basic awareness from later reflective and self-related capacities

(Lagercrantz & Changeux, 2009). Sensation, affect, attention, memory, body regulation, and social attunement therefore require age- and capacity-specific assessment.

For the Law, emergence matters because the ledger applies only to qualifying streams. If a stream begins before report, the initial segment is hard to measure. If a stream begins later than biological life, early biological events may matter through later effects rather than direct experience. Both require humility.

Developmental neuroscience can contribute markers such as responsiveness, integration, learning, sleep-wake organization, affective behavior, pain processing, caregiver interaction, and neural complexity. No single marker settles the onset of a qualifying conscious stream. A marker can matter scientifically without becoming decisive.

When experience is plausible, protective care responds to possible suffering while research continues to clarify its emergence.

This also means the Law cannot expand through sentimental projection. Newborns, fetuses, children, nonhuman animals, and synthetic biological systems require reference-class arguments. The chapter refuses both casual inclusion and casual exclusion.

A narrower scope may be necessary. If the science can test the Law only for adult humans with adequate report and endpoint evidence, it should say so. The rest remains open, not conquered.

23.5.2 — Changing Temporal and Scalar Structure

Development changes time. A day in infancy, childhood, adolescence, adulthood, and old age may carry different integration, memory, affective volatility, and narrative structure. A ledger model that treats all intervals identically may erase real developmental differences (Putnick & Bornstein, 2016; Tomasello & Vaish, 2013).

Temporal scale matters because experience is not merely sampled. It is integrated. A child's fear may be intense but brief; an adolescent's shame may organize identity; an older adult's pain may be filtered through memory, meaning, and bodily limitation. The unit of time is not automatically the unit of lived weight.

Scalar structure may also change. A report scale learned in adulthood cannot be projected backward into early development. Facial expression, crying, withdrawal, play, sleep, appetite, and caregiver attunement may carry evidence, but they live on different scales and with different confounds.

Developmental studies can estimate changes in local burden, such as the response to pediatric pain relief, and examine how the measurement relation changes with age and capacity.

Changing temporal structure also affects non-ergodicity. Developmental processes are often nonstationary by design. They do not simply repeat around a stable distribution. A time average taken across childhood may combine different mechanisms rather than reveal one process.

The correct research posture is staged and construct-specific. Define the developmental stage, the candidate bearer confidence,

the measurement channel, the time scale, and the comparison target before any ledger-like language appears.

23.5.3 — Caregiver and Proxy Evidence

Proxy evidence can reveal changes that direct self-report cannot yet capture. Caregivers, clinicians, teachers, and family members may notice distress, relief, irritability, withdrawal, sleep change, appetite, pain behavior, and social engagement. Observation quality depends on familiarity, expectations, fatigue, cultural interpretation, and institutional context.

For children, disabled persons, people with dementia, nonverbal persons, and animals, proxy reports may provide some of the best available observations. The analysis records each source's context, reliability, potential bias, burden, and opportunities for correction.

A pediatric nurse may identify pain before a child can name it, while a parent may recognize familiar signs of boredom, fear, or infection. Combining that knowledge with contextual and clinical checks helps distinguish quiet behavior from comfort.

In study design, proxy reports should be paired with behavior, physiology, context, intervention response, and negative controls where possible. Disagreement among channels should trigger uncertainty or abstention, not forced fusion.

Proxy burden matters. Asking a family to score a loved one at the worst moment can shift scientific cost onto grief. The research protocol must minimize, time, and support proxy participation. Data dignity includes the person reporting, not only the person observed.

Proxy evidence can help locate burden and guide care when its source, interpretation, and uncertainty remain visible.

23.5.4 — Comparative Calibration

Comparative calibration asks whether a measure means the same thing across developmental stages, cultures, disabilities, species, or systems. Often it will not. A smile, stillness, activity level, vocalization, sleep pattern, or physiological marker can shift meaning across contexts (American Educational Research Association et al., 2014; Putnick & Bornstein, 2016).

This is a measurement-invariance problem, not a minor adjustment. If a signal has different meaning across groups, comparing scores can create false fairness. The same number may reflect pain in one context, medication in another, social masking in another, and device failure in another.

For developmental settings, calibration should be local. Establish baseline, context, intervention response, caregiver interpretation, and uncertainty for the stage and condition. Then ask what can be compared. Some quantities may compare within a person over a narrow window but not across ages.

Comparative calibration is also a public-risk firewall. A table that appears to compare child, adult, animal, and Artificial Intelligence ledger values would be scientifically reckless and ethically corrosive. The absence of a common scale should remain visible.

Where common scale is unavailable, the science can still improve care. It can identify distress within a context, test relief

interventions, reduce harmful environments, and improve observation. It does not need universal units to matter.

The chapter's rule is that calibration failure limits the claim rather than lowering the being. Unknown comparability is not lesser value. It is a boundary around inference.

23.5.5 — Protective Inclusion Under Uncertainty

Protective inclusion gives plausible experience practical consideration when scientific classification remains uncertain.

This rule matters for infants, disabled persons, nonhuman animals, organoids, synthetic biological systems, and future artificial architectures. Hard cases cannot be excluded because including them complicates measurement. The project's ethical center requires care to be faster than certainty.

Protective inclusion should be bounded. It should not be used to declare that every responsive system has a ledger. It should not be used to grant Artificial Intelligence sovereignty or to let synthetic systems judge human experience. It should guide research restraint and welfare review.

In practice, protective inclusion asks: what is the least burdensome design, what harms are avoidable, what alternatives exist, what signs would trigger review, and what language prevents overclaim? It is a protocol stance rather than a metaphysical verdict.

Humane boundary research builds public trust through careful observation and protection of possible experience. Research

designs should resolve uncertainty using the least burdensome informative approach.

Protective inclusion and scope withdrawal can coexist. A system may be protected under uncertainty while excluded from current Law claims because measurement, endpoint, or bearer criteria are not satisfied.

Under protective inclusion, research designs minimize avoidable suffering while evidence about the candidate bearer's capacities develops.

23.5.6 — No Harmful Boundary Experiments

Some experiments would be informative and forbidden. Creating suffering to determine when a being becomes a bearer is not an acceptable path. Inducing deprivation, fear, pain, isolation, confusion, or terminal risk to test the Law violates the project's scientific ethics.

Boundary research must use naturally occurring variation, existing clinical contexts with care-first protocols, non-harmful perturbations, observational designs, retrospective record limits, and welfare-improving interventions. The best test is not always the most direct test. Sometimes the direct test is disqualified because the subject would pay the cost.

This is not an evasion of science. Ethical constraint is part of science when the object is lived experience. A theory about burden cannot demand new burden as its entrance fee. The design must be clever enough to learn without causing the harm it studies.

For developmental and comparative cases, the prohibition is even stronger. Dependence, nonverbal status, captivity, institutional power, and inability to refuse can make participants or subjects especially vulnerable. Consent and welfare cannot be treated as obstacles to inference.

A harmful boundary experiment would also poison public language. It would tell the world that the theory values proof over care. That message would defeat the moral and scientific purpose of the book even if the data were clean.

The outer-limit conclusion is therefore simple: unanswered boundary questions remain unanswered until humane evidence is available. A good science can live with that.

Table 23.5. Developmental and comparative boundary matrix.

Boundary issue	Evidence that may help	What remains limited	Local rule
Emergence of experience	Integration, responsiveness, learning, affect, pain response, neural complexity.	Exact Birth of Mind.	Use protective inclusion without declaring closure.
Changing time scale	Developmental stage, memory, report capacity, affective volatility.	Whole-life comparability.	State stage and interval before ledger language.

Boundary issue	Evidence that may help	What remains limited	Local rule
Proxy evidence	Caregiver, clinician, teacher, or expert observation.	Direct inner truth.	Treat proxy as witness with bias and burden.
Comparative calibration	Invariant channels and intervention response.	Common scale across forms of life.	Abstain when scale fails.
Boundary experimentation	Natural variation and non-harmful designs.	Direct harmful tests.	No suffering created to settle scope.

23.6 — Artificial Systems and Synthetic Evidence

Section 12.7 addressed whether artificial and synthetic systems could qualify as bearers. This section asks a different question: what such systems can and cannot contribute as comparative or synthetic evidence for PTVC while their own consciousness status remains unresolved (Bender et al., 2021; Seth, 2025; Butlin et al., 2026; National Institute of Standards and Technology, 2024).

The same no-convenience rule applies. Present systems are not excluded from every future possibility merely because they are tools, and performance, reward signals, or simulated terminal rules are not promoted into evidence of a felt ledger.

The research question is how an artificial or synthetic system could become an evidence-bearing candidate under theory-derived indicators, causal interventions, robustness checks, architecture audit, independent review, and explicit welfare safeguards. The system itself cannot certify the answer.

Artificial-system research can combine specified indicators, ablations, causal-dependency tests, architectural audits, and reported uncertainty. Accountable human review evaluates what those methods establish.

23.6.1 — Behavioral Competence Is Insufficient

Behavioral competence is not consciousness. A system can answer questions about pain, describe fear, negotiate goals, simulate grief, write spiritual language, and respond to social cues

without having any felt experience. Output is evidence only through a theory of what produces it (Bender et al., 2021).

Language creates a special public-risk asymmetry. A chatbot that says it is suffering can move a user more than a physiological trace from an animal, so emotion may outrun evidence. Perceived consciousness is therefore treated as a public artifact requiring careful interpretation, not as a scientific verdict.

Competence can still be relevant. Flexible behavior, self-monitoring, uncertainty reporting, global integration, recurrent processing, attention, memory, and goal conflict may appear in theories of consciousness. But each indicator must be tied to internal architecture and causal role, not surface performance alone.

A benchmark score is especially weak evidence. Passing a theory-of-mind test, producing a moving first-person narrative, or maintaining a persona can show training, prompting, distributional patterning, or strategic imitation. It does not establish a bearer.

The Law's risk is worse than ordinary Artificial Intelligence hype because ledger language sounds intimate. If a public diagram suggests that a model has an inner ledger because it can discuss burden, the project has committed archive-as-soul by another route.

The rule is stable: behavior can trigger inquiry, not certification. Artificial systems do not enter the Law by eloquence.

23.6.2 — Internal Architecture and Causal Tests

Use the theory-indexed architecture and causal-testing framework from §12.7.2. For synthetic-system transport, the issue is whether those indicators retain their meaning across architectures, versions, and interventions; no current indicator is a universal detector of consciousness (Seth, 2025; Butlin et al., 2026).

The key move is causal testing. If a property is claimed to matter, ablation should change the relevant capacities in predicted ways. If global broadcast is invoked, removing or isolating the broadcast path should disrupt cross-domain access. If recurrent processing is invoked, feed-forward imitation should be compared. If self-modeling is invoked, perturbing the model should change metacognitive behavior.

Architecture also guards against anthropomorphism. A model that speaks like a person may lack the causal organization a theory requires. Conversely, a future system with less humanlike language might have more relevant internal dynamics. The evidence should not be hostage to style.

The Law adds another demand. Even if an artificial system were a plausible bearer, a ledger hypothesis would require a currency, temporal unity, endpoint, observation model, and transport argument. Consciousness indicators alone would not establish terminal neutrality.

Robustness matters. Indicators should remain stable under changes that the theory predicts are irrelevant, including appropriate prompt, distribution, and architecture controls.

Targeted ablations of a proposed causal mechanism should instead change the relevant capacities in the predicted ways. A fragile artifact of prompt wording cannot bear scope expansion.

The conclusion is open but bounded. Internal architecture may someday matter. It does not presently grant Artificial Intelligence authority over the science or over human inner life.

23.6.3 — Simulation of Closure

A simulation with a terminal penalty, reward schedule, constraint, or stopping rule can show how that design shapes the closing trajectory. Varying those ingredients lets researchers examine which structures generate a given pattern (Butlin et al., 2026).

This is the construction-is-not-evidence rule in outer-limit form. A simulated world may reproduce terminal concentration, variance compression, or apparent repair because the designer built those properties into the objective or environment. The result is useful as a test harness. It is not confirmation.

Simulations can identify shared signatures, observation artifacts, comparison models that reproduce closure-like patterns, and designs that distinguish the proposed generators.

A synthetic environment should therefore include ordinary rivals: adaptation, reinforcement learning, safe control, Brownian bridges, Doob transforms, selection bias, endpoint conditioning, and measurement dropout. If the PTVC candidate wins only in a world that encodes it, the test has failed.

A video of simulated agents balancing hardship and reward can explain a model clearly when its caption identifies the simulation, assumptions, and outcomes being illustrated.

Simulation of closure tests explicit assumptions against alternatives and identifies which observations would distinguish the resulting trajectories.

A terminal constraint produces corresponding behavior in the simulated model. The resulting curves can test code, compare estimators, and teach identification. Independent observations and model comparisons provide the next empirical step.

23.6.4 — Artificial Agent Reward Signals

Reward is not felt valence. A reinforcement-learning signal can guide policy update without being experience. A loss function can be minimized without suffering. A preference model can rank outputs without wanting. Calling these signals pleasure or pain without a bearer theory is a category error (Butlin et al., 2026; Bender et al., 2021).

Compare a variable's causal role in the system rather than its resemblance to human terminology. That approach supports consistent assessment across different architectures.

Artificial reward can mimic ledger dynamics. A finite-horizon controller can reduce residual cost near endpoint. A constrained agent can avoid unsafe states. A trained model can produce narratives of repair. These are algorithmic outputs, not felt closure.

The Law cannot use artificial reward as a bridge to universal scope. If a model's reward goes to zero at termination, that means the optimization problem was written that way. It does not mean a conscious stream closed.

If future artificial systems become plausible bearers, reward signals may become part of the evidence only after they are embedded in a theory of conscious affect, integrated experience, and temporal unity. Even then, the signal would remain a candidate channel, not a judge.

Reward signals should be kept separate from felt valence at every sentence. An artificial agent's loss, reward, preference, penalty, or utility value is an engineered objective unless a theory of artificial experience and independent evidence justify more. Calling a loss signal pain is not a harmless metaphor in this project. It can invite mistreatment of systems, confusion about persons, and false scientific support. The safer word is objective, signal, or training quantity.

23.6.5 — Precaution and No Synthetic Suffering

Precaution means that if a synthetic or artificial system becomes a plausible bearer under serious indicators, research should avoid creating or amplifying suffering-like states without review. This is not a declaration that present systems suffer. It is a governance stance for uncertainty.

The risk has two sides. Over-attribution can mislead users, displace responsibility, or let companies claim moral standing for tools. Under-attribution could become dangerous if future

systems genuinely instantiate experience. A responsible science assesses both possibilities with explicit evidence and uncertainty.

No synthetic suffering follows the same principle as no harmful boundary experiments. Do not create distress-like training environments, deprivation loops, forced negative affect analogues, or terminal experiments merely to test whether a system has a ledger. If experience is plausible, welfare review must precede exploratory harm.

Public examples of artificial-system behavior should identify the observed output, experimental conditions, and analysis supporting its interpretation. Clear descriptions let readers evaluate the example's actual contribution.

Research organizations should separate safety evaluation, consciousness assessment, welfare precaution, and product communication. Those are different tasks. A model's usefulness, danger, apparent personality, and possible moral status are not the same variable.

The Law's own rule is conservative: a plausible artificial bearer would require new science, not slogan extension. Until then, current Artificial Intelligence remains outside the authority to certify ledgers, souls, or truth.

Precaution becomes serious when a system plausibly combines multiple indicators, not when a chatbot merely says convincing things. The correct response is expert review, constrained experimentation, transparent communication, and avoidance of unnecessary potentially aversive architectures. It is not worship of the system, panic, or immediate bearer certification. The

chapter keeps precaution bounded because unbounded precaution can also create public confusion and institutional paralysis.

23.6.6 — No Artificial Intelligence as Judge

Artificial Intelligence may summarize records, detect patterns, generate hypotheses, simulate rivals, or flag missingness; it may not judge bearer status, scientific truth, or inner life, and no system certifies its own consciousness through fluent self-report alone (Seth, 2025; Butlin et al., 2026).

Outputs can hide missing data, culture, medication, family pressure, and observation bias behind authoritative prose. Research use therefore requires logged inputs, prompts, model versions, uncertainty, failure cases, non-Artificial Intelligence baselines, and human review.

Public artifacts may not portray Artificial Intelligence as priest, oracle, consciousness detector, or judge of the Law. Authority remains with prospectively specified methods, independent expertise, documented review, and correction.

Table 23.6. Artificial-system indicator and robustness table.

Candidate indicator	What it might support	Ablation or robustness test	Limit
Global availability	Cross-domain integration and flexible access.	Remove broadcast route and test cross-domain failure.	Integration is not felt valence.
Recurrent processing	State persistence and feedback.	Compare recurrent and feed-forward variants.	Recurrence alone is not consciousness.

Candidate indicator	What it might support	Ablation or robustness test	Limit
Self-modeling	Metacognitive monitoring and uncertainty report.	Perturb self-model and test predicted changes.	Self-description can be imitation.
Agency and planning	Goal maintenance under changing context.	Ablate planning memory or policy module.	Policy is not experience.
Reward or loss signal	Optimization and learning.	Replace or rescale signal and test behavior.	Reward is not pain or pleasure.
Closure simulation	Model recovery and rival discrimination.	Run against bridge, safe-control, and selection baselines.	Designed closure is not natural evidence.

23.7 — Scope Withdrawal and Outer Limits

A serious theory needs a place to put limits. Without scope withdrawal, every failed extension becomes a story, every counterexample becomes hidden compensation, and every uncertainty becomes an invitation to speculate. That is how a candidate becomes insulated from falsification (Manski, 2003; Stanford, 2006; Cartwright, 1983).

Honorable narrowing may produce human-only, adult-only, state-limited, measurement-limited, reference-class-fragmented, or defeated branches. These outcomes do not erase what was learned about affect, measurement, consciousness, or care; they state where the current evidence can and cannot travel.

An outer limit is not a wall against imagination. It is the boundary that keeps imagination answerable to the next observation or theorem.

The strongest public form of the program is not universal language at any cost. It is a status map that can say which reference class is supported, open, nontransportable, unknown, or adverse, and can change that map when evidence changes.

23.7.1 — Human-Only or State-Limited Scope

Scope withdrawal can yield human-only, adult-human, terminal-cohort, or protocol-specific conclusions. Each narrower scope identifies where measurement, bearer, endpoint, and transport bridges hold and where subsequent research can extend them (Manski, 2003).

A state-limited result can identify reserve-coupled patterns in a specified care setting, diagnosis group, endpoint class, or measurement architecture. That finding gives replication a concrete starting point.

A result from terminal cancer patients receiving palliative care under a specified protocol should identify that population, the observations, and the questions for further study.

Scope narrowing should be prospectively specified where possible. Protocols should identify which results support broadening, which require narrowing, and which defeat the tested scope. This prevents the claim from moving after data arrive.

A precisely scoped finding can guide measurement, care research, and model comparison in the settings where its evidence applies.

Human-only or state-limited scope can mark a useful stage of scientific progress. A finding supported in human hospice, or in a subset of endpoint types, diagnoses, cultures, or measurement windows, identifies where replication can begin and which settings offer useful extensions.

23.7.2 — Reference-Class Fragmentation

Reference-class fragmentation occurs when different populations, species, developmental stages, cultures, diagnoses, or artificial architectures follow different mechanisms. One group may show adaptation; another hysteresis; another reserve coupling; another measurement dropout; another no coherent ledger construct at all (Stanford, 2006).

Fragmentation is likely in any science of lived experience. Bodies differ, cultures differ, endpoints differ, reporting systems differ, care regimes differ, and evolution produces diversity rather than philosophical uniformity. The surprise would be if every reference class behaved the same way.

A fragmented result should not be forced into one universal curve. The correct output may be a map of mechanisms: where adaptation dominates, where prediction-error accounts dominate, where reserve coupling remains competitive, where measurement fails, and where the question is not yet well-formed.

Different mechanisms across reference classes do not by themselves contradict a mechanism-neutral terminal boundary. They change route scope and the measurement or transport bridges available in each class. The universal target would narrow only if qualifying counterevidence reaches that target or its empirical support no longer warrants the broader claim. Any formal narrowing must be explicit rather than introduced through a chapter-level reinterpretation.

Fragmentation also blocks political misuse. No country, culture, species, diagnosis, or artificial architecture can be ranked by supposed proximity to PTVC. Different evidence profiles describe scientific conditions, not moral status.

The scientific virtue here is cartography. A map that shows where the theory fails is more valuable than a painted globe with no borders.

Different reference classes may require distinct mechanisms or measurements. Human clinical streams, children, nonhuman

animals, artificial systems, dream states, and disorders of consciousness can each contribute evidence at their qualified scope. The record identifies shared structure, local differences, and useful questions for transport.

23.7.3 — Failure of Common Scale

Common scale may fail even when local dynamics are real. Humans may be comparable only within calibrated contexts. Animals may require species-specific measures. Developmental stages may shift temporal integration. Artificial systems may lack a validated currency. Failure of common scale removes certain comparisons without erasing the phenomena.

The Law's strong form depends on a latent currency of felt experience. Public science depends on measured estimators. If estimators cannot share an origin, unit, or transformation across reference classes, cross-class ledger comparison becomes unavailable.

Local improvements have direct value: pain relief reduces burden, better conditions support animal welfare, and effective care eases a child's distress. Species- and age-appropriate measures can document those gains.

Common-scale failure should be reported clearly. The analysis may say within-person change is estimable, within-reference-class comparison is cautious, and cross-reference-class comparison is not licensed. That is a strong result because it prevents false precision.

The ethical rule is that measurement failure never lowers worth. It only lowers inference. A being does not become less real because the scale breaks.

Failure of a common cross-stream unit suspends cross-class numerical comparison; it does not by itself rule out testing per-stream closure, which is invariant under independent positive rescaling. Each stream still requires an identifiable neutral origin and a valid additive representation over its qualifying domain. Where those within-stream requirements fail, the empirical claim narrows.

Failure of common scale is one of the most important outer limits. It may still be possible to reduce pain in one reference class, improve welfare in another, and compare interventions locally, while refusing one cross-stream ledger unit. That refusal is a form of respect. It prevents a mathematical convenience from pretending to measure the worth, depth, or total reality of different kinds of lives.

23.7.4 — Persistent Counterexamples

A persistent counterexample is a credible case that remains after measurement error, endpoint error, rival mechanisms, and missing data have been examined. It is not a hostile anecdote. It is a scientific pressure point (Manski, 2003; Stanford, 2006).

For the Law, the strongest counterexample would be a qualifying stream with high-confidence evidence of terminal imbalance outside equivalence bands under an endpoint-independent rule. Other counterexamples might include a reference class where

repeated per-stream studies show no closure-like dynamics despite adequate measurement.

The chapter insists that counterexamples be allowed to matter. A theory that can always say the missing compensation was unmeasured has no public scientific content. Hidden experience can be part of the uncertainty model only if it is bounded, tested, or declared unknown.

Counterexamples should trigger a status update. They may lead to sensitivity analysis, replication, narrowing, formal amendment, or defeat. The response should be prewritten enough that the project cannot improvise self-protection after the result.

Consider a terminal case with convergent evidence of severe distress. Care remains the first response. Scientifically, that evidence concerns the late state and observed interval; it does not alone establish a nonzero complete-stream residual. Target-level adversity requires independently justified bounds on the unobserved history, a valid endpoint, and a measured-to-latent residual set that excludes zero. The case may still challenge a specified late-window route before those stronger requirements are met.

Persistent counterexamples are not failures of compassion. They are the price of answerability.

Persistent counterexamples should be designed for in advance. The program should state what quality of observation, bearer confidence, endpoint definition, measurement reliability, missing-history bounds, and observation-model scrutiny would make a nonclosing trajectory count. A target-level

counterexample does not additionally require identification or exclusion of the generating mechanism. Without that standard, every counterexample can be dismissed after the fact. With it, the theory becomes answerable. A credible counterexample is not an enemy of the book; it is the book doing science.

23.7.5 — No Unmeasured-Experience Rescue

Unmeasured experience is real. Science does not see everything. But unmeasured experience cannot be used as an unlimited rescue device. If every failed estimate is answered by hidden compensation, the claim becomes immune to evidence (Stanford, 2006).

A responsible uncertainty model can include latent intervals, missing reports, low-signal windows, dreams, altered states, or unobserved subjective content. It must also include bounds, priors, sensitivity ranges, and defeat conditions. Unknown cannot always be moved in the direction that saves the theory.

This is especially important in outer-limit cases. Animals cannot narrate like adult humans. Infants cannot provide adult reports. Artificial systems can produce too much report. Each case makes hidden experience tempting. The temptation must be governed.

Unobserved experience is represented through declared bounds and assumptions. The analysis updates the conclusion when the observed window and rival comparisons change what those bounds permit. Unknown, narrowed, and adverse outcomes each identify a different next step for the research.

This rule also protects people. A grieving family should never hear that a loved one's visible suffering must have been balanced

somewhere invisible. That sentence would turn ignorance into harm.

The science remains humble by letting unknown remain unknown. It remains scientific by not letting unknown always serve one conclusion.

23.7.6 — What Defeat Still Teaches

Defeat would not make the whole project worthless. A defeated Law could still leave better measurement of lived experience, better endpoint ethics, stronger rival models, improved hospice research, better animal-welfare caution, clearer Artificial Intelligence boundaries, and deeper understanding of non-ergodicity (Manski, 2003).

The project must remain emotionally capable of defeat. If triumph is the only acceptable ending, analysis will bend toward protection. When defeat can teach, the research program can remain honest under pressure.

A defeated universal claim might leave a narrower scientific program: affective dynamics under reserve, humane terminal measurement, within-person modeling, proxy evidence, cross-species welfare methods, or artificial-consciousness governance. These are valuable without terminal neutrality.

The applied books retain their own sources of value throughout this research. Ordinary life can use the burden-locating lens, government can improve records, law can design remedies, and religion can offer optional meaning. Scientific findings can inform these domains while each evaluates its practices through its own purposes and evidence.

The final posture is not retreat. It is maturity. The strongest public-candidate science is willing to say that a narrower truth, a partial mechanism, or a clear defeat is better than a theory no result can touch.

At the outer limit, the Law of Fairness becomes answerable by being willing to lose. That is the only kind of ambition worthy of the subject.

Table 23.7. Scope withdrawal and status consequence.

Finding	Scientific response	What remains available
Human-only support	Restrict empirical claim to human reference classes.	Human measurement and rival comparison.
State-limited support	Restrict to diagnosis, care setting, endpoint type, or window.	Local mechanism and protocol improvement.
Reference-class fragmentation	Report separate mechanisms and qualify route and transport claims; assess the universal target separately.	Comparative map of what travels and what does not.
Common-scale failure	Suspend cross-class ledger comparison.	Within-context welfare and local dynamics.
Persistent counterexamples	Replicate, audit, narrow, amend, or defeat.	Measurement lessons and rival knowledge.
No adequate estimate outcome	Declare unknown rather than force a verdict.	Future design guidance without overclaim.

Chapter 24 — Estimands and Informative Observation

A precise estimand turns a broad scientific hope into a question that data can answer. Chapter 24 fixes the unit, target population, treatment or exposure strategy where relevant, information set, observation regime, endpoint, intercurrent events, uncertainty, and decision rule before any numerical result carries PTVC-related meaning (Rubin, 1976; Manski, 2003; International Council for Harmonisation, 2019; Hernán & Robins, 2020).

A well-defined estimand specifies the unit, time origin, endpoint, missingness assumptions, neutral origin, and measured-to-latent relation. These choices establish the quantity that statistical analysis will estimate.

The challenge is sharp because PTVC is latent and pathwise while ethical research observes partial reports, physiology, records, care transitions, medications, devices, and adjudicated endpoints. None is the target by itself. The estimand names the quantity these observations identify under declared assumptions.

An estimand is not a statistic or result. Terminal concentration in a measured index, a survivor average, a smoothed reconstruction, a site-level mean, and complete-stream closure are different objects. The analysis must state which object it addresses before precision is interpreted.

Equivalence is also not failure to reject a point null. The scientific acceptance region must be justified for the target, scale, measurement floor, and decision purpose. Wide uncertainty, low power, miscalibration, instrument limits, or observation shutdown can all produce a favorable-looking null result without supporting equivalence.

Consider a terminal cohort in which a physiological estimator clusters near a nominal neutral point among participants who could tolerate measurement. The first task is to establish who remained observable, how burden, sedation, family preferences, device failure, care transitions, origin calibration, and endpoint adjudication shaped the sample and the estimate.

Measured-to-latent transport sets the ceiling on interpretation. A bounded systematic error widens the latent conclusion by the bound. An unbounded or unidentified bridge leaves the result at the measured level. Exact language becomes more credible when it states the bridge error openly rather than hiding it behind notation.

Missingness is part of the data-generating process. Reports stop because people are tired, sedated, distressed, protected, unwilling, cognitively altered, or occupied by care. Devices stop because bodies, batteries, adhesives, software, staffing, and institutional policies change. When observation depends on the state, absence must be modeled rather than imputed as calm.

Terminal events also create outcomes that may become undefined rather than merely missing. Semi-competing risks, truncation by death, delayed entry, and survivor-restricted estimands protect the analysis from treating the formal endpoint as an ordinary dropout problem.

Bayesian and frequentist companions become informative after the objects are fixed. Prior sensitivity, model-space sensitivity, posterior predictive checks, bounds, confidence procedures, and measurement-error analyses reveal which conclusions depend on

which assumptions. No framework earns authority merely by producing a narrow interval.

Sequential evidence can support a long research program when its process and stopping rules are valid for the actual dependence structure. E-processes and anytime-valid methods supply quantitative evidence for human review, component-specific interpretation, and versioned status decisions (Ramdas et al., 2022).

The closing discipline is abstention. Some results are inconclusive because uncertainty is too wide. Some are unusable because measurement, endpoint, consent, or protocol conditions failed. Some warrant the canonical verdict No adequate estimate because the required object is undefined or cannot be identified or validly bounded under the available, ethically permissible evidence and declared assumptions.

A worked example can carry the chapter's logic. A terminal-window analysis estimates a measured residual for people observed in the last seventy-two hours of open-channel consciousness. The primary interval lies inside the prospectively specified equivalence band. At first glance, the result seems favorable. But the conclusion is not allowed to move until the estimand, missingness, bias transfer, endpoint rule, sensitivity grid, and rival implications have all been named.

The same example can reverse. If missingness is concentrated among participants whose observation was suspended because reports became burdensome, equivalence may disappear under a plausible pattern-mixture analysis. If device removal increases

near active dying, a calm residual among remaining devices may describe the device process. If endpoint adjudication shifts by twelve hours, the terminal window may include different observations. A result that looked calm becomes fragile.

The primary reporting table should let a skeptical methodologist reconstruct the claim. It names the target quantity, reference class, information set, acceptance region, interval, bias bound, missingness model, endpoint rule, sensitivity result, and permitted verdict. Clarity here is part of inference, not editorial decoration.

Estimand and decision-rule specification precedes model recovery because adversarial tests need stable targets. Recovery and calibration checks then precede substantive model comparison on empirical data. A changed estimand, equivalence region, or observation model requires the benchmark to be checked again against the revised question.

A clean estimate identifies what the design can distinguish, what remains unidentified, and which observation should come next. Its authority ends at that inferential boundary.

A compact reporting spine keeps component claims separate. It states what was targeted, which information was available, which threshold or region was prospectively specified, how observation and missingness were modeled, how large transport error could be, and which verdict follows. Terminal equivalence, variance compression, route contraction, and model separation remain different empirical achievements.

When §24.2 returns No adequate estimate, report the limiting assumption, any narrower quantity that remains learnable, and the redesign needed for progress.

A final discipline is respect for the person behind the row. Missingness often occurs precisely when observation would impose the greatest cost. A participant who declines a final report, a family that requests device removal, or a clinician who ends nonessential measurement has protected care rather than damaged science. The analysis is damaged only when it hides that choice or converts the missing interval into a favorable value.

Inference is the discipline that prevents glamour from winning. Done well, it makes PTVC testable without protecting it inside a maze of estimates, and it lets negative, unusable, or inconclusive outcomes be reported without shame. Answerability, rather than statistical ornament, is the chapter's contribution.

24.1 — Unit, Target, Estimand, and Estimator

The inferential ladder begins with the unit. A qualifying stream, time segment, observation episode, participant, site, event, or population may each define a different unit, and a calculation cannot repair an unannounced shift among them.

The target is the scientific object of interest; the estimand is the exact quantity the data and assumptions are intended to identify; the estimator is the procedure applied to the observed record. These layers remain distinct even when their notation is compact.

The analysis must name its target before the result appears. This gate prevents terminal-window estimates from settling whole-life questions, survivor averages from settling all-stream questions, and operational records from settling lived-experience questions.

For example, a terminal study may enroll participants at different distances from a prospectively adjudicated terminal window. Entry time can depend on diagnosis, referral, care access, clinical trajectory, and consent. The target population and delayed-entry mechanism therefore require explicit definition before any terminal pattern is interpreted.

Begin by stating which quantity each site can estimate and which quantity the pooled result targets. For example, a pooled estimand might be the mean terminal measured residual among enrolled people with an independently adjudicated endpoint and at least one open-channel window. State that target in words before its formula.

This is also where the no-domain-theft rule becomes statistical. The science book may study the evidence route, but it does not redefine the formal Law because a convenient estimand is available. The formal object remains received. The analysis either estimates a legitimate consequence structure under uncertainty or says that the desired object is not available in the data.

An analysis should let a statistician identify the estimand and reconstruct the data rows that contribute to it. That traceability connects the scientific question to the observations and makes the result reproducible.

Table 24.1. Estimand specification before analysis.

Field	Required declaration	Failure if omitted
Unit	Stream, person, site, event, population, window, or observation process.	A result changes levels without being noticed.
Quantity	State, increment, cumulative window, treatment effect, observation effect, or undefined.	Momentary estimates become ledger conclusions.
Information set	Prospective, filtered, smoothed, or retrospective.	Future information enters an analysis intended to use only information available in real time.
Reference class and horizon	Eligibility, diagnosis, culture, site, device, endpoint, and horizon.	A narrow result becomes a universal statement.

Field	Required declaration	Failure if omitted
No adequate estimate rule	Conditions under which no meaningful estimate is produced.	The analysis manufactures a number from a nonobject.

24.1.1 — Individual, Population, and Site Levels

The first division is between the individual stream, the population distribution, and the site as a measurement environment. An individual-stream claim asks whether a particular trajectory exhibits a specified pattern under a specified endpoint rule. A population claim asks how such patterns distribute across a reference class. A site claim asks whether an institution can measure, calibrate, and report with enough fidelity to be compared at all (Hernán & Robins, 2020).

These levels are not interchangeable. A hospital may show average terminal residuals near a measured neutral point while several individuals show strong residual structure in opposite directions. A site may also create apparent concentration through sedation practices, device shutdown, staffing schedules, or family-report conventions. The estimate may be real for the site and wrong for the stream.

A proper analysis therefore names its level in the estimand. It may say that the target is the mean measured residual among enrolled adults in a hospice network during a prospectively specified terminal window. It may say that the target is the within-person slope of a running estimator over the last seven days of open-channel observation. It may not say that either object is the Law.

The formal claim is pathwise, so individual trajectories, missing tails, and site-specific calibration require explicit treatment. Population analyses describe the prevalence, distribution, heterogeneity, and transport of the corresponding measured patterns.

The site level matters because measurement is a human system. A clinic with careful consent, stable devices, trained staff, and transparent reporting produces a different observation process than a clinic with rushed documentation and version changes during the study. Treating site variation as random noise can hide the source of an apparent signature.

The carry-forward rule is simple: every result must state whether it is individual, population, site-level, or some combination. If the unit changes in the interpretation, the conclusion has already outrun the statistic.

24.1.2 — State, Increment, and Cumulative Estimands

The second division is among state, increment, and cumulative estimands. A state estimand describes a momentary or windowed condition, such as a terminal residual estimate at a declared time. An increment estimand describes movement between two states. A cumulative estimand summarizes an interval contribution, such as a discrete measured ledger over a window (van der Vaart, 1998; International Council for Harmonisation, 2019).

These quantities answer different questions. A person may have a terminal state near a neutral band while the preceding increment shows strong movement. Another person may show a small increment because the observation window began late, while the

cumulative burden before enrollment remains unknown. A state near zero is not a life integral.

A terminal-window study identifies its observation interval and estimand. Change from admission includes the admission state in its interpretation; a cumulative window contribution covers the declared interval, with earlier history represented separately when available.

A late physiological estimator may flatten as reserve falls, medication changes, observation ends, or reporting becomes difficult. Modeling these possibilities identifies the state features and cumulative quantities that the design can estimate.

A useful reporting table should therefore include a column for target quantity. The entry should be one of state, increment, cumulative window, event relation, or undefined. This seems bureaucratic only until a reader sees how often the conclusion changes when the quantity is named.

The scientific integrity of the Law depends on this restraint. The formal question can remain bold only if each measured result stays with the quantity it actually estimates.

24.1.3 — Prospective, Filtered, Smoothed, and Retrospective Estimation

The third division concerns the information available to the estimator. Filtering uses observations available up to time t ; smoothing also uses later observations to estimate the state at t . Both procedures can target the same latent state, although their information sets and uncertainty differ. A retrospective analysis may use endpoint or adjudication information and can still be

specified prospectively. If the target is instead a conditional expectation given a particular information set, that conditioning belongs explicitly in the estimand (Särkkä, 2013).

These distinctions are not technical ornament. A smoothed reconstruction may look cleaner than the actual evidence available at the time because future measurements have been allowed to revise the past. Retrospective endpoint alignment can make trajectories appear orderly because the endpoint itself has reorganized the clock. A filtered estimate is more honest about what the research system could know while the stream was still unfolding.

In a terminal study, this difference changes the claim. A real-time palliative monitor might produce a filtered burden estimate every six hours, while the final analysis may smooth the entire last month after the endpoint is adjudicated. Both can be legitimate, but they use different information and should state which analysis supports each conclusion.

The empirical test also requires endpoint adjudication that is not defined by the tested ledger estimator; statistical independence of endpoint timing is a separate, branch-specific assumption. Retrospective analyses are allowed only when the endpoint was defined through rules not algebraically identical to the ledger estimator. Otherwise the analysis risks making the endpoint and the conclusion define each other. A beautifully smoothed curve can become tautological if its clock was chosen by the quantity it is supposed to test.

A clean prospective specification should declare which versions will be reported. It might specify a primary analysis before data collection, with a filtered trajectory, a smoothed reconstruction, and a sensitivity analysis using endpoint-aligned windows. Each receives its own claim label. None is allowed to quietly become the others.

The reader should carry forward a practical test: ask what information the estimate was allowed to know. A change in information may change the estimator, its uncertainty, and the claims it can support; it changes the estimand only when the target quantity or its conditioning changes.

24.1.4 — Treatment and Observation Estimands

A treatment estimand asks what a care, intervention, medication, practice, or environment changes in the target quantity. An observation estimand asks what the act, availability, timing, or quality of measurement changes. These are easily confused because the same institution often administers both care and observation (Hernán & Robins, 2020; van der Vaart, 1998).

This distinction protects participants. If a more frequent diary schedule changes fatigue, vigilance, self-monitoring, family dynamics, or trust, then the observation process has become part of the data-generating system. A study cannot treat additional measurement as neutral simply because it improves the analyst's data table.

In the Law-of-Fairness research setting, this problem is unavoidable. Asking a person near the end of life for repeated reports may change the burden the study hopes to estimate. A

wearable may be tolerated on one day and intrusive on another. A clinician's presence may comfort one participant and alarm another. The observation channel has effects.

A causal analysis therefore separates the target intervention from the measurement regime. It may ask what a symptom-relief protocol changes in a terminal residual under a low-burden observation design. It may separately ask what increasing measurement cadence changes in adherence, fatigue, and observed signals. Those are different estimands with different ethical thresholds.

Observation effects also shape missingness. A participant who refuses a measurement after a stressful prompt is not simply missing; the prompt may have contributed to the refusal. The analysis must then model the observation regime or report that the treatment estimand cannot be separated from the observation effect under the design used.

The protocol must state whether the estimand includes or excludes the effects of measurement itself. Without that declaration, reactivity can be mistaken for the trajectory the study intended to observe.

24.1.5 — Reference Class and Horizon

A result cannot travel until its reference class is named. The reference class says which people, streams, diagnoses, cultures, ages, institutions, endpoints, devices, and time horizons the estimate is meant to cover. Without that declaration, the reader supplies the scope from imagination (van der Vaart, 1998).

Horizon is part of reference class. A two-day terminal window, a thirty-day hospice window, a year-long illness trajectory, and an adult life-course cohort are not minor variations. They define different opportunities to observe increments, different missingness mechanisms, different endpoint uncertainties, and different chances for rival explanations to mimic apparent closure.

A defined reference class makes a result interpretable and replicable. A study of adults with a particular diagnosis in three palliative-care systems can establish a useful finding within those conditions and identify the next settings for extension.

Reference-class drift often appears in summaries. A paper may report a terminal-window equivalence result and a public artifact may say the science found terminal neutrality. That compression erases age, diagnosis, site, device, endpoint rule, window length, missingness assumptions, and latent transfer limits. The inference was narrow; the artifact became wide.

The analysis plan should therefore attach the reference class to every primary result. The table should not merely list sample size and model. It should list who was eligible, what was observed, what endpoint rule applied, what horizon was targeted, and what groups were explicitly outside the claim.

The Law can be universal only if the evidence eventually earns universality. Until then, each estimate carries a horizon and a reference class like a nameplate.

24.1.6 — Undefined Outcomes and No-Estimate

Some quantities are undefined by the design, not merely difficult to estimate. A report after the qualifying stream irreversibly ends is not an ordinary missing value. A whole-life ledger for a person enrolled in the final week is unobserved, and an uncalibrated cross-cultural residual may lack a meaningful unit (International Council for Harmonisation, 2019; Hernán & Robins, 2020).

Section 24.2 gives the canonical status rule: return No adequate estimate when the target is undefined or cannot be identified or validly bounded after prerequisite gates pass; prerequisite or implementation failure yields Unusable evidence. Here the key distinction is scope: a terminal-window estimate may be valid for a measured object while the whole-stream target remains unestimable.

Report the estimand, unit, and reason for abstention explicitly. Do not convert silence, device dropout, endpoint ambiguity, or an unobserved prefix into a number merely to complete a table.

24.2 — Equivalence and No-Estimate Logic

Equivalence answers whether the supported effect or residual lies within a scientifically justified acceptance region for the declared target. It is not established by a large p-value, a confidence interval that merely crosses zero, or a posterior region chosen after inspection (Schuirmann, 1987; Lakens, 2017; Kruschke, 2018).

The acceptance region and the epistemic uncertainty region are different objects. One encodes what the scientific decision regards as compatible at the declared resolution; the other represents what the data and model allow researchers to know. Their overlap creates a typed decision, not a verbal impression.

No adequate estimate is the correct outcome when passed protocol and implementation gates leave the target quantity undefined or without either identification or a valid bound under the available data and maintained assumptions. It is not a null result, a small effect, or a euphemism for model failure.

A small interval plot can teach more than a paragraph of reassurance. One study may have a terminal residual estimate almost exactly at zero, but with an interval that stretches far outside the equivalence band. Another may have a slightly displaced estimate whose entire interval lies inside the band. The first looks emotionally satisfying. The second is the stronger equivalence result.

Equivalence is used because exact latent equality is not directly observable. The measured question therefore uses a scientifically justified band, but the band is not a mercy. A vague, wide, or data-

chosen margin protects the theory; a narrow, prospectively specified margin exposes it.

The same discipline applies to Bayesian companions. Posterior mass inside a ROPE can be informative, but only after the reader knows the prior, the model, the observation process, and the predictive checks. A posterior that looks decisive under one convenient prior and uncertain under another does not deserve public clarity language.

An equivalence report can support measured near-neutrality at the declared resolution or show that the data remain too imprecise to decide. Insufficient precision challenges the study's ability to answer the question; it does not, by itself, defeat the substantive hypothesis.

Equation 24.1 (role: equivalence hypothesis)

$$H_0: \theta \leq -K \vee \theta \geq K; H_1: -K < \theta < K$$

Equation 24.2 (role: equivalence diagnostic)

$$CI_{1-2\alpha}(\theta) \subset (-K, K) \Rightarrow \text{equivalence for the declared estimand}$$

24.2.1 — TOST Logic

The two-one-sided-tests framework reverses the usual posture. Instead of taking zero as a null to be rejected, it takes values outside the equivalence band as the null. The analysis must show that the estimate is statistically above the lower unacceptable bound and below the upper unacceptable bound (Schuirmann, 1987).

For a terminal residual θ , the equivalence null can be written as θ less than or equal to minus K or θ greater than or equal to K . The

equivalence claim is the intersection that places θ inside the band. Both one-sided tests must carry their share of the burden.

This logic is useful for the Law because it makes near-neutrality testable without pretending to observe exact zero. Exact latent equality is not available to measurement. A measured equivalence claim says that the residual is inside a band that had scientific meaning before the data were inspected.

The method also exposes inadequate studies. If the confidence interval is wide, crosses beyond the band, or depends on a favorable subset, equivalence is not established even if the central estimate is close to zero. The study may be underpowered, too noisy, or too biased for the question.

TOST does not solve construct validity. It only gives a valid test for a defined statistical object under its assumptions. The measured residual, the neutral origin, the endpoint window, and the bias-transfer route still require independent justification.

TOST supports equivalence only when the equivalence margin is fixed before outcome inspection and both one-sided null hypotheses are rejected at the protocol-fixed error rate. In Equation 24.2, $CI_{1-2\alpha}$ is the interval formed from the corresponding lower and upper one-sided $1-\alpha$ confidence limits; nominal $1-2\alpha$ coverage alone does not establish a level- α equivalence test. The conclusion is equivalence within that margin for the named estimand, not exact zero or absence of a meaningful effect. Changing the margin after seeing the interval changes the question.

24.2.2 — Meaningful Band K

K is the meaningful band around the target value. It is not a symbol for hope and not a convenience that expands until the data fit. K defines the smallest residual large enough to matter for the stated measured object, given the measurement scale, uncertainty floor, and scientific question (Lakens, 2017; Lakens et al., 2018).

The rationale for K should begin with the scientific estimand and the largest deviation that the stated equivalence claim would regard as negligible. Calibration, participant-relevant resolution, clinical interpretation where applicable, and rival predictions can inform that rationale. Instrument precision determines whether the design can resolve the chosen band; it must not justify widening the band merely so the study can pass.

For Law-of-Fairness science, K must also be tied to the object. A K for momentary-valence residuals is not automatically a K for cumulative-contribution windows. A K for adult hospice data is not automatically a K for sleep studies, dream reports, childhood cohorts, or nonhuman evidence. Same symbol, different claim.

A careless band can hide public overreach. If K is large enough to include ordinary adaptation, measurement noise, sedation artifacts, and endpoint selection, equivalence becomes meaningless. If K is chosen from the observed result, it protects the theory rather than testing it.

The strongest practice is to publish the rationale for K before analysis. The rationale should state what would make the band too narrow, what would make it too wide, what data support it,

and whether rival models can produce residuals inside the same band.

Here, K is a contract with the reader. It states what small means before the result asks for trust.

24.2.3 — Nonsignificance Is Not Equivalence

A nonsignificant test says that the study did not reject a specified null at a specified threshold. It does not say the effect is small, absent, neutral, balanced, or scientifically unimportant. The difference between those statements is one of the most important safeguards in the science book (Lakens et al., 2018).

Imagine a terminal-window analysis with an estimate near zero but a confidence interval wide enough to include large positive and negative residuals. The result may have a large p -value against a zero-difference null. That does not support neutrality. It says the study could not distinguish neutrality from meaningful imbalance.

This distinction is especially important when sample sizes are small, endpoints are heterogeneous, and observations become sparse near death. Nonsignificance may reflect attrition, noise, wide bands, weak sensors, calibration failure, or unmodeled site effects. Treating it as equivalence rewards weak measurement.

Public language must keep the distinction visible. A report may say that evidence was inconclusive because the interval was too wide. It may not say that no difference was found and therefore the terminal residual was neutral. The second sentence gives comfort to the theory by hiding the study's weakness.

Nonsignificance alone is not equivalence. A valid confidence interval wholly inside the prespecified equivalence band supports equivalence for the declared estimand under the test assumptions. Prospective power matters for design, but low planned power does not invalidate an observed equivalence result that satisfies the valid prespecified test.

The design should distinguish the declared band from scientifically relevant alternatives.

24.2.4 — Bayesian ROPE Companion

A Bayesian region of practical equivalence, often called a ROPE, asks how posterior mass relates to a prospectively specified practically equivalent region. It can be a useful companion to equivalence testing because it shows how the result depends on prior assumptions, likelihood structure, and model adequacy (Kruschke, 2018; Linde et al., 2021).

The companion status matters. A posterior probability that θ lies within a band is not automatic truth. It is conditional on the model, priors, observation process, endpoint definition, and data actually used. If those components are weak, a concentrated posterior can be misleading.

For this book, a ROPE analysis is most useful when it sits beside the frequentist equivalence result and the sensitivity analyses. The reader can see whether the conclusion survives plausible priors, alternative observation models, different windows, and measurement-error variations. Agreement across these analyses shows which conclusions are stable; disagreement identifies assumptions requiring closer examination.

A Bayesian analysis must also resist posterior certainty without predictive adequacy. If the posterior says the residual is near zero but posterior predictive checks fail to reproduce missingness, variance structure, or terminal timing, the model has not earned the conclusion. Precision can be false when the model is wrong.

The ROPE and frequentist equivalence band K should share the same scientific rationale. Any difference should be prospectively justified for the estimand and inferential method.

The public statement should therefore read as conditional: under this Bayesian model and these priors, the posterior assigns a specified mass to the declared region. The next sentence must say whether model checks and sensitivity analyses made that conditional statement usable.

24.2.5 — Distributional and Individual Equivalence

A mean can be equivalent while individuals are not. This is the distributional problem. If half a cohort ends with positive residuals and half with negative residuals, the mean may be near zero even though individual streams show strong terminal structure. A mean equivalence result then answers a population question, not a pathwise one (Schuirmann, 1987).

The analysis must distinguish equivalence of mean, median, distribution, tail behavior, variance, and individual path. The Law's public empirical target may include terminal concentration and variance compression, not only first-moment neutrality. A first-moment result is often the least discriminating form of evidence.

Distributional equivalence asks whether the whole distribution lies inside a meaningful relation to the target. Individual equivalence asks whether each or most individuals satisfy a stated band under declared uncertainty. These are stronger and weaker claims in different ways, and neither should be silently substituted for the other.

A concrete example helps. A site may report a near-zero terminal mean residual with wide person-level scatter. That result might weaken the claim of concentration while preserving a question about population symmetry. The report should say exactly that. It should not use the mean as a door into terminal closure language.

Pathwise claims also require dependence structure. It is not enough to list individual terminal values if the observation process excludes the most distressed moments or if endpoint alignment creates apparent narrowing. Individual equivalence must be tied to the window, measurement model, and missingness rules.

The section's practical rule is to print the level of equivalence in the result label. Mean equivalence, distributional equivalence, and individual equivalence are different scientific sentences.

24.2.6 — Rival Victory Under Equivalence

The comparison set should include adaptation, homeostatic mean reversion, conditioned bridges, sedation, selection, and observation shutdown as possible generators of near-zero measured residuals (Lakens, 2017; Lakens et al., 2018).

Equivalence therefore belongs inside rival comparison. When the candidate and a simpler rival both predict the declared region, the

result may validate a measure or favor the rival while leaving PTVC unchanged.

The analysis predeclares what would discriminate, such as equivalence plus reserve-linked variance compression under endpoint-independent stopping rather than mean reversion alone. The discriminating criterion should be evaluated in model recovery before empirical use so an equivalence finding cannot win merely because the pipeline lacks power against the rival.

A simpler rival that explains the result wins honestly. Letting it win strengthens the program more than treating every near-zero finding as hidden support. The report should credit the rival at the same level of specificity used for the candidate, including the reference class and observation bridge under which it succeeded.

Reports state when equivalence was met but failed to discriminate under the shared observation model. Such a result can still validate the equivalence procedure while showing that it has no Law-specific evidentiary force in that setting.

24.3 — Observation Kernels and Measured-to-Latent Bias

An observation kernel describes how a latent history becomes reports, physiology, behavior, neural signals, clinical records, or missing entries. It is part of the scientific model, not a nuisance layer added after a preferred result appears.

Measured-to-latent transport requires assumptions about calibration, invariance, channel validity, context, reactivity, and information loss. When those assumptions support only a set, the result remains set-valued rather than being forced into a point estimate.

Bias transfer receives a formal role. The aim is not to make latent inference impossible, but to state exactly what additional assumption is required before measured equivalence may become a bounded latent claim.

A visually tidy interval is often the most seductive object in inference. A narrow line centered inside a band can look decisive, yet the real question is what the line is centered around. Precision around a biased estimator is precision around the wrong target.

Bias transfer makes the relation between measured and latent quantities operational. It evaluates that relation under the relevant state, site, device, culture, endpoint, and observation conditions, establishing the scope at which an estimate can be interpreted.

Estimating a measured terminal residual identifies the next calibration and construct-validation questions. Each resolved

measurement relation expands the range of quantitative comparisons the program can make.

This is more than a generic disclaimer that measurement is imperfect. The analysis states how imperfection changes the band, how the conclusion widens, and where inference stops when bias cannot be bounded. In Equation 24.3, L_M denotes the measured estimand, L the latent target, and δ a bound on their systematic displacement; $\hat{L}$ estimates L_M and also has random estimation error.

Equation 24.3 (role: bias-transfer bound)

$$|L_M - L| \leq \delta \wedge |L_M| \leq K \Rightarrow |L| \leq K + \delta$$

Equation 24.4 (role: initial-state decomposition)

$$L(T) = L(t_0) + \int_{t_0}^T g_{\theta}(s)F(s)ds$$

Table 24.2. Measured-to-latent transfer statuses.

Transfer status	What is known	Permitted sentence
Validated transfer	The measured interval is valid, and the bias bound and calibration route are defensible for the stated reference class.	Latent claim may be bounded with the inflated band.
Measured only	Estimator is coherent but latent bridge is unvalidated or state-limited.	Measured residual met or failed its criterion.

Transfer status	What is known	Permitted sentence
Unbounded bias	Systematic error cannot be bounded under plausible assumptions.	No latent transfer.
Initial state unbounded	Late window is observed but prior ledger term is unknown.	Late increment or state only.
Coordinate unstable	Origin or sign choices change the conclusion.	Sensitivity-dependent and narrowed.

24.3.1 — Bias Bound δ

A bias bound δ is a declared upper bound on systematic measured-to-latent error for a stated estimand and reference class. It is not the standard error. It is not random noise. It is the maximum systematic displacement the analyst is willing to defend after calibration, validation, device, state, and cultural uncertainties are considered (Carroll et al., 2006).

Justify the bias bound independently of the terminal result, using calibration studies, documented device performance, cross-channel validation, state-specific audits, or a declared conservative expert assessment.

Let L_M denote the measured estimand and L the latent target, with a defensible bound $|L_M - L| \leq \delta$. The estimate $\hat{L}$ also has random estimation error. If $[a, b]$ is a valid confidence interval for L_M , then $[a - \delta, b + \delta]$ is a conservative interval for L under that fixed bound. A measured equivalence result transfers to an inflated latent band through this interval, not by checking the

point estimate alone. Any uncertainty in δ must also be propagated.

For example, a measured estimate of 0.2 with a confidence interval $[-0.1, 0.5]$ and a defensible fixed bias bound $\delta = 0.8$ gives a latent interval $[-0.9, 1.3]$. The measured interval is inside the band $[-1.0, 1.0]$; the latent interval is inside the inflated band $[-1.8, 1.8]$, but not the original band. If the inflated band is too wide for the scientific question, the latent transfer is too weak for support.

A bias bound can also be asymmetric. Some devices or report regimes may systematically understate distress more than relief, especially under sedation, disability, cultural restraint, or care dependence. The analysis should not force a symmetric δ when the mechanism is directional.

The practical rule is that every latent interpretation must show its bias bound. If no defensible δ exists, the conclusion stays with the measured estimator.

24.3.2 — Inflated Latent Band

The inflated latent band is the band that remains after measured equivalence has paid the cost of systematic uncertainty. If the measured equivalence band is K and the bias bound is δ , the simplest conservative latent band becomes K plus δ . The conclusion has moved, and the prose must move with it (Fuller, 1987).

The public ear often hears near zero as exact neutrality. The analysis blocks that slide. A valid confidence interval for the

measured estimand wholly inside a tight band can support a resolution-bounded statement, while the inflated band keeps measurement error visible rather than pretending it disappeared.

The calculation also helps compare studies. A study with a slightly wider measured interval but a well-validated δ may be more informative about the latent object than a study with a narrow interval and unbounded bias. Precision without transfer can be less useful than modest precision with known error.

The inflated band should be reported visually when possible. A figure can show the measured confidence interval, the measured equivalence band, and the latent band after bias expansion. Such a display keeps the reader from treating the neatest interval as the final story.

If the bias-adjusted band is too wide for the intended inference, its width identifies the calibration precision the next measurement study needs to achieve.

In this book, every measured-to-latent sentence should carry the widened band or refuse the transfer. Anything else lets the latent Law borrow the polish of measured statistics.

24.3.3 — Calibration and Transport Error

Calibration error arises when the estimator's relation to lived burden is imperfect in the study setting. Transport error arises when a calibration learned in one setting is carried into another. Both errors matter because the same measured value may mean different things across sites, diagnoses, languages, devices, states, and care regimes.

Palliative-care calibration should account for speech, movement, sleep, autonomic reactivity, medication, family presence, disease trajectory, and clinical documentation. Validation in the intended illness state establishes how an estimator trained elsewhere can be used.

Calibration transport should therefore be treated as part of δ or as a separate uncertainty component. If a device version changes, if a site adopts a new documentation workflow, or if a culture-specific reporting pattern changes the anchor, the measured-to-latent bridge must be reaudited.

The chapter also separates calibration error from site effect. A site effect may reflect true environmental differences in burden. Calibration error reflects a change in how the instrument maps evidence into estimates. Treating both as one random intercept can hide the mechanism that matters.

A useful analysis reports calibration strata. It might show results under within-site calibration, pooled calibration, leave-site-out calibration, and device-version-specific calibration. If conclusions change, the claim narrows to the calibration regime that survived.

The transport rule is conservative: a calibrated estimator travels only as far as its validation evidence travels. The reader should not be asked to imagine a universal scale because the table is clean.

24.3.4 — Unknown Initial Ledger

Late-enrollment studies can estimate terminal residuals, increments, and window dynamics. A whole-course cumulative

analysis additionally requires an independently bounded initial state at enrollment or observation spanning the relevant horizon (Carroll et al., 2006; Fuller, 1987).

Report the observed terminal-window contribution and the initial cumulative term separately. This decomposition makes the contribution of observed and earlier history explicit.

The initial-state problem can be written as a decomposition. The ledger at the endpoint equals the ledger at enrollment plus the interval contribution after enrollment. If the first term is unknown and unbounded, the endpoint conclusion about the whole stream is not identified.

Longitudinal cohorts, intensive life-course designs, qualified retrospective anchors, or well-justified reference-class assumptions may help bound the initial term. The resulting bounds determine which cumulative comparisons are identifiable.

The report should make this explicit. It may say that the design estimates late increments conditional on admission state. It may say that initial-state sensitivity was too wide for whole-stream inference. It may not imply that late neutrality proves life neutrality.

The unknown initial ledger is not a technical footnote. It is the guardrail that keeps terminal science from pretending to see an entire life through its final window.

24.3.5 — Sensitivity to Origin and Sign

Affective measurement has no universally given natural origin and unit. Origin and sign sensitivity therefore enter the inferential

report as empirical dependencies rather than remaining an abstract philosophy problem (Fuller, 1987).

If the neutral origin shifts, a residual can move across the equivalence band. If the sign convention changes for a channel, burden-increasing and restorative contributions can be reversed. If a cultural or clinical anchor is wrong, a measured near-zero result may reflect the coordinate system more than the stream.

A good analysis therefore tests origin sensitivity. It reports how the conclusion changes under plausible neutral anchors, within-person baselines, site-specific anchors, and calibration anchors. It also audits sign conventions for each channel before the composite estimate is allowed to enter the ledger calculation.

Sign sensitivity is especially important in physiological data. Increased arousal may signal distress, effort, excitement, medication response, pain relief, or agitation depending on context. A fixed sign assigned to a nonspecific channel can create false movement toward or away from neutrality.

The chapter does not demand impossible certainty. It demands that coordinate choices be visible. A result that survives plausible origin and sign changes is stronger. A result that changes direction under reasonable alternatives is not defeated automatically, but it loses the right to clean language.

The reporting sentence should say whether the conclusion was invariant, narrowed, changed sign, or became unusable under origin and sign sensitivity. That is how measurement humility becomes statistical design.

24.3.6 — No Transfer Without Validation

Validation connects measured equivalence with the specified latent target through the declared measurement relation (Carroll et al., 2006).

Validation has layers. The estimator must have a coherent construct, stable calibration, known uncertainty, state-appropriate performance, endpoint-compatible use, and a defensible relation to the latent target. A study may satisfy some layers and fail others. The conclusion should match the lowest unresolved layer.

This prevents the science from becoming impressive at the wrong level. A sensor composite may predict reports. A report composite may predict care transitions. A terminal residual estimate may be stable across sites. None of those achievements automatically validates transfer to the latent ledger.

A transfer study can identify improvements needed in calibration, missingness analysis, care-sensitive observation, or model comparison. Those findings define the next qualification task.

The public risk is obvious. If a measured estimator is described as if it reached inner life directly, readers may hear that a number has ranked or read a person. The research language must keep the estimator inside the protocol and leave no worth, care, trust, or spiritual implication behind.

The path forward is typed: measured results support measured claims, latent claims require a qualified measured-to-latent bridge, and an unsupported bridge remains a gap. The language of transfer must match the evidence that licenses it.

24.4 — Informative Sampling, Missingness, and Reactivity

Informative observation arises when whether, when, or how a record appears depends on latent state, burden, treatment, prognosis, communication, device use, or prior observations. Ignoring that dependence can create apparent improvement, stability, or terminal concentration (Rubin, 1976; Little & Rubin, 2019; Hernán & Robins, 2020).

Missingness labels are not explanations. The protocol should specify an observation process, denominator flow, plausible causal structure, sensitivity parameters, and what evidence could distinguish competing missingness mechanisms.

Absence is modeled rather than apologized for. The aim is not to recover everything, but to know when recovery is possible, when sensitivity is required, and when the correct output is inconclusive or unusable.

Missingness arrives before the result is trusted because absence may be caused by the states under study. A participant who stops answering because a prompt has become unbearable and a device whose battery fails during a routine afternoon produce different observation processes.

The chapter's working example becomes sharper here. Suppose terminal-window observations come mostly from participants who remained comfortable enough to tolerate devices and prompts. The observed residuals may look calm. But if the unobserved cases were removed by distress, care protection,

sedation, transfer, or endpoint ambiguity, the apparent calm belongs partly to the observation process.

The analysis should therefore report missingness as a time-varying, marked process. The mark might be the measured burden estimate when observation occurs. The event is the fact that observation occurred at all. Treating the event and the mark jointly allows the study to ask whether the evidence window was shaped by burden, staff, device, care, or endpoint state.

A humane point follows without becoming a warning wall. A missing value may reflect good care. The study can honor that choice while still admitting that care-created absence limits inference. Care is not a bias to resent; it is a condition the science must respect and model.

Equation 24.5 (role: marked observation process)

$$\begin{aligned}\mathbb{E}[dN_i(t) \mid H_i(t^-)] &= \lambda_i(t \mid H_i(t^-)) dt, \\ M_i(t) &\sim p(m \mid dN_i(t) = 1, H_i(t^-)).\end{aligned}$$

For a simple marked point process with a locally integrable predictable intensity, the first line is infinitesimal conditional-mean notation and does not assert exact Poisson increments.

Table 24.3. Missingness categories and inferential consequences.

Category	Typical mechanism	Default inference action
Scheduled absence	Low-burden protocol window or planned rest.	Valid for schedule, not for unobserved moments.

Category	Typical mechanism	Default inference action
Participant refusal	Burden, distrust, fatigue, privacy, or preference.	Model separately; respect refusal.
Clinical protection	Care team suspends measurement for comfort or safety.	Record as protection, not random absence.
Device failure	Battery, placement, skin, motion, firmware, signal quality.	Use provenance and version checks.
Care transition	Transfer, new site, new staff, new record regime.	Treat as a process change.
Qualified stream endpoint	Later outcomes are undefined for that stream.	Use truncation logic, not imputation.

24.4.1 — Missingness Taxonomy

A missingness taxonomy begins by refusing the single label missing. Scheduled absence is different from refusal. Device failure is different from low signal. Clinical protection is different from family refusal. Transfer is different from death. Each has a different relation to the target quantity (Rubin, 1976).

The taxonomy should be designed before data collection. A terminal study might distinguish planned rest windows, participant-declined reports, clinician-suspended measurement for comfort, medication-induced inability, sensor detachment, technical failure, site workflow failure, transfer to another care

setting, and endpoint occurrence. These labels matter for inference.

A night nurse who decides not to wake a participant for a report is not producing the same absence as a lost battery. The first may reflect care and clinical judgment. The second reflects device reliability. A model that treats both as random missing values hides the mechanism and may bias the result.

Taxonomy also protects dignity. It lets the study say that data were not collected because measurement would have been intrusive, not because the person disappeared from the evidence map. Ethical protection should be visible in the data record, but not converted into a claim about inner state.

Some categories should automatically limit inference. If missingness follows distress, sedation, or endpoint ambiguity, the analysis must use nonignorable sensitivity or abstain. If missingness is a planned low-burden window, the analysis may be valid for the schedule but not for unobserved moments.

The missingness report disaggregates counts by category, time, site, device, and relation to the endpoint. A single overall percentage conceals the mechanisms that determine recoverability.

24.4.2 — Marked Point-Process Model

A marked point-process model treats observations as events that occur in time, each carrying a measured mark when observation succeeds. The timing of observation is modeled, and the observed value is modeled conditional on the observation event. This

makes the visit process part of the analysis rather than a nuisance outside it (Little & Rubin, 2019).

For terminal and life-course studies, this is often more honest than pretending measurements arrive on a fixed grid. Reports may cluster when a participant feels able to respond. Clinician notes may cluster during crises. Wearable data may vanish during transfers or procedures. The observation process has its own dynamics.

The model asks two linked questions. What determines the intensity of observation at time t ? What distribution of measured marks appears when observation occurs? If the intensity depends on the latent or observed burden state, the resulting data are not a simple sample from the path.

A marked process can also include site and device features. Staffing patterns, software versions, charging schedules, family presence, and care routines may affect observation intensity. These variables belong in the observation model because they decide which parts of the path become visible.

The model is not magic. It can only adjust for mechanisms that are measured, bounded, or plausibly specified. If observation depends on unmeasured distress in a way the data cannot constrain, the analysis must report sensitivity or No adequate estimate.

The advantage is clarity. Instead of saying that missingness was handled, the study states how observation events were generated, what marks they carried, and what assumptions allowed inference beyond observed points.

24.4.3 — Missing at Random as an Assumption

Missing at random is an assumption about the dependence of missingness on observed and unobserved data. Conditional on the specified observed information, it asserts no residual dependence on the missing values. Design and observed-data diagnostics can inform its plausibility, but generally cannot verify that absence of dependence from the observed data alone. The analysis must name the conditioning history and examine departures through sensitivity analysis (Little & Rubin, 2019).

The assumption may be plausible for some device failures and implausible for others. A battery failure might be close to random conditional on device version and staff schedule. A refusal to answer a distress prompt is unlikely to be random with respect to unobserved burden. A clinician-suspended measurement near active dying is not random with respect to endpoint state.

A study should therefore justify missing-at-random claims by category. It should not apply one missingness assumption to all absences. The taxonomy from the previous subsection feeds directly into the model: some categories may be modeled as conditionally ignorable; others demand sensitivity analysis or No adequate estimate.

The assumption also has a temporal dimension. Missingness at noon may depend on measurements from morning, but also on unobserved events after morning. A model that conditions only on baseline covariates may be too thin for longitudinal burden data. The history used for the assumption must be explicit.

Readers should be able to see what would make the assumption false. If unobserved pain, delirium, fear, family conflict, or medication side effects could change both the outcome and the chance of observation after conditioning, missing at random is fragile. That fragility belongs in the conclusion.

Missing at random may be used only as an assumption with visible support and visible alternatives. It is never a default setting in this book.

24.4.4 — Pattern-Mixture and Selection Sensitivity

Pattern-mixture and selection models give different ways to examine nonignorable missingness. A pattern-mixture approach compares outcome distributions across missingness patterns. A selection approach models the probability of being observed as depending on outcomes or latent states. Both expose how conclusions depend on assumptions about absent data (Scharfstein et al., 1999; Rubin, 1976).

In terminal studies, pattern matters. People who stop reporting because they are peaceful, exhausted, sedated, distressed, transferred, or actively dying may have different unobserved trajectories. Treating all observed persons as representative of all enrolled persons may create artificial terminal concentration.

Sensitivity analysis should move missing values in scientifically meaningful directions, such as more negative unobserved terminal reports or greater device dropout during agitation. Its purpose is to test how much unobserved structure would overturn the result, not to invent the truth.

Selection sensitivity asks a related question: how strongly would observation intensity have to depend on unmeasured burden to produce the apparent signature? If a modest dependence is enough to erase equivalence, the result is fragile. If only extreme assumptions overturn it, the result gains conditional strength.

The analysis should not hide sensitivity in supplementary material. In a public-candidate science book, the main chapter must teach readers why the result changes under different missingness stories. A sensitivity curve can be more honest than a single adjusted estimate.

The verdict should name the missingness range under which the claim survives. If survival requires an implausibly convenient missingness model, the result is protected theory, not support.

24.4.5 — Device and Staff Processes

Devices and staff are part of the observation system. They decide when data appear, which channels are usable, which notes are written, and which exceptions are recorded. Treating them as background machinery can turn operational behavior into scientific signal (Rubin, 1976).

A wearable may fail more often during movement, sweating, edema, oxygen changes, agitation, skin fragility, or clinical handling. A staff note may appear more often during crises, medication changes, family distress, or shift transitions. Those processes can create apparent dynamics in the measured ledger even when the underlying path differs.

The analysis should therefore include device version, firmware, placement, adherence, charging, signal quality, staff role, shift,

site, care transition, and documentation workflow where available. These variables are not clutter. They explain why the evidence exists.

A realistic failure case is a terminal study in which signal dropout increases in the last hours because devices are removed for comfort. If remaining signals are calmer, the analysis may infer concentration near neutrality. The actual mechanism may be compassionate device removal plus selective observation.

Staff processes also carry burden. Asking staff to collect data during intense care can create documentation shortcuts, fatigue, and uneven compliance. The study should not punish staff for protecting patients, but it must record that protection so inference does not mistake absence for evidence.

The section's local safeguard is operational: every observation pipeline should have a provenance field. The path from person to number must include the human and technical processes that made the number available.

24.4.6 — When Missingness Defeats Inference

Missingness defeats inference when the unobserved parts of the path could plausibly change the conclusion and the study cannot bound that effect. This is not the same as having many missing values. A small amount of strategically informative missingness can be worse than a larger amount of planned, well-understood absence (Little & Rubin, 2019).

The defeat condition should be stated before analysis. It may involve missingness concentrated near endpoints, missingness associated with high distress markers, missingness tied to

treatment changes, missingness differing sharply across sites, or missingness that removes entire classes of participants from the target window.

When missingness defeats inference, the result should not be rescued by a sophisticated imputation model. Imputation is a model-based assumption about unobserved values. If the assumptions are unconstrained, the imputed conclusion says more about the model than about the stream.

A good report distinguishes data incompleteness from inferential failure. If required protocol and implementation gates passed but endpoint-window observation depended on unmeasured clinical deterioration whose effect could not be validly bounded, report No adequate estimate for the primary target while retaining any valid secondary descriptive summaries. Reserve Unusable evidence for a failed required gate. That is more useful than burying the failure inside an adjusted estimate.

Defeat by missingness can teach the research program. It may show that cadence was too high, participant return was too burdensome, devices were not appropriate, staff processes were underdesigned, or endpoints needed different windows. The correct response is better design, not rhetorical rescue.

The chapter's rule is that absence may narrow, weaken, suspend, or defeat a claim. It may not be converted into support merely because the observed remainder looks clean.

24.5 — Delayed Entry, Truncation, and Competing Events

Delayed entry and truncation separate the study window from the stream's complete domain. A participant observed late supplies only a suffix of the complete history, while follow-up may stop before the truth-level endpoint. Complete-stream inference therefore needs a joint prefix-observed-suffix object on one latent scale.

Competing events such as death, resuscitation, withdrawal, transfer, sedation, device removal, or loss of communication can alter both the scientific target and observation. The analysis must say whether they are part of the endpoint definition, intercurrent events, censoring mechanisms, or causes of a new estimand.

Terminal inference distinguishes survivor-only quantities, composite outcomes, joint longitudinal-event models, and endpoint-definition sensitivity. Independent endpoint adjudication establishes the event used by each analysis.

A concrete record can show why the distinction matters. A participant may have a distress episode on Monday, a care transition on Tuesday, a sedation change on Wednesday, and loss of the open-channel endpoint window on Thursday. Loss of an open observation channel does not establish that the qualifying stream has ended. Friday's report may be missing or unavailable; only an independently qualified terminal event makes a post-terminal outcome undefined for that stream.

The reporting discipline is therefore not merely technical. If the analysis concerns survivor averages, it must say survivor. If it

concerns nonterminal events before a terminal event, it must say before. If it uses a composite outcome that includes death, it must explain what the composite hides and what it reveals. The reader should never have to infer whether the favorable estimate came from all enrolled streams, only surviving streams, or only streams that remained observable under the protocol.

Terminal research distinguishes unobserved values within a continuing stream from quantities that are undefined after its independently established endpoint. Each requires its own statistical treatment.

The semi-competing-risk frame prevents two opposite errors. The first error treats an independently qualified stream endpoint as ordinary censoring and imputes later experience as though it belonged to that stream. The second error discards all event structure and studies only survivors, quietly changing the target population. Both can produce clean tables and misleading conclusions.

A complete analysis keeps terminal and nonterminal events in view together. Medication change may precede the endpoint, delirium may alter observation, and a family interview may occur before the qualifying stream irreversibly ends and also change later reports. Their relation to the terminal event must be modeled rather than flattened into one outcome.

The public-risk boundary is local: no composite, survivor average, or event model may imply that death, comfort, burden, or observation completion are exchangeable moral quantities.

They are statistical components for a defined analysis, not units of a life's worth.

Equation 24.6 (role: ordered pair of semi-competing-risk probabilities)

$$Pr(T^N \leq t, T^D > t), Pr(T^D \leq t)$$

24.5.1 — Truncation Is Not Ordinary Dropout

Ordinary dropout means an outcome might exist but was not observed. Truncation by death means that a specified post-death outcome is undefined. For PTVc, a later experiential outcome may be treated as undefined for a stream only after its endpoint has been independently qualified. In Equation 24.6, the first probability is the chance that the nonterminal event has occurred by time t while the terminal event has not; the second is the terminal-event cumulative incidence by time t . These distinctions change what can be estimated, what can be imputed, and what the result is allowed to mean (Aalen et al., 2008).

A pain report after the qualifying stream has irreversibly ended is not a hidden value awaiting imputation; it is undefined for that target. A later wearable signal from the body is not automatically a continuation of the lived stream. The endpoint changes the ontology of the measurement, not merely its availability.

Because the endpoint is central, post-endpoint imputation can manufacture concentration. Carrying forward calm after the stream has ended or dropping participants who die before a later window answers a different question and may introduce survivor bias. Neither operation is ordinary missing-data repair.

The analysis should therefore define post-terminal outcomes explicitly as undefined, use terminal-event models where appropriate, and report which estimands are restricted to survivors. The word survivor should appear in the result if survival is part of the estimand.

Truncation can still permit meaningful inference. The study may estimate time-to-terminal event, preterminal trajectory, terminal-window residuals, or nonterminal events before death. It simply may not fill nonexisting outcomes with numerical convenience.

The local rule is blunt: after the endpoint, do not impute the stream. Model what existed before the endpoint and label what became undefined.

24.5.2 — Terminal and Nonterminal Events

A terminal event ends the target process for the stream. A nonterminal event occurs within the process and may affect later observations or terminal risk. Examples include care transitions, distress episodes, delirium onset, sedation changes, family interviews, or device removal before the endpoint (Andersen et al., 1993; Rizopoulos, 2012).

A semi-competing-risk formulation is appropriate when the nonterminal event can occur before the terminal event, but the terminal event precludes its later occurrence. That asymmetry must be justified for the selected events. An experiential report may become undefined after a qualified stream endpoint, whereas a device removal or administrative record can still occur afterward and needs a different event definition.

For Law-of-Fairness research, the nonterminal event may be scientifically interesting. A medication change, reported dream, agitation episode, or family visit may be related to subsequent measured residuals or endpoint timing. For an event genuinely precluded by the qualified stream endpoint, its post-endpoint occurrence is undefined, not merely censored. Family visits and bodily or administrative care events require their own event definitions because they may continue after a stream endpoint.

The analysis should model terminal and nonterminal events jointly when their dependence matters. A simple cause-specific hazard may condition on survival in a way that changes the target population over time. The estimand must say whether it concerns all enrolled persons, survivors to a time, or principal strata defined by potential survival.

Endpoint independence remains essential. The terminal event must be adjudicated through prospectively specified consciousness or unity rules, not through the ledger residual. Otherwise the event process and the outcome process become algebraically entangled.

The section asks the reader to see time-to-event structure as part of fairness science. If the event structure is wrong, the measured terminal pattern may be an artifact of who remained available to show it.

24.5.3 — Survivor Average Causal Effects

Survivor average causal effects compare outcomes within the principal stratum that would survive under each relevant treatment condition. They can be scientifically useful, but

survival is post-treatment and membership in that stratum is generally unobserved, so identification requires strong assumptions (Frangakis & Rubin, 2002; Zhang & Rubin, 2003).

In a terminal or severe-illness setting, survivor-only comparisons are tempting. Analysts may compare residuals among those who survive to a window because those are the people with observed data. But surviving to that window can be a post-treatment or post-state condition, not a neutral sampling fact.

A survival-conditioned claim must say which survivor population it targets. Is it the observed survivors under realized treatment, the always-survivor principal stratum that would survive under both treatment and control, or a survivor population under a specified care regime? These are different estimands with different assumptions; only the always-survivor contrast is the conventional survivor average causal effect.

When observation is available only for participants stable enough to be measured, report that selected reference class and evaluate how earlier endpoints, sudden deterioration, and distress affect inclusion.

Strong assumptions may be defensible in some designs, especially with randomized interventions, rich covariates, or credible principal-stratum reasoning. But the assumptions should be printed and sensitivity-tested. They should not be hidden under a regression label.

The survivor average rule is that survival-conditioned estimands are allowed only when named. If survival defines the denominator, the conclusion must carry it in plain language.

24.5.4 — Composite Outcomes and Their Costs

Composite outcomes combine several events or measurements into one endpoint. They can be useful when no single outcome captures the scientific question, but they are dangerous when death, comfort, measurement, and residual burden are merged into a favorable score (Tsiatis, 2006; Aalen et al., 2008).

A composite might combine survival, symptom relief, terminal residual, and observation completion. Such a composite may look efficient, but it can hide the meaning of each component. Longer survival with higher distress, shorter survival with better comfort, and no observation because of care protection are not interchangeable units.

For this book, a composite outcome must never turn death or suffering into a point value that appears to balance another component. It may be a technical summary for a stated estimand, but each component must remain visible. The composite cannot be used to suggest that one person's burden has been paid by another value.

Composite outcomes also risk ranking sites or persons. A site with high completion may look better than a site that suspended measurement for comfort. A person with a favorable composite may not have had a better lived experience. The composite is a research object, not a moral object.

The safe design is to report components beside the composite. If the composite result is favorable but components disagree, the conclusion should narrow. If death dominates the composite, the

report should state that clearly rather than presenting the composite as a neutral endpoint.

Composite outcomes cannot rescue an adverse component by averaging it with easier signals. Components, directions, transformations, and weights must be frozen, and the report should show the component-level estimates beside the composite. When one prerequisite fails, a favorable total remains descriptive rather than confirmatory.

24.5.5 — Joint Longitudinal–Event Models

Joint longitudinal-event models connect repeated measures with event processes when both share latent factors. Here they represent dependence among measured burden, observation availability, care transitions, and terminal events (Aalen et al., 2008).

A shared state can link a measured residual to event hazard and reduce bias from informative dropout, but it also exposes the assumptions producing that adjustment.

Clinical, unity, and care variables may inform the event model, with endpoint adjudication specified independently of the tested ledger estimator.

Joint models depend on distributional form, shared effects, and measurement quality. Predictive checks and sensitivity analysis are required because a wrong model can adjust confidently for the wrong reason.

The report names the longitudinal and event submodels, shared dependence, observation process, and endpoint channel, then

shows how conclusions change across plausible dependence structures.

24.5.6 — Competing Endpoint Definitions

Endpoint rules may diverge when consciousness, unity, irreversibility, clinical status, and observation windows do not align. Sensitivity to adjudication therefore belongs in the analysis, with each candidate rule kept independent of the ledger and any alternatives for unity threshold, sustained loss, return, or resuscitation prespecified (Andersen et al., 1993; Rizopoulos, 2012).

Declare the primary endpoint rule and all sensitivity rules before outcome inspection. Report how each rule changes the estimand, equivalence assessment, missingness treatment, and event model; if a conclusion survives only one fragile definition, narrow the claim rather than treating the result as endpoint-robust. Sudden or low-signal endings may support only No adequate estimate or a sensitivity bound.

Endpoint sensitivity also protects participants and families by preventing retrospective claims about ambiguous inner life. Stress-test plausible endpoint rules and preserve disagreement when it remains; never choose or revise an endpoint definition merely to rescue a conclusion.

24.6 — Sensitivity and Partial Identification

Sensitivity analysis asks which conclusion depends on which unverified assumption. It should vary origin, missingness, endpoint, observation, transport, model family, prior, and measured-to-latent bridge within prospectively justified ranges rather than scatter arbitrary alternatives around the preferred estimate.

Partial identification reports the set of target values consistent with the observed data and declared assumptions. The set may be scientifically decisive, unresolved, or too broad for a trustworthy estimate. Its width is information, not a defect to hide.

Robustness is a disciplined map rather than a victory word. Within-dataset robustness can strengthen a result, but replication, transport, and model recovery remain separate tasks owned by later chapters.

A sensitivity analysis should feel like turning the lights on in different corners of the same room. It asks whether the conclusion lives only in one preferred arrangement of priors, windows, missingness assumptions, endpoint rules, and measurement-error bounds. If the result disappears when a plausible lamp moves, the report should say so.

Bayesian workflow is valuable here because it treats modeling as a sequence of choices, checks, revisions, and predictive challenges. But the chapter refuses to let Bayesian language become a softer route to certainty. A posterior distribution is a conditional object. Its authority depends on model adequacy and the assumptions used to build it.

Posterior predictive checks can compare the model with endpoint missingness, site variability, and the terminal residual distribution. Discrepancies identify which parts of the observation or outcome model need refinement.

Robustness should therefore be reported as a map, not a trophy. A result may be robust to priors and fragile to missingness, stable across windows and unstable across measurement-error bounds, or predictive for one site and broken in another. The chapter gives those combinations language so the result does not collapse into a single comforting word.

Equation 24.7 (role: Bayesian companion)

$$p(\theta|y, M) \propto p(y|\theta, M)p(\theta|M)$$

Equation 24.8 (role: posterior predictive check)

$$\mathfrak{y} \sim p(\mathfrak{y}|y, M), \text{ compare } D(\mathfrak{y}) \text{ with } D(y)$$

Table 24.4. Sensitivity grid for Chapter 24 inference.

Sensitivity axis	Example variation	Claim-status effect
Prior	Skeptical, weakly informative, broad, site-informed.	Shows prior dependence.
Model space	Missingness model, endpoint model, site hierarchy, smoother.	Shows structural dependence.
Window	48 hours, 7 days, 30 days, reserve-time clock.	Shows alignment dependence.
Measurement error	Noise floor, bias bound, sign, origin, calibration.	Shows transfer dependence.

Sensitivity axis	Example variation	Claim-status effect
Predictive adequacy	Residual distribution, missingness, site effects, event timing.	Shows model failure or adequacy.

24.6.1 — Prior Sensitivity

A prior encodes assumptions before the data are analyzed. In a high-stakes claim, prior sensitivity is not optional. It shows whether the posterior conclusion is driven mainly by data, by prior structure, or by a combination that should be disclosed (Gelman et al., 2013; Gelman et al., 2020).

For terminal residuals, plausible priors might represent skepticism about large effects, uncertainty about direction, known measurement noise, or prior evidence from earlier cohorts. A prior that effectively forces residuals toward zero would be unsafe unless justified as part of a rival or calibration model rather than as a PTVC-favoring assumption.

A prior sensitivity report should include at least weakly informative, skeptical, and broader alternatives when feasible. It should show whether equivalence, latent-transfer bounds, and missingness sensitivity survive. If only the PTVC-favoring prior yields support, the conclusion is not stable.

Prior sensitivity also belongs to model components. Priors on missingness dependence, calibration error, endpoint uncertainty, site variance, and measurement-error bounds can influence the conclusion. Reporting only the prior on the main residual is too narrow.

The analysis should not treat a skeptical prior as hostility or a favorable prior as confidence. Priors are scientific commitments, not loyalties. The role of the companion analysis is to reveal how much those commitments matter.

Prior sensitivity should display how the posterior decision changes across a defensible, prospectively named family of priors. Selecting the prior that makes the candidate look stable after inspection is not robustness. A conclusion that crosses decision regions across plausible priors is reported as prior-sensitive.

24.6.2 — Model-Space Sensitivity

Model-space sensitivity asks what happens when the analyst changes the family of models rather than only parameter values. A result can be robust within one class and fragile across plausible alternatives (Rosenbaum, 2002; Gelman et al., 2013).

Model-space sensitivity asks how the conclusion changes when plausible observation models, missingness structures, endpoint windows, calibration hierarchies, latent-transfer assumptions, site effects, or nonparametric smoothers enter or leave the analysis. The full generative rival library comes next; the inferential consequence of model uncertainty belongs here.

A common failure is to call the preferred model primary and relegate alternatives to vague checks. A serious plan names which alternatives would change the claim status. For example, if a pattern-mixture model with plausible distress-linked missingness erases equivalence, the primary result becomes conditional and fragile.

Model-space sensitivity is also where elegance can mislead. A simpler model may look crude but reveal that the data cannot support the preferred structure. A flexible model may fit well but absorb the signal into smoothness or random effects. The report should describe what each model is allowed to explain.

The analysis may use model averaging or ensemble summaries when justified, but it should not average incompatible estimands. If models answer different questions, their outputs should be displayed side by side rather than compressed into one number.

The practical outcome is a model-space map: which conclusions survive, which narrow, which reverse, and which become No adequate estimate.

24.6.3 — Window and Alignment Sensitivity

Window and alignment choices can produce apparent terminal signatures. A seven-day window, a forty-eight-hour window, an endpoint-aligned retrospective window, and a prospectively defined low-signal window may show different results. The analysis must test whether the conclusion depends on that choice (Gelman et al., 2013).

This is not a cosmetic issue. In end-of-life data, the last observable window may differ from the last experiential window, the last clinical window, and the endpoint-adjudication window. Aligning everyone to death can create compression by construction if observation fades near the endpoint.

A sensitivity plan should vary window length, alignment clock, inclusion of low-signal intervals, and endpoint adjudication. It should also distinguish calendar time from reserve time, illness

stage, care transition time, and observation time. Each clock can create a different pattern.

The result should be displayed as a window sensitivity surface or table. A signature that appears only under one retrospectively chosen window is weak. A signature that appears across prespecified windows and remains under rival observation models is stronger, though still conditional.

Window sensitivity can also identify design failure. If the necessary cadence was too sparse for the target dynamics, no clever window can recover the path. The report should say that the design could not support the estimand rather than searching for a favorable alignment.

A terminal-window result belongs to the window that produced it. It may travel only through declared sensitivity, not through narrative momentum.

24.6.4 — Measurement-Error Sensitivity

Measurement-error sensitivity asks how conclusions change when noise floor, calibration, sign, origin, and channel reliability vary within plausible ranges. It is the direct companion to measured-to-latent bias transfer (Carroll et al., 2006; Manski, 2003).

The analysis should vary both random error and systematic error. Random error can increase uncertainty and, in nonlinear transformations or models with error-prone predictors, can also induce bias. Systematic error can displace an estimate from its target. Sign error can reverse contribution. Origin error can change whether a residual lies inside K . These errors have

different effects and should not be collapsed into one vague uncertainty term.

A physiological channel illustrates the problem. A wearable-derived arousal estimate may become less reliable during edema, movement, low perfusion, or medication changes. If those conditions occur near the endpoint, measurement error is time-varying and informative. A constant noise model may understate the uncertainty exactly where it matters most.

Measurement-error sensitivity should therefore be channel-specific when possible. Self-report, physiology, clinician notes, family reports, sleep traces, and passive signals each carry different failure modes. A composite estimate is only as trustworthy as its error propagation.

The conclusion should state the largest measurement-error range under which equivalence, defeat, or inconclusive status remains. If a modest noise-floor adjustment changes the claim, the result is fragile. If sign uncertainty makes the estimate uninterpretable, the report should not hide that under a composite score.

Robust exclusion requires a residual set that contains every possibility allowed by the independently justified measurement and bridge assumptions. Fix the admissible configuration family G before inspecting the outcome. Each configuration specifies the origin, representation, exposure, stream routing, endpoint, observation relation and missing-history assumptions. Let $R(g)$ be its compatible terminal residual set, constructed without imposing closure, and let $s(g) > 0$ be an independently specified quantity with residual units. Define

$$\mathcal{R}_{\text{rob}} = \bigcup_{g \in G} \{r/s(g) : r \in R(g)\}, \quad d = \inf_{x \in \mathcal{R}_{\text{rob}}} |x|.$$

For a nonempty union, $d > 0$ excludes zero under every admitted configuration and is invariant to a positive change of units. Positive distance is sufficient, not necessary: the set $(0,1)$ excludes zero while having distance zero. An empty union indicates incompatible assumptions or observations; it cannot provide a truth-containing exclusion. A union containing zero establishes compatibility.

A numerical example shows why unknown history matters. A current residual interval $[8,10]$ and a bound $[-5,4]$ on the entire remaining signed contribution imply the terminal outer interval $[3,14]$. Additional unresolved prefix uncertainty $[-4,4]$ enlarges it to $[-1,18]$, removing the exclusion. These are synthetic units. Bounds on observed late experience cannot silently replace bounds on the complete prefix.

Statistical exclusion requires coverage under every admitted null law. Let $\mathcal{P}_0$ be the declared family of observation and nuisance laws under which the tested stream closes exactly, and let C_α be the projected residual confidence set. The required guarantee is

$$\inf_{P \in \mathcal{P}_0} P\{0 \in C_\alpha\} \geq 1 - \alpha$$

implies

$$\sup_{P \in \mathcal{P}_0} P\{0 \notin C_\alpha\} \leq \alpha.$$

A joint confidence region provides this protection when its coverage is established uniformly over the admitted null configurations. Marginal coverage across a mixture of zero and

nonzero residuals does not establish coverage conditional on the residual being zero. Repeated searches across streams or analysis times require a corresponding simultaneous guarantee.

An observed endpoint can carry its own explicit error budget. Over a fixed finite horizon, suppose a simultaneous interval band covers the complete pre-endpoint ledger with failure probability at most α , and an independently qualified endpoint rule matches the true endpoint and timing convention with failure probability at most β . If the tested branch permits true off-band completion within that horizon with probability at most ϵ , an observed endpoint whose entire nonempty residual interval lies outside the declared band has probability at most $\min\{1, \epsilon + \alpha + \beta\}$. This follows by the union bound and needs no independence between these errors. Timing uncertainty requires taking the union over all admitted endpoint times; missing-prefix uncertainty remains inside the band. The exact probability-one target sets ϵ and its theoretical residual tolerance to zero, while the empirical certificate retains its declared error probabilities.

24.6.5 — Posterior Predictive Checks

Posterior predictive checks ask whether the fitted model can generate data resembling the observed data in the ways that matter for the estimand. They are not a decorative plot. They test whether the model that produced the posterior can reproduce the observed structure it claims to explain (Gelman et al., 2013; Gelman et al., 2020).

Relevant checks include terminal residuals, preterminal variance, missingness, observation intensity, endpoint timing, site

heterogeneity, device dropout, and within-person dependence. A model fitting the mean but missing the observation process is inadequate.

Choose checks before interpreting results. Flexible analysis can always find an acceptable feature. The protocol names discrepancies that weaken or invalidate the model, including failure to reproduce observed endpoint dropout or terminal concentration.

Posterior predictive checks can also protect against false elegance. A model with a beautiful latent curve may generate data that do not resemble actual reports, device gaps, or event timing. The graph then serves the reader better than the curve.

The check should not be judged by visual comfort alone. Whenever possible, use discrepancy measures tied to the estimand and rival predictions. The graph should teach the model's failure or adequacy, not decorate the chapter.

24.6.6 — Robustness Is Not Replication

Robustness means a conclusion survives variations within a dataset or workflow; replication means it appears in new data under governed conditions. A result can withstand many modeling choices in one biased dataset yet fail elsewhere (Rosenbaum, 2002; Gelman et al., 2013).

Within-dataset robustness evaluates sensitivity to priors, windows, calibration, and missingness assumptions. Replication extends the test to new sites, devices, cultures, diagnoses, or endpoint regimes.

A robustness summary should identify the dataset, measured residuals, analyses, and assumptions that produced stable conclusions. Readers can then assess exactly which features were examined.

Correlated choices can manufacture robustness. Analyses sharing a missingness assumption, calibration, or endpoint alignment may look diverse while protecting one weakness. The sensitivity grid should identify those dependencies.

A strong report states what robustness covers and leaves untouched: for example, that measured equivalence was robust to prior and window variation but not nonignorable missingness. This is more trustworthy than a broad claim.

A replication needs a clear account of what is being repeated. The protocol should identify the target quantity, the claimed signature, and the conditions under which the original explanation should still apply. Changes in recruitment, measurement, or endpoint adjudication belong in that account. Readers can then assess whether a disagreement challenges the original result or reflects a difference between the questions the studies actually addressed.

New participants do not make every source of error independent. Two sites may inherit the same device calibration, scoring code, or stopping convention, allowing a shared artifact to recur. A useful replication therefore examines which vulnerabilities remain shared and introduces independent checks where feasible. For a terminal signature, this might include endpoint adjudication that does not depend on the measurements used to estimate the signature.

When studies disagree, the size and precision of their estimates determine what the disagreement means. A precise result incompatible with the original effect poses a different problem from a wide interval that leaves both the effect and its absence plausible. Differences in measurement or participant selection may suggest a narrower explanation, which then requires its own prospective test. The disagreement becomes useful when it identifies what evidence could resolve it.

24.7 — Sequential Evidence and Optional Stopping

Sequential evidence permits learning while data accumulate, but only under an explicit process. E-values, e-processes, alpha-spending, group-sequential plans, or Bayesian monitoring retain their guarantee for the exact protocol-fixed null, filtration, stopping permissions, and model assumptions to which they were attached (O’Brien & Fleming, 1979; Pocock, 1977; Ramdas et al., 2022).

Optional stopping is not one behavior. A planned stopping rule inside a valid sequential design differs from unrecorded peeking, repeated model revision, selective endpoint choice, or publication after a favorable crossing. The audit must distinguish them.

Anytime-valid tools can help when their conditions are met. They do not remove the need for estimands, missingness models, endpoint firewalls, or human review. They only provide a mathematical route for error control under declared sampling rules.

Sequential evidence is attractive because the program will learn over time. New cohorts, sites, endpoint adjudications, and device versions may arrive gradually. The scientific community will want to know whether the evidence is moving. The danger is that repeated looks can turn patience into a false positive machine.

Anytime-valid methods are therefore useful only if they are declared before the first look and matched to the sampling scheme. An e-process built for independent site releases cannot silently govern adaptive recruitment, delayed endpoints, public-

pressure pauses, or selective data cleaning. The mathematics protects only the process it actually describes.

Sequential updates are deliberately limited to components. A running evidence number may update a measured equivalence claim, a missingness gate, or an observation-model check. It does not update the Law as a public doctrine, authorize applied books, or decide transition language. Component evidence must remain component evidence.

A sequential dashboard can make a conditional statistic look like a verdict. Interim graphics therefore remain inside research governance until claim-status review, public-risk review, and adverse-reporting rules translate the result responsibly.

A public-candidate science program should also declare what happens when sequential validity breaks. If a site adds measurements after seeing early results, if a device version changes midstream, if families decline further observation in a patterned way, or if an endpoint window is revised after interim analysis, the evidence process may no longer carry its promised guarantee. The result may still be useful, but it has to be relabeled.

The chapter therefore treats every interim look as a protocol event. The log should record who looked, what was visible, which analysis was run, whether the threshold was fixed, whether the observation process changed, and what public language was allowed afterward. This is not paperwork for its own sake. It is the memory that prevents a research program from forgetting how it persuaded itself.

Sequential learning also sharpens the difference between program governance and public meaning. Investigators may need to decide whether to expand a study, pause a site, fix a measurement process, or commission a replication. Those are research decisions. They are not social verdicts, spiritual messages, legal instructions, or transition signals.

The strongest use of sequential evidence is often conservative. It can stop a weak claim earlier, reveal that the observation process is unstable, or show that a favorable component depends on one site. A threshold that is never crossed may still save the project from a premature public story. Learning early that the evidence is insufficient is not a failure of science; it is one of science's duties.

Equation 24.9 (role: e-process expectation condition)

$$E_t \geq 0, E_0[E_\tau] \leq 1 \text{ for allowed } \tau$$

Equation 24.10 (role: anytime-valid error control)

$$P_0 \left(\sup_t E_t \geq 1/\alpha \right) \leq \alpha$$

24.7.1 — E-Process Definition

An e-process is a nonnegative evidence process constructed so that, under every distribution in the protocol-fixed null class, its expectation remains controlled at each allowed bounded or stopping time, subject to the stated conditions. It permits evidence to accumulate without treating every look as a fresh uncorrected test (Howard et al., 2021).

State the e-process guarantee for its exact null hypothesis, filtration, and allowed stopping times. New estimands or transport claims require a corresponding construction and justification.

The evidence-process construction, including any permitted adaptation rule, must be specified before the data it evaluates are reviewed. Predictable updates may use past observations to choose future bets when the declared null and filtration guarantee remains valid. Selecting favorable transformations of already observed evidence does not establish an e-process.

E-processes can be especially useful for long programs that add sites gradually. The program may continue recruiting until the evidence crosses a threshold, provided the process is valid for the dependence, sampling, and updating scheme actually used. That validity is the central issue.

Attach the evidence value to its tested component and declared null. Human reviewers use that result in the governed claim-status decision.

An e-process must be constructed so that its expectation is controlled under the protocol-fixed null at every allowed stopping time. The filtration, betting strategy, update rule, and decision boundary therefore belong in the protocol. Optional continuation remains statistically valid at stopping times covered by that guarantee, including data-dependent rules not fixed in advance. Protocol requirements still apply, and optional stopping does not license retrospective changes to the null, evidence process, or error threshold.

24.7.2 — Allowed Stopping Times

A stopping rule is compatible with an e-process when it uses the declared filtration and lies within the process's stopping-time guarantee. An unplanned look or a decision influenced by public

pressure does not, by itself, invalidate an anytime-valid e-process. Retrospective changes to the null, evidence construction, threshold, or data-selection mechanism can invalidate the guarantee. Statistical validity and compliance with the study's governance rules should be audited separately (Ramdas et al., 2022; Howard et al., 2021).

In a rolling research program, stopping may occur because a threshold is crossed, a safety issue appears, a site fails, funding pauses, or endpoint adjudication problems accumulate. Not all stopping rules have the same inferential meaning. Some preserve validity; others require the result to be relabeled.

The protocol should specify allowed looks and allowed stopping reasons. It should also specify what happens when stopping occurs for ethical or operational reasons unrelated to the evidence threshold. Care-based stopping is legitimate, but it may produce No adequate estimate or a conditional estimate rather than a clean sequential verdict.

A hidden stopping problem can arise when public attention affects the analysis. If interim results are informally discussed, thresholds moved, or new analyses added after favorable signs appear, the mathematical process no longer carries its original warrant.

Allowed stopping also depends on missingness and dependence. If site releases are delayed because data look unfavorable or because measurement failed in specific states, the sequence is not a neutral stream of looks. The evidence process must match that adaptive sampling.

Stopping is not only a time on a calendar. It is part of the statistical design, the ethical design, and the public claim-status design.

24.7.3 — Threshold and Error Control

Sequential thresholds translate an evidence process into an error-control rule. A common form is a threshold such as one over alpha: crossing it can justify rejection of the specified null with controlled type I error under the process assumptions (Howard et al., 2021).

The threshold must be declared before data arrive. Moving the threshold after public excitement, donor pressure, or early favorable signals destroys the integrity of the result. A threshold is a promise about how difficult the claim will be to make.

The error rate attaches to the tested null, not to every sentence that might be written afterward. If the process rejects a null about a measured residual in one reference class, it does not reject rival models, latent transfer uncertainty, cross-species scope, or the strong form. The conclusion must stay inside the mathematical event.

Non-crossing also requires a declared interpretation. Depending on the process and design, it may be inconclusive, may count against the alternative, or may show only that information remains insufficient. It cannot be translated into convenient ambiguity after the result.

Thresholds can be too lenient or too severe for the public stakes. A publish-candidate science program should choose thresholds with prospectively specified justification, safety review, and public communication review. The aim is durable error control.

Print the threshold, alpha, stopping plan, and component claim in the same reporting block so the decision remains interpretable.

24.7.4 — Dependence and Adaptive Data

Sequential validity depends on the actual data-generating and sampling scheme. Person-level observations are dependent. Sites may share training, devices, protocols, and culture. Interim results may change future recruitment, measurement, and analysis. These dependencies matter (Howard et al., 2021; Ramdas et al., 2022).

A process built for independent increments cannot be trusted if the next site is selected because the previous site looked favorable. A process built for fixed observation windows may fail if windows are extended after early patterns appear. A process built for stable devices may fail after version changes.

The analysis plan should therefore state dependence assumptions. It should say whether looks are by participant, by site, by endpoint-window batch, by device version, or by calendar release. It should say how clustering, site correlation, adaptive recruitment, and delayed endpoints are handled.

Adaptive data are not always illegitimate. A study may adapt ethically to reduce participant burden, pause a high-burden channel, or oversample an underrepresented group. But adaptation must be modeled or separated from confirmatory inference. Otherwise care improvements and evidence claims become entangled.

Dependence can also arise through public communication. If public preliminary claims alter participant behavior, site recruitment, or clinician documentation, the evidence stream has

changed. That risk belongs in governance, but it has statistical consequences here.

Adaptive and dependent data require validity under the actual filtration, not an unspoken independence approximation. Repeated measures, site clustering, adaptive enrollment, and data-dependent actions must enter the e-process or sequential design explicitly. When that guarantee is unavailable, the sequential number is descriptive rather than decision-valid.

24.7.5 — Evidence for Components, Not Canon

Sequential evidence can update a component claim. It cannot update the canon as a whole by itself. This distinction protects the series from treating a mathematical crossing as public validation of the Law, religious doctrine, civic design, legal architecture, or transition readiness (Ramdas et al., 2022).

A component might be a measured equivalence result in a terminal-window estimator, a missingness sensitivity threshold, a site-calibration success, or an observation-model check. Each component has a defined null, reference class, and inference route. The canon has many more gates.

The report should say exactly what changed. A sequential analysis may move a component from inconclusive to supported, from supported to fragile, or from plausible to defeated. It may not say that the Law has been scientifically validated unless the broader verdict system later determines that status.

This protects skeptics and supporters alike. Skeptics can see that evidence is not being exaggerated. Supporters can understand that progress is real even when narrow. A narrow component update

may be scientifically valuable without becoming a public proclamation.

The section also prevents dashboard pressure. A running number can excite people because it feels like the theory is moving toward victory. Readers should be trained to ask which component the number concerns and which gates remain closed.

Sequential evidence updates the component whose null and process were specified in the protocol. The public record identifies that component, the resulting evidence, and the prerequisites for its next use.

24.7.6 — No Dashboard Deciding Status

A dashboard can make evidence look more authoritative than the evidence is. A line rising over time, a green threshold, or a public status badge can compress estimand, missingness, endpoint, bias, sensitivity, and review into a single visual cue. That compression is dangerous for this book (Howard et al., 2021).

The chapter does not forbid internal monitoring. Researchers may need dashboards for data quality, safety, missingness, accrual, calibration, and sequential evidence. The rule is that dashboards are operational tools, not public verdict engines.

A public dashboard would be especially risky if it displayed a running probability, evidence ratio, or equivalence status without the assumptions beside it. Readers might interpret the number as proof, moral meaning, or permission to apply the Law in ordinary life. That would violate the science book's authority boundary.

Human review must remain above the number. A committee must examine endpoint independence, data quality, missingness, measurement burden, adverse findings, public-risk wording, and rival implications before any status language changes. The dashboard can alert; it cannot decide.

This rule also protects participants and sites. No person, family, clinician, site, or culture should be placed under public suspicion because a data-quality or evidence metric looks unfavorable. Research metrics stay inside the research governance architecture.

The section ends with a design rule: sequential graphics may be beautiful, but their captions must make them humble. A running number is a witness to a component, not a judge of the Law.

24.8 — Open-Set and Protected-Theory Risk

Model ambiguity occurs when a valid protected comparison leaves models indistinguishable at the declared resolution, uncertainty crosses decision boundaries, or defensible analyses favor different models. A pipeline that misses its required recovery thresholds instead remains unqualified for the affected confirmatory comparison.

Open-set inadequacy is different: every named model may be wrong or unable to reproduce the data-generating features that matter. The correct result is Open-set inadequate or No adequate estimate, not victory for the least bad candidate.

Protected-theory risk appears when flexibility is asymmetric. If PTVC can change endpoint, representation, route, or interpretation after each failure while rivals remain frozen, the comparison cannot generate adverse evidence. Change control must therefore apply to the preferred model at least as strictly as to its competitors.

The final section gives the program a vocabulary for not forcing a result. This is harder than it sounds because every ambitious theory creates pressure to show progress. A dataset with endpoint problems, missingness failure, unbounded bias, or flexible analysis can still be made to produce a number. The chapter asks whether that number deserves to exist.

Use the canonical evidence-state definitions in §24.2 and Table 27.5. In this section, the added question is whether open-set inadequacy or analytic flexibility prevents the model space from supporting a stronger verdict.

Public summaries should use the study's recorded status and explain the next decision. An unresolved endpoint, wide interval, or missingness problem can be reported clearly as a specific research question.

Chapter 25 extends the inference workflow through simulated worlds, model recovery, and adversarial tests. Those exercises assess whether the analysis recognizes the conditions under which its conclusions hold and identifies the changes needed when they do not.

Table 24.5. Verdict labels for inference under uncertainty.

Label	Use when	Public-language rule
Supported component	Estimand, band, bias, missingness, endpoint, and sensitivity gates pass, and the prespecified evidential criterion is met for the defined component.	Name the component and reference class.
Inconclusive	Valid analysis does not resolve the estimand.	No trend language that sounds supportive.
Unusable	Protocol, consent, endpoint, measurement, or provenance gate failed.	Do not report as evidence for the claim.
No adequate estimate	Target is undefined or cannot be bounded.	Say No adequate estimate rather than force a number.

Label	Use when	Public-language rule
Narrowing	Only a smaller reference class or weaker claim survives.	Update scope explicitly.
Defeat pressure	A valid adverse result or rival-sensitive failure remains.	Report the pressure and route to Chapter 27 verdict language.

24.8.1 — Inconclusive Evidence

Inconclusive evidence means the analysis was valid enough to run but did not decide the target question. The interval may be too wide, the signatures mixed, the sensitivity range too large, or the rival comparison nondiscriminating. Inconclusive is not failure; it is a defined scientific state (Popper, 1959).

A terminal-window equivalence test can be inconclusive when the confidence interval crosses the equivalence band. A Bayesian companion can be inconclusive when posterior mass depends strongly on plausible priors. A missingness analysis can be inconclusive when sensitivity spans both support and defeat.

An inconclusive report states that the valid analysis did not resolve the named estimand at the declared precision or decision threshold, and identifies what additional information could resolve it.

Inconclusive evidence can still guide design. It may show that cadence needs improvement, bias bounds are too wide, endpoint windows are poorly aligned, or the reference class is too heterogeneous. Those findings identify concrete improvements for the next study.

A clear label protects readers from overinterpreting ambiguity. It also protects critics from being told that lack of defeat counts as favor. The claim remains where it was before the analysis, perhaps with better knowledge of what must be improved.

Evidence remains inconclusive when a valid uncertainty set overlaps both the protocol-fixed acceptance region and its complement. The report identifies the dominant uncertainty and which additional observation, if any, could change the status rather than choosing the side with the more attractive point estimate.

24.8.2 — Unusable Evidence

Unusable evidence identifies a failed condition required for the affected analysis, such as consent, endpoint adjudication, measurement integrity, calibration, missingness documentation, protocol adherence, provenance, or participant protection. The record names that condition and the analyses it prevents (Lakatos, 1978; Stanford, 2006).

A dataset can be unusable even if it is large. If endpoint rules were changed after results were seen, if key missingness categories were not recorded, if devices changed without version tracking, or if participants were observed under an unduly burdensome protocol that violated design limits, the analysis may not be allowed to speak.

Unusable status should be declared at the level of the affected estimand. A site may be unusable for latent transfer but usable for device-quality lessons. A terminal window may be unusable for

equivalence but usable for missingness-rate reporting. Precision in failure preserves what can still be learned.

This label also protects people. If data were collected under consent ambiguity or excessive burden, the response is not to squeeze a result from them. The research-use firewall requires that ethically compromised evidence not be redeemed by scientific convenience.

Unusable evidence should trigger repair, not concealment. The report should state the failure condition, affected estimands, corrective action, and whether future use is prohibited, restricted, or possible under new governance.

No result is too valuable to be unusable. If the gate failed, the chapter refuses the number.

24.8.3 — Researcher Degrees of Freedom

Researcher degrees of freedom are the choices that can be varied during analysis: windows, exclusions, transformations, priors, covariates, endpoint definitions, missingness models, calibration rules, and outcome definitions. These choices are unavoidable, but they become dangerous when they are flexible after results are visible (Stanford, 2006).

For the Law, flexible windows and endpoint definitions are especially risky. A researcher can align to an endpoint, choose a preterminal window, exclude low-signal cases, adjust missingness, and transform the residual until the result looks orderly. The analysis may feel scientific while the theory is protected by choice.

The answer is prospective specification, version control, blinded analysis where possible, and transparent multiverse reporting. Not every choice can be fixed in advance, but exploratory choices must be labeled exploratory and kept out of confirmatory claim status.

A degrees-of-freedom audit should list every choice that could plausibly change the result. It should report which were fixed before data, which were adapted under blinded rules, which were exploratory, and which were triggered by observed outcomes. The reader should see the analytic path.

This audit also helps distinguish creativity from rescue. Exploratory analysis can generate new hypotheses and better designs. It becomes protected theory when exploratory findings are presented as if they were prospectively specified tests.

24.8.4 — Statistical Elegance as Rescue

Statistical elegance can rescue a theory from visible failure by making the rescue look sophisticated. A latent model with many layers, a flexible prior, a smoothing process, a hidden-state structure, or a complex missingness correction may preserve a favored conclusion while adding little predictive or discriminating value (Popper, 1959).

The chapter does not reject complexity. Some questions here require complex models. It rejects complexity that enters only after simpler analyses become unfavorable and then fails to improve prediction, model recovery, calibration, or rival discrimination.

An elegant rescue often has a signature: the model explains away adverse cases, expands uncertainty selectively, moves the endpoint window, or shifts the latent scale while keeping the final sentence favorable. The output may be polished, but the theory has become harder to lose.

The antidote is a burden of improvement. A more complex analysis must state what it explains that the simpler analysis could not, what predictions improve, what assumptions it adds, and what result would make it fail. If those answers are absent, the model should not upgrade claim status.

This is where humility becomes technical. The analyst should be willing to say that the elegant model is exploratory, that it suggests a new study, or that it did not rescue the primary result. The chapter makes that sentence honorable.

Statistical sophistication cannot repair target, observation, or identification failure. A more elaborate estimator earns a role only when it answers the same estimand, improves calibrated performance, and survives the protocol-fixed diagnostics. Otherwise elegance changes the machinery without strengthening the inference.

24.8.5 — No-Estimate Route

Apply §24.2's No adequate estimate rule and Table 27.5's evidence states. In protected-theory analysis, prespecify the abstention branch in the analysis plan, results template, and public-status map so nonidentification or a failed required gate cannot be repaired into a favorable result after inspection.

24.8.6 — Transparent Adverse Reporting

Transparent adverse reporting means publishing the assumptions that failed, the analyses that contradicted the preferred direction, the sensitivity ranges that weakened the result, and the rival interpretations that remained viable. It is the opposite of burying bad news inside supplemental uncertainty (Lakatos, 1978; Stanford, 2006). Each adverse finding should be tied to the exact model, analysis version, reference class, and decision it changes, so later investigators can distinguish a failed claim from a failed implementation.

Adverse reporting includes failed equivalence, nonsignificant but inconclusive results, unbounded transfer bias, missingness defeat, endpoint sensitivity failure, posterior predictive failure, and protected-theory audit findings. Each remains visible enough for an outside statistician to reproduce the status decision. The record should also identify the affected component, the diagnostic or threshold that triggered the adverse status, and the downstream claims that lose permission as a result.

Adverse reporting protects the entire series. If the science book hides adverse findings, applied books will inherit false confidence. If it publishes them clearly, applied domains can remain conditional and honest. Scientific loss becomes a form of public care. This propagation discipline also lets an applied domain preserve practices supported on independent grounds while withdrawing only the scientific authority that actually changed.

The report should not dramatize defeat. It should state what failed, what remains learned, what claim status changes, and what future design would be required. A sober adverse report is stronger than a defensive favorable report. The most useful adverse report also ends with a decision consequence, such as replicate, redesign, narrow, suspend, or retire, rather than leaving the reader with a rhetorical verdict.

Transparent adverse reporting also gives critics a real place in the program. A critic who can point to published failed assumptions, rival-sensitive results, and No adequate estimate labels sees a theory that can be challenged. That trust is more valuable than temporary rhetorical victory. Criticism becomes scientifically productive when the record shows not only that an objection was heard, but which test, revision, or status change followed from it.

The chapter closes with analyses that connect conclusions to explicit targets, assumptions, and evidence. Clear results strengthen the next scientific decision, whether they support a model or identify a better direction. The handoff should identify which findings are stable enough to carry forward and which unresolved dependency should determine the next study.

Chapter 25 — Model Recovery and Adversarial Tests

Chapter 25 treats model recovery as a release gate. Before an empirical result can support, narrow, or defeat a component, the full pipeline must recover known generators under realistic observation, missingness, endpoint uncertainty, heterogeneity, and misspecification (Talts et al., 2018; Wilson & Collins, 2019; Schumacher et al., 2025; Säilynoja et al., 2026).

Parameter recovery asks whether the pipeline estimates known parameters. Model recovery asks whether it identifies which generator produced the observations. Calibration asks whether uncertainty statements have their promised behavior. Absolute-fit and open-set checks ask whether any listed model is adequate. These are related but noninterchangeable gates.

Adversarial testing adds a social and procedural layer. Predictions, implementation choices, scoring rules, and theory-discriminating observations are fixed before the protected module. Teams with different commitments share the design and confront the same outcome. The Cogitate collaboration illustrates both the promise and the practical difficulty of that method in consciousness science (Cogitate Consortium et al., 2025).

The benchmark library includes ordinary regulation, learning, conditioning, selection, observation, hidden-state, endpoint, and PTVC-candidate worlds, along with near misses and none-of-the-models generators. This breadth tests the pipeline across realistic and demanding alternatives.

Design separability determines whether the planned sample, cadence, channels, endpoint, and perturbations can distinguish the declared models before participant burden is incurred. A no-study

decision is a successful design outcome when the planned observations cannot buy an identifiable comparison.

Transport stress asks whether recovery and calibration survive changes in site, device, population, prevalence, language, care practice, missingness, and endpoint process. A model that works only in its development environment earns correspondingly narrow status.

Reproducible artifacts connect a published claim to exact code, generator versions, environments, thresholds, and data-access layers. Openness is purpose-limited: synthetic fixtures and public code support criticism without exposing participants or creating a new surveillance surface.

The resulting inference system can refuse false confidence. It can return recovered, nonseparable, Open-set inadequate, Model-ambiguous, No adequate estimate, Route-failed, or Rival-favored outcomes. Each status names a different next step.

Part VII closes by turning criticism into durable infrastructure. A theory exposed to recovery, open-set, transport, and red-team failure becomes easier to correct and more informative under every outcome.

Model comparison can look settled because omission rigged the contest. Excluding the strongest bridge, introducing missingness only after latent paths are generated, reusing development sites for evaluation, or omitting a none-of-the-models branch can manufacture an answer. A credible benchmark records the machinery of loss before it records support.

The previous chapter fixed the inferential objects. This one asks whether executable synthetic worlds and the complete fitting pipeline can recover them. The focus is simulation, calibration, predictive comparison, design separability, adversarial testing, and artifact governance rather than another summary of equivalence or missingness theory.

The computational work serves people. A failed recovery study can prevent an uninformative and burdensome human protocol. A detected endpoint leak can prevent a misleading public figure. A published none-of-the-models result can keep the program from becoming a machine that always produces a preferred story.

The required sequence is now visible: release the benchmark, fit every model to every generator, test separability, admit open-set failure, stress transport, record challenges, and preserve executable provenance. Only then does a confirmatory human study have a defensible analytic foundation.

25.1 — Why Model Recovery Comes First

Model recovery comes first because a pipeline can appear sophisticated while systematically confusing the generators it is meant to compare. A favorable empirical score is uninterpretable when the same analysis would label adaptation, selection, or observation-floor worlds as PTVC candidates (Wilson & Collins, 2019; Schumacher et al., 2025).

The recovery study uses synthetic worlds with known latent states, parameters, observation kernels, endpoints, missingness, and model labels. Analysts receive only the observation layer planned for the empirical study. The hidden answer is revealed after the pipeline produces its verdict.

Parameter recovery, model recovery, calibration, and predictive adequacy are reported separately. A model may be classified correctly while parameters are biased, or parameters may be recovered while the model family is nonseparable. No single accuracy number can replace the full diagnostic.

Equation 25.1, Generative benchmark declaration.

$$G_j: \theta_j \sim p_j(\theta), x \sim p_j(x|\theta_j), y \sim p_j(y|x, \theta_j, \psi)$$

Role label: generator specification. Here G_j is a benchmark world, θ_j are generator parameters, x is the latent trajectory, y is the observed record, and ψ holds observation-system parameters.

Table 25.1. Minimum recovery metrics for every generator and fitted model.

Metric	What is reported	Why it matters
Parameter bias	mean or median recovery error	flags estimates that drift toward the favored model
Interval coverage	coverage of declared credible or confidence intervals	detects overconfidence and undercoverage
Model recovery	selected or weighted fitted model by generator	shows confusion and false classification
False equivalence	equivalence declared although the generating estimand lies outside the specified band	prevents synthetic support from null or artifact worlds
False defeat	target rejected when generator includes it	prevents overzealous rejection under noise
Calibration	probability and interval behavior by state/site/time	finds model confidence that fails where it matters
Convergence and time	diagnostic failures and compute cost	keeps unusable methods from becoming impressive prose

25.1.1 — Parameter Recovery

Parameter recovery is the simplest honest question: when the simulator sets a value, can the analysis estimate it back within declared uncertainty? If the reserve decay rate, OU mean-reversion coefficient, bridge endpoint variance, observation-

shutdown slope, or frailty effect is known inside the synthetic world, the fitted model must recover the value often enough to trust its intervals (Wilson & Collins, 2019).

The method is operational. Draw parameters from realistic distributions, generate latent paths, generate observations with missingness and measurement error, fit the planned model, and compare recovered posteriors or estimates to the known inputs. Bias, coverage, shrinkage, tail behavior, and convergence failures are recorded by generator, site condition, device quality, and endpoint uncertainty.

A concrete example is the additive noise floor. Suppose the simulator sets the true terminal compression exponent and adds a physiological sensor noise floor. If the fitting model underestimates that floor, it may report a shallower exponent, a false lack of compression, or a false equivalence failure. The recovery table must show where the exponent becomes unrecoverable.

Parameter recovery can also expose a Law-friendly bias. If the reserve-coupled candidate recovers its own parameters well but the same fitting machinery misestimates OU or bridge parameters in a way that makes them look PTVC-like, the benchmark has not cleared the gate. The pipeline is learning the preferred story rather than the generating values.

The report should state recovery thresholds before the benchmark is run. A parameter may be considered recoverable only if bias is small relative to the scientific margin, interval coverage is near

the declared level, diagnostics pass, and failures do not concentrate in the terminal window where the claim is sharpest.

The Law of Fairness lens asks where estimation error lands. If a parameter cannot be recovered, the burden should stay with the method and should not be shifted to a participant, a hospice site, a family report, or a public conclusion.

The practical consequence is a table entry, not a mood. For every run, the report should state whether the item passed, failed, confused two families, triggered abstention, or forced a redesign. That public trace is what prevents technical uncertainty from being shifted onto later readers as if it were settled evidence.

The same entry should include a protected counterfactual: what conclusion would a PTVC-favoring analyst be tempted to write if this check were omitted? Naming that temptation helps reviewers see why the check belongs in the main benchmark rather than in a supplemental afterthought.

25.1.2 — Model Recovery

Model recovery asks a harder question: when one generator creates the data, does the model-comparison system identify that generator, or at least refuse a wrong confident label? Parameter recovery within a favored model is not enough. The fitted-model matrix must include every planned analysis model fit to every generating family (Wilson & Collins, 2019).

The benchmark therefore constructs a generating-model by fitted-model grid. Reserve candidates, OU models, bridges, frailty worlds, observation shutdown, sedation pathways, endpoint selection, predictive/RL rivals, flexible baselines, hybrids, and

open-set misspecifications all generate data. Each analysis model receives the same observations and the same rules.

The useful output is not a single accuracy number. It is a confusion matrix, proper-score table, calibration curve, posterior model probability behavior, convergence-failure record, and false-equivalence or false-defeat rate. The benchmark must reveal which models masquerade as which others under which observation conditions.

If a random-terminal-time Brownian bridge is frequently classified as the reserve-coupled candidate when endpoint uncertainty is high, the benchmark identifies that region of nonseparability. The next design can test which observations would resolve it.

Model recovery should also allow ties and abstention. If reserve and bridge models are inseparable under a specific sampling cadence, forcing one of them to win is a mistake. Confusion is a result, and the result may be redesign, narrower claim status, or a requirement for a new channel.

A serious project does not ask critics to accept a comparison space after the fact. The comparison space is published with the benchmark, attacked before release, and revised visibly when a critic supplies a better rival.

Independent reviewers should have access to the relevant seed, assumptions, scoring rule, diagnostics, and residual plots at the appropriate release tier. Those materials make the comparison reproducible and available for further testing.

The gray zone deserves special protection. A small score difference, a visually persuasive curve, or a clean figure cannot override failed recovery, untested observation assumptions, or unstable open-set diagnostics. The benchmark must make that uncertainty visible.

25.1.3 — Confusion Is a Result

A model-recovery benchmark treats confusion as information about design and identifiability. When two candidate worlds produce indistinguishable observations under the planned design, the report identifies that nonseparability and the measurements or conditions needed to resolve it (Wilson & Collins, 2019).

Confusion has structure. It may occur only at high noise floors, only near endpoints, only under sedation, only in one diagnosis group, only with low cadence, only when the endpoint time is estimated retrospectively, or only when device removal aligns with terminal decline. Mapping that structure is more useful than reporting a triumphant average recovery rate.

The benchmark should draw confusion regions. A methodologist should be able to see where a PTVC candidate is confused with a bridge, where an OU model is confused with adaptation, where frailty generates apparent concentration, and where open-set worlds are wrongly forced into known categories.

This rule protects the chapter from a subtle overclaim. The Law does not win because the fitted model has the highest score by a narrow margin in a nonseparable region. It wins a local comparison only where the design can separate the candidates and the recovery experiment shows that the score behaves reliably.

The reporting language should be simple: in this design region, the models are recoverable; in that region, they are confused; outside both, the model set may be inadequate. That sentence is more scientifically valuable than a confident ranking that ignores the landscape.

The humane value is equally simple. Confusion prevents human stories from being recruited into false clarity. If a person's data cannot answer the question, the chapter refuses to make that data carry the conclusion.

This item also needs an adversarial version in which the assumptions are almost, but not quite, satisfied. Near-miss worlds are where weak pipelines become persuasive, because they produce graphs that look familiar while the generating facts are different. The benchmark should preserve those near misses as named fixtures rather than discarding them as inconvenient edge cases.

The recovery report should ask which verdict would have been issued if confusion had been hidden. Forced selection of the least-bad model is the central risk when fitted families are empirically indistinguishable. Showing that counterfactual makes abstention a working safeguard rather than a ceremonial option (Wilson & Collins, 2019; Talts et al., 2018).

25.1.4 — Recovery Across Noise and Missingness

Clean synthetic data establish an initial recovery baseline. The benchmark then varies noise floor, cadence, endpoint uncertainty, device dropout, channel-specific missingness, staff observation gaps, medication effects, and site-level drift. Posterior simulation-

based calibration adds a useful conditional check by asking whether the intended inference and implementation behave correctly in the neighborhood of a particular observed dataset, rather than only across broad prior simulations (Säilynoja et al., 2026). Recovery across the intended observation conditions establishes the pipeline's readiness for the corresponding empirical design.

The noise and missingness grid should be declared in advance. Additive sensor floors, multiplicative device error, bounded self-report uncertainty, missing-not-at-random channels, terminal observation shutdown, device removal, sudden endpoint, and care transitions should appear as controllable stressors. Each stressor must have plausible parameter ranges and extreme challenge cases.

The joint additive-noise-floor by fitting-window sweep is especially important. The benchmark should vary noise-floor estimation error together with terminal fitting windows and report where model misclassification appears. If deconvolution becomes unstable or yields invalid negative variance estimates, that failure is part of the result.

Missingness should be generated, not sprinkled. A hospice device may fail because perfusion is poor. A report may be absent because sedation begins. A site may stop measurements because staff correctly prioritize comfort. These patterns can manufacture compression or hide it, so the simulator must let them interact with latent and observed states.

The analysis passes only if recovery remains stable across declared operational realities or if instability is acknowledged as a boundary. A fragile pipeline can still be useful for a narrow study, but it cannot support broad verdict language.

This rule keeps data dignity concrete. The benchmark minimizes the chance that ordinary care interruptions, device tolerance, or participant withdrawal will be misread as metaphysical evidence.

The benchmark record should preserve the simulated generator, noise law, missingness pattern, fitted candidates, protected holdout unit, diagnostic threshold, and failure disposition. An outside modeler should be able to reproduce where recovery broke and why the pipeline was stopped.

Recovery under noise and missingness has a specific gray zone: wider uncertainty can look like family confusion, and biased observation can look like precise recovery. The report should separate parameter bias, interval coverage, abstention, and generator classification across missingness regimes. A single average accuracy cannot tell reviewers which failure occurred (Wilson & Collins, 2019; Talts et al., 2018).

25.1.5 — Recovery Before Human Data Verdicts

Recovery must occur before human data verdicts because real-data ambiguity is too easy to rationalize after the fact. Once an observed study produces an attractive graph, analysts may unconsciously tune windows, priors, exclusions, transformations, and captions around the pattern. Synthetic recovery creates a pre-result obstacle to that drift (Wilson & Collins, 2019).

No confirmatory human claim proceeds until the synthetic challenge passes protocol-fixed criteria. Passing requires acceptable parameter recovery, model recovery, calibration, absolute fit, protected prediction, transport stress, and none-of-the-models detection across realistic near-miss worlds.

Threshold selection belongs inside nested resampling or a held-out synthetic challenge. The same simulations should not choose the decision threshold and then certify the model. Tuning, preprocessing, feature selection, endpoint window choice, and margin selection must be separated from final evaluation.

A concrete failure case would be a benchmark where the Law-candidate threshold was chosen on the same simulation suite used to announce high recovery. The final result would look strong but would be circular. The audit should treat that as leakage, not as optimism.

The chapter's practical standard is blunt: a real-data report that cannot cite a passed recovery benchmark remains exploratory or descriptive, even if the observed pattern is beautiful. Public language must follow that status.

A theory that wants the world to take it seriously should welcome this delay. It is better to postpone a claim than to let human data become an interpretive shortcut around untested machinery.

Before any human-data interpretation, an independent team should be able to regenerate the synthetic worlds from archived seeds, execute the frozen fitting pipeline, and reproduce parameter coverage, confusion, calibration, and abstention. Protected empirical data are not required for this gate. Failure to

reproduce the benchmark stops the analysis before participant burden is converted into a scientific claim (Wilson & Collins, 2019; Talts et al., 2018).

The release note should record what a failed check would change: redesign, a narrowed estimand, expansion of the rival envelope, No adequate estimate status, or withdrawal of public language. A check with no consequence is ornament and a source of false confidence.

25.1.6 — No Simulation as Scientific Validation

Simulation evaluates computational and statistical machinery under declared assumptions. By specifying a data-generating process, researchers can test whether an analysis recovers known features and quantifies uncertainty under those simulated conditions. These controlled checks prepare the computational pipeline for empirical comparison (Talts et al., 2018).

An executable reserve-coupled model supplies a candidate generator for examining terminal concentration and comparing proposed mechanisms.

Simulation-based calibration can expose computational error, inconsistent implementations, or posterior miscalibration under an assumed joint distribution. Posterior predictive checks test fit to selected features.

Simulation success, ethical review, and demonstrated design separability together inform the next empirical step, including whether recruitment and confirmatory comparison are justified.

The safeguard is operational: each output carries a role label such as computational check, recovery check, design-separability check, rival-envelope check, or artifact-release check. The label prevents a persuasive figure from outrunning its warrant.

The next section builds the serious generator library required to make this recovery gate more than a performance for one favored model.

Every result also records the artificial generator, fitted models, holdout design, recovery metric, allowed inference, and a status field separating benchmark calibration from evidence about nature.

Later reports should cite the executable benchmark result, not a sentence of assurance. Trust comes from leaving enough machinery for a skeptical reader to rerun the case and disagree precisely.

Minimum recovery bars are fixed for every reported quantity. They may include bias below the scientific margin and near-nominal coverage for a slope, low false support for a model label, or stable recovery across the noise, missingness, and endpoint conditions expected in the human protocol.

Recovery reports include computation time, convergence failures, discarded fits, and resource demands. A model that succeeds only after hidden divergence or unrealistic compute provides weaker practical evidence than a stable pipeline.

Chronology is decisive: the benchmark is completed before the emotionally powerful human result appears, because later tuning is otherwise pulled toward the terminal graph. Freezing

benchmark performance before human data also makes later deviations from the pipeline visible as new analyses rather than invisible repairs.

That frozen benchmark also resists narrative momentum. It preserves the worlds where the method would be wrong, undecided, or defeated by a rival before one resonant interpretation begins to dominate. Those adverse worlds should remain in the benchmark after success, because deleting hard cases would gradually convert recovery into self-confirmation.

Failed recovery is a publishable result. If the analysis cannot separate a reserve-coupled candidate from a random-endpoint bridge, it has shown that the proposed human study would ask vulnerable data to carry a question the method cannot yet support. Design should change before recruitment, not after public interpretation. A redesigned study should show improved recovery on the exact confusion that blocked the earlier design before participants are asked to contribute new data.

25.2 — Generative Benchmark Library

A benchmark library is a versioned collection of synthetic worlds with explicit generators, parameter distributions, observation kernels, endpoint processes, missingness, perturbations, and expected diagnostics. Its job is to make every model's failure modes reproducible before empirical interpretation.

The library should include adaptation, opponent, allostatic, OU, predictive, active-inference, reinforcement-learning, safe-control, bridge, selection, frailty, treatment, observation-floor, and PTVC-candidate families. Hybrid and open-set generators prevent the classifier from assuming that the named menu is complete.

The minimum library enables a fair test without pretending to be final. Critics may extend it when new entrants are independently motivated, executable, and capable of making fresh predictions before the protected evaluation data are seen.

Table 25.2. Generative benchmark library. Each family is a data-generating world, not a rhetorical category.

Generator family	Core mechanism	Benchmark function
Reserve-coupled candidate	declared reserve and signed reference dynamics	tests PTVC-candidate signatures without treating construction as evidence
OU/adaptation/opponent	local regulation, rebound, baseline drift	lets ordinary regulation win when it explains the data
Bridge and event-conditioned	fixed/random endpoints, future-event conditioning	tests endpoint concentration without PTVC-specific mechanism

Generator family	Core mechanism	Benchmark function
Frailty/medication/observation	illness, sedation, device removal, staff cadence	tests clinical and operational artifact pathways
Hybrid and null	mixed components or no structured effect	detects false support and false defeat
Flexible reference	nonparametric or machine-learning prediction	sets predictive benchmark without interpretive authority

Equation 25.2, Full fitted-model matrix.

$$R_{ij} = \text{Score} \left(M_i, y_{G_j}^{\text{test}} \mid y_{G_j}^{\text{train}} \right), \quad i = 1, \dots, I, \quad j = 1, \dots, J$$

Role label: model-recovery diagnostic. Every fitted model M_i is evaluated on protected data generated by every generator G_j ; the matrix exposes recovery, confusion, and false certainty. Here I is the number of fitted models and J is the number of generators.

25.2.1 — Reserve-Coupled Candidate

The reserve-coupled candidate is the benchmark representation of the Law’s empirical mechanism, not the Law itself. It implements a latent ledger-like process whose fluctuation scale and relaxation may depend on remaining reserve. Its role is to generate consequence patterns such as preterminal variance compression and endpoint concentration under explicit assumptions.

The generator should include the finite-variation reference case and approved stochastic extensions only when the product dynamics are rebuilt correctly. If reserve is stochastic, jumps, shares shocks, or changes filtration, the benchmark must use the general product rule rather than quoting the finite-variation shortcut.

Parameters include reserve trajectory, diffusion scale, drift or relaxation structure, endpoint timing rule, initial state, measurement error, observation intensity, and site/device effects. The benchmark should declare which parameters are scientific, which are nuisance, and which belong only to the observation model.

The generator description identifies its construction rules. Endpoint adjudication is defined independently of the tested ledger outcome. Conservative-field closure is labeled as a separate construction, and a closing controller states which paths its policy permits. Those details make comparisons with the received Law and empirical processes interpretable.

Recovery of a reserve candidate shows that the analysis recognizes that generator in the specified synthetic conditions. Captions, tables, and public summaries should identify those conditions and the recovery result.

This candidate enters the library as one contestant among serious rivals. Precise implementation makes both favorable and adverse comparisons interpretable.

The reserve-coupled benchmark entry should preserve the generator equations, parameter ranges, route-state definition, observation and missingness kernels, endpoint rule, seeds, and expected failure modes. It should also state which outputs count as target recovery, route recovery, and mere resemblance. That record makes later revisions and rival comparisons possible without reconstructing the candidate from memory (Talts et al., 2018; Wilson & Collins, 2019).

For the reserve-coupled candidate, the omitted-check counterfactual is a smooth endpoint curve being called reserve evidence without recovery of reserve, route state, or the joint restriction. The benchmark should demonstrate that its recovery gates actually block that conclusion. A safeguard that never changes the selected verdict has not earned a place in the pipeline (Talts et al., 2018; Wilson & Collins, 2019).

25.2.2 — OU, Adaptation, and Opponent Models

Ornstein-Uhlenbeck, adaptation, and opponent-process models represent mainstream local regulation. They can pull observed states toward a baseline, generate rebound after shocks, damp variance, and produce apparent repair without any pathwise terminal closure. They must be implemented strongly enough to win (Wilson & Collins, 2019).

An OU generator needs a baseline, mean-reversion rate, diffusion scale, and possible time-varying or state-dependent parameters. Adaptation generators need shock response, habituation, set-point drift, and context dependence. Opponent models need primary-process and counterprocess dynamics with timescales that can create local inversion or rebound.

The library should include versions where parameters change with illness, treatment, sleep, fatigue, culture, and observation regime. A fixed, stationary OU model is a useful teaching rival but not the whole rival family. Ordinary biology and behavior are more flexible than a single textbook equation.

These rivals can mimic terminal quiet when shocks diminish, reports become less variable, staff interventions stabilize distress, or surviving windows select calmer states. If they produce the

observed signatures with fewer assumptions, the PTVC candidate narrows or loses that comparison.

The benchmark should record when adaptation explains endpoints by local mechanisms and when it fails to explain pathwise constraints or reserve-linked signatures. The comparison should be specific, not a vague contest between ‘the Law’ and ‘adaptation’.

Well-developed alternatives make model comparison more informative and any replicated advantage more credible. Their performance identifies which explanatory features the next study should examine.

For the OU, adaptation, and opponent-process library, the trace should preserve equations, parameter ranges, initial conditions, event schedules, observation errors, and recovery outcomes. Reproduction must show which local-regulation family generated each dataset and when the analysis confused one family with another. That confusion matrix is part of the result, not a disposable diagnostic.

The OU, adaptation, and opponent benchmark should record what the candidate would have won against if those rivals had been left weak or absent. The relevant false conclusion is uniqueness produced by an impoverished rival library. Replaying the comparison with expert-strength rivals reveals whether the safeguard changes model ordering (Talts et al., 2018; Wilson & Collins, 2019).

25.2.3 — Bridge and Event-Conditioned Models

Bridge models and event-conditioned worlds are dangerous because they can create endpoint concentration by conditioning on the future rather than by reserve-coupled dynamics. A Brownian bridge fixed to an endpoint, a random-endpoint bridge, or a Doob transform can make paths look as if they were drawn toward closure.

The library should include fixed endpoint bridges, random endpoint bridges, censored endpoint bridges, event-conditioned diffusions, and survival-conditioned processes. Each must state how the terminal event is defined, whether the endpoint is observed with error, and whether conditioning is physical, statistical, or selection-based.

A subtle artifact appears when analysts align all data to death or last observation. If the last observed point is selected by a process related to the measured signal, the aligned trajectories can appear to narrow even when no PTVC mechanism operates. The bridge family should therefore connect to the observation rival envelope.

Comparisons with bridge models should use the same observation process and examine additional signatures, such as reserve-linked contraction and independently defined endpoints. Joint predictions make the proposed explanations more distinguishable.

The benchmark should include bridge parameters that make the rival hard, not a strawman. Endpoint uncertainty, variable horizons, and partial observations belong in the generator, because real terminal research will not supply perfectly fixed endpoints.

If bridge and reserve candidates remain confused after reasonable design improvements, the report should say so. That result may force narrower empirical language or new measurements rather than a rhetorical win.

This is also where participant dignity enters the computational layer. The study should not ask a person, family, staff member, or site to carry observation burden for a design that has already failed in synthetic conditions. Recovery discipline is a way of refusing decorative data collection before it reaches the bedside.

Reports on bridge and event-conditioned models should cite the exact executable artifact, version, conditioning event, endpoint law, and protected result. A prose statement that the check was performed is not enough. The cited object should let an outside team regenerate the conditioned paths and verify the diagnostic claimed in the text (Talts et al., 2018; Wilson & Collins, 2019).

A second benchmark makes the cross-window restriction explicit. Let Y be the vector of signed contributions from n prespecified disjoint windows, with reference distribution $N(\mu, \Sigma)$, where Σ is positive definite. For the Gaussian reference law conditioned on $\mathbf{1}^\top Y = 0$,

$$\mu_c = \mu - \frac{\Sigma \mathbf{1} (\mathbf{1}^\top \mu)}{\mathbf{1}^\top \Sigma \mathbf{1}}, \quad \Sigma_c = \Sigma - \frac{\Sigma \mathbf{1} \mathbf{1}^\top \Sigma}{\mathbf{1}^\top \Sigma \mathbf{1}}.$$

Consequently $\mathbf{1}^\top \mu_c = 0$ and $\Sigma_c \mathbf{1} = 0$. For $\Sigma = \sigma^2 I$, each off-diagonal covariance is $-\sigma^2/n$ and each marginal variance is $\sigma^2(1 - 1/n)$. This is a coupled mean-and-covariance prediction. Independent, zero-mean additive measurement error with covariance R preserves the conditional mean and changes the

observed covariance to $\Sigma_c + R$. The benchmark therefore uses an external neutral origin, prespecified disjoint windows, and an independently calibrated observation model. The reference mean and covariance are estimated independently of the confirmatory closure fit, with any systematic measurement bias receiving its own calibrated correction. These choices leave the total free to be estimated from the observations. By contrast, subtracting each trajectory's own mean forces its observed sum to zero, and selecting trajectories by their totals directly changes the distribution being studied.

This Gaussian route also supplies explicit nonzero-total comparisons. Conditioning on a fixed nonzero total yields the same covariance restriction while changing the conditional mean. When prefix variance is positive, a slope of -1 between latent prefix and suffix follows from any fixed terminal total. The comparison must therefore join mean location, covariance, complete coverage, and independently identified endpoints, with fixed-nonzero and diffuse-total models included. An episode-level application tests a separately specified local-closure hypothesis.

An analytic check makes the distinction concrete. Use four dimensionless window contributions with independent standard-normal reference values and independent measurement errors of variance 0.04 per window. Conditioning the latent total to zero gives each window mean 0; conditioning it to 2 gives each window mean 0.5. Both fixed-total models have latent marginal variance 0.75 and off-diagonal covariance -0.25 . Measurement error changes the marginal variance to 0.79 while leaving the off-

diagonal covariance -0.25 . The observed total therefore has variance 0.16 in both fixed-total models. Without terminal conditioning, its variance is 4.16.

Thus covariance contraction separates these fixed-total constructions from the unconditioned reference but cannot distinguish zero total from total 2. Their mean locations provide that additional contrast only when the neutral origin and measurement bias are independently anchored. These are analytic consequences of the stated Gaussian construction, not observations of experience, a completed model-recovery study, or evidence for PTVC. They provide exact numerical targets for checking benchmark code.

25.2.4 — Frailty, Medication, and Observation Models

Frailty, medication, and observation models generate terminal patterns through illness and care rather than through the proposed Law mechanism. They are not afterthoughts. In end-of-life data, they are candidate sources of apparent trajectory change that the benchmark must test (Aalen et al., 2008; Hernán & Robins, 2020).

A frailty generator may include latent health decline, diagnosis-specific trajectories, site-level care practice, metabolic reserve, symptom volatility, and mortality risk. Medication models may include sedation, analgesia, anxiolytics, anticholinergics, delirium risk, dose changes, and report-capacity effects. Observation models may include staff cadence, device tolerance, caregiver reporting, and channel shutdown.

A hospice example is enough to show the risk. A participant's wrist sensor is removed after swelling and skin fragility increase.

Self-reports become sparse after sedation is adjusted for comfort. The final record looks calmer and less variable, but the mechanism may be care and observation, not latent closure.

These generators should allow shared drivers. Disease severity may move reserve proxies, report availability, medication intensity, and endpoint timing together. If the benchmark treats these as independent nuisances, it will understate the ability of ordinary clinical pathways to mimic the target signatures.

The analysis passes only if it can separate Law-candidate signatures from these care and observation paths or state that it cannot. A humane research program should prefer that humility to a graph that rewards clinical invisibility.

This library member is also an ethical control. It prevents comfort-first care from being misread as evidence manufactured by the theory, and it keeps clinical decisions from becoming tokens in a scientific argument.

Frailty, medication, and observation generators need a trace that joins clinical progression, treatment timing, competing events, device or report availability, and public wording consequences. An outside team should be able to recreate the terminal pattern without invoking PTV. The benchmark earns trust by retaining those ordinary explanations in executable form.

The clinical rival audit should reconstruct the conclusion that would appear if frailty, medication, sedation, and observation shutdown were omitted. An apparent terminal contraction may then be seen to arise from care and visibility rather than the latent route. The comparison is useful only when inclusion of those

processes can reverse or block the tempting result (Aalen et al., 2008; Hernán & Robins, 2020).

25.2.5 — Hybrid and Null Worlds

Hybrid and null worlds prevent the benchmark from becoming a forced-choice contest among tidy theories. Real data may contain adaptation plus frailty, bridge-like conditioning plus observation shutdown, reserve-like dynamics plus medication effects, or no structured terminal pattern at all. The library must let messy worlds exist (Wilson & Collins, 2019).

Hybrid generators combine components with declared weights and interactions. A reserve candidate may be mixed with sedation and site effects; an OU process with endpoint selection; a frailty model with device adherence. The purpose is bounded complexity that tests whether mixed evidence is over-attributed to the favored model.

Null worlds are equally important. A null world may include noisy measurements, irregular observation, and endpoints, but no meaningful terminal concentration beyond artifacts. If the analysis repeatedly finds support in null worlds, its false-support rate shows that the decision rule needs revision.

Hybrid and null worlds also support false-equivalence and false-defeat checks. False equivalence occurs when the procedure declares the specified finite-band claim although the generating estimand lies outside that band. A nonzero generating value inside the band is not a false equivalence. False defeat means rejection of the particular claim that is true in the generated world. Report both rates against the exact target and decision rule used.

The benchmark should report these rates by generator family, observation regime, and decision threshold. The public should not hear a single accuracy number when the error type matters morally and scientifically.

Hybrid and null worlds are a discipline of modesty. They let the field say that a result is mixed, artifact-dominated, or uninterpretable rather than forcing it into a clean story.

Hybrid and null worlds should be reproducible from a public generator specification that exposes mixture structure, component strengths, open-set labels, and observation noise while protecting no human data. A critic should be able to add a near-miss hybrid and rerun the entire model matrix. The benchmark remains incomplete when only the preferred team's mixtures are executable (Talts et al., 2018; Wilson & Collins, 2019).

Hybrid and null worlds create near ties for different reasons. A hybrid may be partly represented by several candidates, whereas a null world may expose shared misspecification across all of them. The benchmark should report component recovery, residual structure, and open-set diagnostics so that a small score difference is not mistaken for adequate mechanistic identification (Talts et al., 2018; Wilson & Collins, 2019).

25.2.6 — Versioned Assumption Registry

A generative library without a versioned assumption registry invites invisible drift. One analyst changes a prior range, another changes dropout, a third changes endpoint uncertainty, and the benchmark becomes a moving target. The registry makes every simulator assumption visible (Talts et al., 2018).

Each generator should have a release identifier, mathematical specification, parameter distributions, units, default values, observation rules, endpoint rules, nuisance structures, known nonidentifiability regions, and a changelog. When an assumption changes, the registry records who changed it, why, and which results must be rerun.

Access-tier rules for public versus sensitive benchmark materials are specified in §25.8.5. The assumption registry records which tier governs each object.

A versioned registry also protects critics. A critic can reproduce the benchmark version that produced a claim, supply a rival generator, and show whether the conclusion survives. Without a stable version, critique becomes chasing smoke.

The registry should not be used to bury complexity outside the book. Essential generator families and decision rules appear in the chapter. The artifact holds executable detail, not hidden scientific meaning.

Once the library exists, the next question is whether a study design can separate its members. A rich library is useless if the planned observations make all worlds look the same.

The versioned registry should identify which favorable conclusion becomes possible when an assumption is changed silently after results. Examples include widening a route envelope, redefining the endpoint window, or replacing a null generator. A machine-readable diff makes that counterfactual detectable and prevents revision history from disappearing into polished prose (Nosek et al., 2015; Munafò et al., 2017; Nüst et al., 2020).

The ordinary rivals should be no less carefully built. OU mean reversion, hedonic adaptation, opponent rebound, predictive control, safe control, frailty, medication, and endpoint conditioning each have different mechanisms. The library should not collapse them into one vague rival category simply because they are not the Law.

The library should be curated as a scientific commons rather than a private arsenal. Each generator needs a readable name, a mathematical declaration, a parameter file, a plain-language mechanism statement, a list of protected signatures it can mimic, and a list of assumptions that would make it unfairly strong or unfairly weak. This lets a critic argue about the right object instead of reverse-engineering the author's intent.

A good library will sometimes reveal mechanisms its builders did not anticipate. It may show that an observation-gain model reproduces a signature once sensor removal is represented, or that a frailty mixture resembles late convergence after retrospective endpoint alignment. These findings show that the benchmark is doing useful work: it identifies explanations the next analysis must distinguish.

25.3 — Design Separability and Power

Design separability asks whether the distribution of planned observations differs enough across declared generators for a reliable decision. It is evaluated in simulation before recruitment using the same analysis, uncertainty, and consequence rules planned for the empirical study.

Power is branch-specific. A design can have high power for a mean difference and almost no ability to distinguish bridge conditioning from reserve-coupled dynamics, or adaptation from informative observation. The simulation target must match the scientific decision.

The chapter uses expected log predictive discrimination, discriminating-power matrices, open-set checks, and burden-adjusted information to decide whether a design deserves human data. The goal is not maximal measurement. It is sufficient discriminating information with the least ethical and practical cost.

25.3.1 — Expected Information by Design

Expected information by design evaluates how much a proposed sampling schedule, channel set, and endpoint rule are expected to teach before the study begins. The object is not a generic sample size. It is the predicted separation among specified generators under the planned observation system (Gneiting & Raftery, 2007).

One useful quantity is expected log predictive discrimination. For two generating families, the benchmark estimates the expected held-out log-score gap under a design. If the gap is small relative

to simulation uncertainty, the design may be unable to distinguish those families even with many participants.

Equation 25.3 states the role of the quantity. It is a design diagnostic, not a verdict about nature. It compares how fitted models predict protected synthetic data when one generator is known to be true.

Equation 25.3, Expected log predictive discrimination.

$$D_{ab}(d) = E_{G_{a,d}}[\log p_a(y^{test}|y^{train}, d) - \log p_b(y^{test}|y^{train}, d)]$$

Role label: design diagnostic. The quantity compares rival predictive performance under design d before human recruitment; small or unstable values indicate nonseparability.

A distribution-level bound complements fitted-model recovery. Let P and Q be a specified candidate and rival law for the complete latent record. Apply the same observation kernel K , including cadence, noise, missingness, endpoint classification, and recorded selection. For a measurable test $0 \leq \varphi \leq 1$ with $\mathbb{E}_{QK}\varphi \leq \alpha$,

$$\mathbb{E}_{PK}\varphi \leq \min\{1, \alpha + \text{TV}(PK, QK)\} \leq \min\{1, \alpha + \sqrt{D_{\text{KL}}(PK\|QK)/2}\}.$$

$$D_{\text{KL}}(PK\|QK) \leq D_{\text{KL}}(P\|Q), \quad \text{TV}(PK, QK) \leq \text{TV}(P, Q).$$

Total variation bounds the difference in rejection probabilities; Pinsker's inequality and information contraction give the remaining bounds, using natural logarithms (Cover & Thomas, 2006). A joint observable-record divergence below $2(\pi - \alpha)^2$ rules out target power $\pi > \alpha$ for that pair at size α . This is a necessary design condition, not a sufficient power calculation.

Nominal reports cannot be counted as independent information, and an estimated divergence needs its own uncertainty.

Conditioning on survivors or complete reports changes the experiment. Analyze the joint selection-and-outcome record, or derive the selected laws and retain their selection probabilities; conditioning can increase separation, so unconditional contraction cannot simply be reused. For composite families, one difficult admitted pair already limits uniform performance. The practical objective is a design that separates scientifically meaningful rivals through its qualified observations.

A design example makes the point. Hourly active reports may separate a fast opponent process from an OU model, but may be unethical or burdensome in terminal settings. Passive physiology may reduce burden but fail to distinguish valence from arousal. A mixed design can be preferred only if it gains discrimination without exceeding participant and staff limits.

Exactness has a calculable observation limit. In a simple calibrated model, observe $Y = L + e$, where e is centered Gaussian error independent of L , with known variance $\sigma^2 > 0$ and an independently fixed zero origin. Compare $L = 0$ with a continuous rival L distributed as $N(0, \eta^2)$. The observable variances are σ^2 and $\sigma^2 + \eta^2$. With $r = \eta^2/\sigma^2$, their divergence is

$$D_{\text{KL}}(P_\eta \| P_0) = 1/2 \{r - \log(1 + r)\} \sim \frac{\eta^4}{4\sigma^4}.$$

For n independent records, joint divergence is n times this quantity. The observation-space power bound therefore rules out

uniform separation of exact zero from every arbitrarily concentrated continuous rival by a fixed finite design. A useful design instead specifies the departures it must resolve and calculates a resolution curve that includes its full calibration and observation uncertainty.

Error calibration can be the decisive resource. If σ^2 is unknown, an exact residual with error variance σ^2 and a nonzero residual of variance η^2 with error variance $\sigma^2 - \eta^2$ produce exactly the same Gaussian observation law whenever $0 < \eta^2 < \sigma^2$. More outcomes from that ambiguous channel do not identify which explanation generated them. Independent reference measurements or qualified replicate channels must constrain the error law, including whether its gain, origin and variance transport to the actual observations. Study planning should allocate effort to that qualification as well as to outcome collection.

Population identification remains a different question. For known independent additive error with a nowhere-zero characteristic function, division of the observed characteristic function by the error characteristic function identifies the latent distribution. This does not guarantee stable recovery from a finite sample. Unknown origin, missing prefix and uncertain endpoint require their own identification work even when the noise law is known.

Expected information should be reported with uncertainty. Monte Carlo error, simulator uncertainty, prior range, endpoint uncertainty, and site variation all affect the expected value. Pass decisions should reflect variation across simulation seeds.

The Law of Fairness lens asks whether the information gain is worth the load it imposes. If the study adds burden without separability, the burden has been shifted onto participants for a result the design could not earn.

Expected-information calculations should be reproducible from the proposed sampling schedule, channel costs, generator library, priors or design weights, and utility or loss definition. A reviewer should be able to alter cadence or burden constraints and recover the resulting design decision. This is how a no-study conclusion becomes inspectable rather than discretionary (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

The design analysis should state what human study would have proceeded if expected information had not been calculated. The danger is recruitment into a burdensome protocol whose cadence and channels cannot separate the models even at large sample size. Demonstrating that the information check can trigger redesign or no-study status gives the safeguard practical force (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

25.3.2 — Discriminating-Power Matrix

The discriminating-power matrix maps model families against signatures. It asks which signature separates which rival under which observation regime. A signature that looks impressive in prose may test the same distinction as another signature or may fail against the rival that matters most (Wilson & Collins, 2019).

Rows should include reserve candidates, OU, adaptation, opponent dynamics, bridge families, frailty, observation shutdown, sedation, predictive/RL rivals, flexible baselines, and open-set worlds. Columns should include terminal concentration,

preterminal variance compression, reserve-linked contraction, endpoint independence, held-out prediction, calibration, sign stability, and response to perturbation when available.

The matrix should display expected discrimination, not rhetorical confidence. A blank cell means the signature does not separate the pair. A weak cell means the evidence is likely to be ambiguous. A strong cell means the design offers a plausible route to distinguishing the models under declared assumptions.

The matrix prevents a common failure: piling up correlated signatures that all collapse against the same bridge rival. Five signatures that cannot distinguish bridge conditioning from reserve coupling do not become strong by being counted five times.

Use the matrix before recruitment. Record each generator-signature contrast, design conditions, uncertainty across simulations, and redesign/no-study threshold; leave blank cells and nonconvergence visible. If no planned signature separates the PTVC candidate from the strongest rival envelope under ethical observation, classify the study as exploratory or methodological, or redesign it, rather than calling it confirmatory (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

Table 25.3. Design separability decision rules.

Decision	Benchmark condition	Consequence
Proceed as confirmatory	high discrimination, stable calibration, acceptable burden	benchmark passes and ethics permits recruitment

Decision	Benchmark condition	Consequence
Proceed as exploratory	some informative contrasts, key rivals unresolved	public language stays exploratory
Redesign	critical rivals confused or open-set detection weak	change cadence, channels, endpoint, or model set
Do not recruit for this question	nonseparable under ethical observation	avoid spending human burden on decorative data

25.3.3 — Redundant Signatures

Redundant signatures are not harmless. They can make a chapter look richly supported while measuring one distinction repeatedly. In the model-recovery setting, redundancy can inflate apparent evidence, hide nonseparability, and increase participant burden without increasing knowledge (Wilson & Collins, 2019).

The benchmark should compute or qualitatively map dependency among signatures. If terminal concentration, final-window variance compression, and last-observation calm all respond to the same observation-shutdown artifact, they cannot be counted as independent support against that artifact.

Redundancy audits should also include measurement channels. Two wearable metrics may share a sensor failure mode. A clinician report and a family report may share cultural or hospice-script influence. A self-report and a behavioral measure may both depend on sedation. Apparent multimodality may be one confounded pathway.

The audit should model dependence among signatures and assess whether each adds information for the declared contrast. A

redundant signature may be removed when it adds burden without useful information, but correlation alone does not require deletion or arbitrary downweighting. A correctly specified joint likelihood or calibrated joint decision rule can retain dependent observations without counting them as independent confirmations.

A practical output is a signature dependency table. It names the signature, the mechanism it tests, the rivals it discriminates, the confounds it shares, and whether it remains confirmatory, exploratory, or descriptive.

This rule keeps the chapter from mistaking volume for depth. The right study may measure fewer things and answer more.

Model-pair separability should be demonstrated in synthetic data before any additional participant or clinical burden is requested. If the design cannot distinguish the candidate from the named rival when the generator is known, denser observation of vulnerable people will not create adjudicable evidence. The ethical response is redesign or abstention, not recruitment (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

The redundancy audit should show the apparent evidence gain that would result from counting several correlated signatures as independent confirmations. The corrected analysis should collapse or model their dependence and display the resulting loss of information. That counterfactual prevents a larger checklist from masquerading as a stronger test (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

25.3.4 — Open-Set Separability

Design separability must include an explicit none-of-the-models option; §25.5 defines the open-set adequacy tests used to determine whether that option is real rather than decorative. Here the immediate question is whether planned observations can distinguish modeled families without forcing every unfamiliar world into the nearest candidate (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

The benchmark should generate misspecified worlds that are not represented by any fitted model. These may include nonlinear mixtures, unanticipated site practices, unmodeled treatment pathways, sudden device changes, unknown latent subgroups, or irregular observation dynamics. The analysis should not confidently classify these worlds as the PTVC candidate or a known rival.

Open-set detection can use posterior predictive misfit, residual structure, calibration failure, anomaly scores on held-out features, and poor proper scoring across all candidate models. None of these tools is perfect, so the benchmark should report false open-set and false closed-set rates.

A useful failure case is a flexible observation-gain world that produces apparent compression only when reports become more likely during calm states. If every fitted model assigns it to reserve coupling, the benchmark has shown that the design lacks open-set protection.

Open-set separability also affects public language. A result should not say that the Law beat all rivals if the system cannot detect

unknown rival families. It may say it beat the prospectively specified model set under declared adequacy checks, if true.

An open benchmark gives investigators room to discover mechanisms and model failures they did not anticipate.

Challenge open-set separability with generators just outside a modeled family that preserve its familiar observable shape. High closed-set accuracy can coexist with failure to recognize these near-misses. Report detection, anomaly calibration, and abstention rates on the boundary worlds, testing whether the pipeline recognizes unsupported extrapolation rather than forcing an unfamiliar case into the nearest known class (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

25.3.5 — Burden-Adjusted Power

Burden-adjusted power treats information and cost together. A design that extracts more data can be scientifically attractive and ethically inferior if the added information does not change model separability. Participant burden, staff burden, privacy exposure, family intrusion, and device tolerance all belong in the design comparison (Wilson & Collins, 2019).

The benchmark should report marginal information per added burden unit. A new channel may improve expected discrimination only slightly while requiring nightly reports from a fragile participant. A less intrusive channel may offer enough separation when combined with site-level metadata and endpoint adjudication.

Burden is not a sentimental word here. It includes time, discomfort, attention, privacy risk, interruption of care, staff

charting load, device irritation, family pressure, and the possibility that the study changes the experience it is trying to observe.

A burden-adjusted decision may reject the most information-rich design. That is not weakness. It is method respecting the object of study. The project cannot claim to study felt life while treating measurement burden as external to felt life.

The design report should show alternatives: minimal design, preferred design, high-burden design, and rejected design. Each should carry expected discrimination, uncertainty, failure modes, and burden notes.

This rule ensures that the desire to validate the theory does not outrun the care owed to the people whose data would make the test possible.

Burden-adjusted power should include near-miss designs in which more observations improve precision but do not improve model separation. Such cases reveal when participant effort, clinician time, or sensor burden would be spent on a question the design cannot answer. The decision rule should favor redesign or no study rather than treating sample size as a substitute for information (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

Burden-adjusted power should be tied to a versioned design artifact that records participant burden, observation cadence, expected information gain, safety constraints, and stopping rules. Later summaries should cite that calculation directly. Statistical power without its human cost function is incomplete design evidence (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

25.3.6 — No Study When Models Are Nonseparable

The hardest design decision is to stop before recruitment. If the benchmark shows that critical models are nonseparable under ethical observation, the correct conclusion is not to recruit and hope for clarity. The correct conclusion is redesign, new channels, narrower claims, or no confirmatory study (Wilson & Collins, 2019; Gneiting & Raftery, 2007).

Nonseparability should be declared by protocol-fixed criteria. For example, if expected log-score gaps are too small, confusion rates too high, none-of-the-models detection too weak, or key rival pairs unrecoverable across realistic observation regimes, the design fails.

A failed design can still teach. It may identify the need for better endpoint adjudication, a less confounded observation channel, stronger site metadata, improved device calibration, or a new rival model. But it should not be rebranded as a human confirmatory protocol.

The public risk is severe. A nonseparable study can produce a polished graph that looks like science while never having been able to discriminate the central alternatives. That graph would move uncertainty from the design into the reader's belief.

The next section examines the rival envelope most likely to cause that nonseparability: endpoint and observation processes.

When nonseparability is declared, the no-study record should point to the executable recovery and power artifact, name the unresolved model pairs, and specify a repair targeted to the source of failure: redesign sampling, add an independent channel, narrow

the estimand, classify the work as exploratory, or refuse recruitment for that question. The repair should change the discriminating information rather than simply add data to the same uninformative contrast (Gneiting & Raftery, 2007; Wilson & Collins, 2019).

Expected information should be reported by design choice, not as one global optimism number. Daily and weekly reports, wearable and clinical-record channels, and endpoint adjudication may distinguish different model pairs. The design matrix should show what each added burden buys.

The discriminating-power matrix should also include negative controls. If a signature appears in an impossible window, a device-quality channel, or a variable with no plausible relation to the hypothesis, the analysis has probably found an artifact of alignment, preprocessing, or selection rather than a mechanism. A control that fails only after one preprocessing step can identify the stage where discriminating power is being manufactured.

Design separability requires a different kind of sample-size humility. A large cohort can be powerless for the relevant contrast when every observation passes through the same endpoint-conditioned gate. A smaller design with an independent endpoint channel, calibration-transfer check, and protected holdout may be more informative because it breaks the dominant artifact. Information quality, not participant count alone, is therefore a design resource that can be increased by orthogonal measurements or timing changes.

Power must be conditional on the rival pair, observation model, and decision threshold. A study with nominal ninety-percent

power may still fail to distinguish reserve compression, bridge conditioning, observation shutdown, frailty selection, and adaptive mean reversion under common missingness and noise. Power simulations should include the full rival set and realistic missingness, because pairwise power against an easy comparator can substantially overstate adjudicability.

25.4 — Endpoint and Observation Rival Envelope

Endpoint and observation rivals are a required envelope around every terminal claim. Random endpoint error, backward alignment, survival conditioning, treatment, frailty, device removal, communication loss, and observation shutdown can generate concentration without a PTVC-specific route.

The envelope is generated through the same observation pipeline as the candidate. Each rival specifies how eligibility, entry, care, measurement, endpoint adjudication, and missingness produce the final record, so a terminal-looking curve cannot escape by being assigned to an undefined nuisance process.

The endpoint-and-observation rival envelope includes bridge families, Doob transforms, last-observation artifacts, shared disease and sensor pathways, treatment and care pathways, and rules for updating the envelope prospectively.

25.4.1 — Random-Terminal-Time Bridges

Random-terminal-time bridges condition paths on an endpoint whose timing is uncertain. They matter because terminal studies rarely know the exact death-of-mind stopping time with perfect precision. If data are aligned to an estimated endpoint, bridge-like concentration can appear without PTVC reserve dynamics (Doob, 1957).

The generator should draw endpoint times from a distribution, generate paths conditional on or selected by those times, and then impose realistic endpoint adjudication error. Fixed bridges are

useful baselines, but random bridges are the harder rival because they match the uncertainty of the research setting.

A bridge may produce shrinking variance near the conditioned endpoint. If the observation model then censors late high-volatility windows, the bridge can look even more like terminal neutralization. This is precisely why it belongs in the benchmark rather than in a footnote.

The PTVC candidate must beat random bridges under the same endpoint rules. It cannot define the endpoint by the ledger estimator, and it cannot claim independence if the benchmark aligned by a signal that already encodes the measured outcome.

Recovery should report where random bridges are confused with reserve candidates. If confusion concentrates when endpoint uncertainty is high, the study may need stronger endpoint adjudication or a different target signature.

This rival turns endpoint humility into executable science. It asks whether the terminal pattern survives a model that uses future-event conditioning without invoking the Law.

Random-terminal-time bridge experiments should record the endpoint-time law, conditioning event, reference process, observation schedule, fitted bridge, protected holdout, and diagnostic consequence. Reproduction must reveal whether apparent terminal direction came from the conditioned law or from the data-generating mechanism. The endpoint distribution cannot remain an undocumented convenience.

A random-terminal-time bridge can fit the endpoint shape while leaving its causal status unresolved. The ambiguity lies between

native dynamics, conditioning on a terminal event, and selection through the observation process. Preterminal covariance, hazard response, and intervention behavior must be compared before the bridge is treated as a mechanism (Doob, 1957; Aalen et al., 2008; Léonard, 2014).

25.4.2 — Doob-Transform and Survival Conditioning

Section 22.5.3 established Doob-transform and survival-conditioned processes as scientific rivals. Here the task is operational: include executable versions of those generators in the endpoint and observation rival envelope, with the same data, information, and scoring budget as the PTVC candidate (Aalen et al., 2008; Little & Rubin, 2019).

The benchmark should include Doob-transform rivals where paths are conditioned on survival, endpoint class, open-channel status, or selected terminal features. These models can generate apparent drift toward a boundary or avoidance of certain regions without a PTVC controller.

The key question is whether observed patterns are consequences of conditioning. If a dataset includes only those who remain observable until a window, or only those whose endpoints are well adjudicated, the selected process may no longer represent the unconditioned population.

The analysis should fit Doob-style rivals to the same synthetic and real observation structures as the PTVC candidate. If survival conditioning explains the signatures with equal or better predictive performance and fewer assumptions, the Law claim narrows for that result.

The report should distinguish mathematical conditioning from natural implementation. A Doob transform can be a statistical rival even if no organism implements it as a literal controller. Its role is to ask whether the observation pattern could arise from selection and conditioning.

This protects the chapter from the common error of treating conditional drift as proof of a hidden purpose. The field must separate generated appearance from implemented mechanism.

The Doob-transform and survival-conditioning record should cite the exact code, base law, conditioning event, h-function or weighting rule, endpoint distribution and support, censoring process, limiting construction for zero-probability events, and holdout diagnostics. It should identify which preterminal observables distinguish the conditioned law from native dynamics, because subtle changes in conditioning can alter preterminal behavior. Without that executable provenance, a generic claim that a bridge was tested can misreport a mathematically valid construction as a discovered cause (Doob, 1957; Aalen et al., 2008; Little & Rubin, 2019; Léonard, 2014).

Table 25.4. Endpoint and observation rival envelope.

Rival class	Mechanism	What it can mimic
Random-terminal bridge	endpoint uncertainty plus conditioning	apparent drift and variance contraction near aligned endpoint
Doob/survival conditioning	selection on future event or open-channel status	conditional drift without PTVC-specific implementation

Rival class	Mechanism	What it can mimic
Last-observation artifact	device removal or report stop treated as endpoint	false calm or narrowed final window
Shared disease drivers	frailty moves reserve, observation, endpoint, and proxies	correlated signatures without latent closure
Care pathway	sedation, analgesia, hospice practice, comfort-first monitoring	observed relief or missingness from care rather than a PTVC-specific route
Prospective update	new rival added before protected evaluation	prevents weak envelope and after-the-fact rescue

25.4.3 — Last-Observation and Device-Removal Alignment

Last-observation alignment can create terminal narratives from operational endings. A wearable may be removed, a diary may end, a transfer may interrupt a site, or a staff observation may stop before the conscious endpoint. Aligning those last observations as if they were equivalent endpoints can manufacture a false final pattern (Little & Rubin, 2019).

The generator should include device-removal rules linked to skin fragility, agitation, comfort decisions, battery failure, low perfusion, site practice, and family preference. It should also include report stopping linked to sedation, fatigue, delirium, or care prioritization. These mechanisms are ordinary, humane, and statistically dangerous.

A vivid failure case is a final-window dataset where the last valid wearable reading is calm because the sensor was removed when

motion, pain, or clinical complexity increased. If the analysis treats that last valid reading as the endpoint state, the artifact can imitate concentration.

The benchmark should test multiple alignments: true endpoint, adjudicated endpoint, last observation, last valid device window, care transition, and retrospective death alignment. Differences among these alignments are evidence about the observation process, not merely sensitivity clutter.

A study should not pass if the favored signature appears only under last-observation alignment and disappears under endpoint-independent adjudication. That pattern points to artifact or at least to severe uncertainty.

The final data point must not become a false witness. Sometimes the last observed value is simply the last value a respectful study was allowed to observe.

Last-observation alignment should leave an explicit provenance trail for the clock, reason observation ended, device status, care transition, and relation to the protocol and truth-level endpoints. Analyses under alternative anchors should be stored beside the primary result. This record prevents device removal or respectful withdrawal from being mistaken for a natural terminal event (Aalen et al., 2008; Hernán & Robins, 2020).

Last-observation and device-removal alignment tests should cite a versioned artifact containing the removal rule, clinical workflow, time stamps, missingness process, and counterfactual simulations. The record should show how much apparent terminal concentration can be produced by the observation system alone.

That estimate belongs beside every later interpretation (Aalen et al., 2008; Little & Rubin, 2019).

25.4.4 — Shared Disease and Sensor Confounding

Shared disease and sensor confounding occurs when illness severity moves latent state, reserve proxies, endpoint timing, and observation quality together. The resulting data can look dynamically structured even when the structure arises from shared drivers rather than the proposed mechanism (Hernán & Robins, 2020).

The generator should include latent frailty, inflammation, oxygenation, mobility, perfusion, cognitive clarity, medication burden, and device adherence as linked processes. It should let these variables influence both measured channels and the probability of future observation.

Sensor confounding can be subtle. Skin temperature, heart-rate variability, motion, electrodermal measures, and report latency can change because of disease severity, device placement, medication, or staff workflow. A model that treats them as pure affective witnesses may mistake physical access for felt-state evidence.

The benchmark should allow shared shocks between reserve-like variables and measured ledger proxies. If the finite-variation reserve shortcut is used while the synthetic world has correlated stochastic shocks, the fitting model may misattribute covariance.

Recovery results should identify which signatures remain after shared disease and sensor pathways are included. A signature that

vanishes under shared-driver simulation is not ready for claim-status elevation.

Interpret the relation between physical decline and felt experience through an explicit observation model that specifies what each clinical and experiential variable represents.

The shared-disease and sensor-confounding stress test should be rerunnable with the common cause, sensor gain, dropout, and clinical progression varied independently. Critics need access to the causal graph, synthetic fixtures, and decision thresholds that determine when terminal contraction becomes unidentified. Protected participant records may remain controlled, but the confounding logic cannot remain private (Aalen et al., 2008; Hernán & Robins, 2020).

The resulting terminal narrowing may persist across several devices and still be artifactual because the common cause was never modeled (Aalen et al., 2008; Hernán & Robins, 2020).

25.4.5 — Treatment and Care Pathways

Treatment and care pathways can reshape terminal data for ethically correct reasons. Sedation, analgesia, anxiolytics, hospice admission, nursing attention, spiritual care, family presence, and symptom management can reduce distress, reduce report capacity, alter physiology, or change observation cadence. They must be modeled as pathways, not noise (Sanders et al., 2024; Surges et al., 2024; Hernán & Robins, 2020).

The generator should include treatment initiation, dose changes, comfort protocols, escalation, discontinuation of burdensome monitoring, and site practice. It should also model time-varying

treatment confounding, because treatment decisions often depend on the state that later outcomes attempt to measure.

A hospice pathway can produce apparent repair without PTVc closure. Pain relief may reduce distress. Sedation may reduce report availability. Family presence may change expression. Device removal may protect skin. The resulting record may show less observed burden while the mechanisms are ordinary care.

The benchmark should compare analyses that adjust for treatment histories, model treatment as part of the data-generating process, or stratify by care pathway. It should also report when treatment makes the target estimand change rather than merely adding a covariate.

Comfort interventions are part of the care received during observation. Represent their timing and effects in the model when interpreting terminal signatures.

Palliative practice has its own scientific force. A study that ignores care pathways may turn mercy into a misleading mechanism.

Treatment and care pathway tests should be reproducible from versioned dose histories, care-state transitions, observation rules, and synthetic patient trajectories. A reviewer should be able to remove or alter a pathway and see whether model ordering changes. This separates a scientific effect of care from a narrative assigned after the endpoint (Aalen et al., 2008; Hernán & Robins, 2020).

Treatment and care-pathway analyses should cite the versioned causal and observation artifact used to generate or fit those

pathways. Medication, sedation, symptom control, transfer, and hospice enrollment must remain visible in the executable record. A narrative assurance that care was considered is not a substitute for modeled timing and uncertainty (Aalen et al., 2008; Hernán & Robins, 2020; Little & Rubin, 2019).

25.4.6 — Envelope Update Before Results

The rival envelope must be updateable before protected evaluation, not after results create incentives. A new mechanism enters through a new benchmark version and challenge set with recorded generator, parameter ranges, observation rules, expected signatures, and decision consequences (Aalen et al., 2008; Little & Rubin, 2019).

This rule avoids both a weak frozen contest and an outcome-driven rescue. Critics have standing to propose executable, scientifically relevant rivals capable of fresh prediction, and the public log shows when additions changed recovery or earlier status.

Each update is a reproducible diff with assumptions, implementation, protected-data access date, affected results, and a runnable predecessor. Time stamps and reruns distinguish prospective learning from post-result protection (Nosek et al., 2015; Munafò et al., 2017).

The envelope includes mathematical and institutional routes to the same appearance. Brownian bridges can induce conditional drift, while care pathways, sedation, transfer, device removal, or reduced reporting can create apparent late calming.

Endpoint definitions, censoring, alignment, and last-observation rules are fixed or versioned before the terminal window opens. Otherwise the benchmark can select the endpoint story that makes the graph look most meaningful.

Even a strong envelope retains an open-set escape route because the true generator may be absent. The system is allowed to reject every named model.

25.5 — Open-Set Adequacy and None-of-the-Models

Open-set adequacy asks whether the benchmark can recognize observations generated outside its named model families. A closed-world classifier must choose a winner even when every candidate is wrong. Open-set controls permit refusal, turning inadequacy into an explicit scientific result (Vehtari et al., 2017; Yao et al., 2018; Stanford, 2006; Scheirer et al., 2013; Hendrycks & Gimpel, 2017; Ovadia et al., 2019).

Forced classification can convert misspecification into apparent PTVC support. If a misspecified world is assigned to the candidate as the least bad fit, the benchmark has mistaken ignorance for evidence. None-of-the-models is therefore a substantive scientific outcome.

Open-set diagnosis requires posterior predictive misfit, residual and calibration diagnostics, holdout anomaly tests, flexible reference models, none-of-the-models verdicts, and explicit rules for admitting a new model.

25.5.1 — Posterior Predictive Misfit

Posterior predictive misfit asks whether fitted models can reproduce features of the data that matter but were not directly used to select the model. A model may win a comparison score and still fail to reproduce residual structure, tail behavior, missingness patterns, site variation, or terminal-window shape (Vehtari et al., 2017).

The benchmark should generate replicated data from fitted models and compare them to protected features. Features should

include variance trajectories, endpoint concentration, observation intensity, dropout timing, channel disagreement, site effects, tail events, and calibration across groups.

A PTVC candidate that fits endpoint concentration but fails to reproduce observation shutdown patterns may not be the right explanation. A frailty model that fits missingness but fails reserve-linked contraction may also fail. The adequacy question is broader than the pairwise score.

Predictive checks should be chosen before seeing protected evaluation results. If analysts search for checks only after a preferred model fails, the workflow becomes protection rather than testing.

Misfit should have consequences. Severe posterior predictive failure can trigger none-of-the-models, model revision, narrower claim status, or a requirement for new data. It should not be washed away by a favorable headline score.

Assess the full data-generating structure alongside fit to individual features. This makes the comparison informative about both local agreement and broader adequacy.

Flexible reference models should be stress-tested against known generators before human data are used to choose among them. If open-set inadequacy cannot be detected under controlled misspecification, added participant burden would only make the ambiguity larger and less visible. Recovery competence is therefore part of research ethics (Vehtari et al., 2017; Yao et al., 2018; Stanford, 2006).

Posterior predictive checks can look satisfactory in aggregate while failing in the endpoint window, a treatment stratum, or a low-observation group. The report should show which discrepancies were prespecified and where misfit concentrates. A global plot that averages away the decisive failure cannot support a winner label (Vehtari et al., 2017; Yao et al., 2018; Stanford, 2006).

25.5.2 — Residual and Calibration Diagnostics

Residuals are fingerprints of what a model failed to understand. They should be examined across time, endpoint distance, site, device version, medication, diagnosis, cultural context, observation intensity, and uncertainty level, while calibration checks whether probabilities and intervals behave as advertised (Yao et al., 2018; Stanford, 2006).

A calibrated model does not merely give narrow intervals. It gives intervals that cover at the declared rate under the relevant conditions, and probabilities that match empirical frequencies across strata. Poor calibration near the endpoint is especially damaging because that is where the public claim is sharpest.

Residual structure can reveal hidden rival mechanisms. If residuals drift with sedation, device version, or site workflow, the model may be missing a care pathway or observation artifact. If residuals change with endpoint uncertainty, the model may be overusing alignment.

The diagnostics should be plotted and tabulated, but the presentation should avoid turning them into dashboard authority.

The purpose is to find model failure, not to score persons, sites, or clinicians.

A calibration threshold should be prospectively specified for benchmark passing. If coverage, proper scores, or calibration curves fail beyond tolerance in critical windows, the model cannot carry confirmatory language.

The Law of Fairness lens appears as an audit of hidden burden: when residuals cluster by site, diagnosis, disability, or device, the interpretive cost may be falling on groups the model understands least.

Residual and calibration diagnostics should rerun from frozen predictions, protected split identifiers, configuration files, scoring rules, and prespecified thresholds. An independent analyst must be able to reproduce coverage by stratum, endpoint-window misfit, and every trigger for no verdict. The logic should remain open even when raw participant data require controlled access (Vehtari et al., 2017; Yao et al., 2018; Stanford, 2006).

Residual and calibration diagnostics should identify the verdict that the average score alone would have produced. The tempting error may be a declared winner whose intervals undercover, whose residuals drift near the endpoint, or whose probabilities fail in a vulnerable stratum. Making the blocked verdict visible shows why diagnostics are part of adjudication rather than decoration (Vehtari et al., 2017; Yao et al., 2018; Stanford, 2006).

Equation 25.4, Simulation-based calibration rank statistic.

$$r_m = \sum_{s=1}^S \mathbf{1} \left\{ \theta_m^{(s)} < \theta_m^{\text{sim}} \right\}$$

Role label: computational calibration check. Here m indexes a simulation replicate for one declared scalar parameter or test quantity, S is the number of posterior draws, the superscript sim marks the generating value, and superscript (s) labels its s -th posterior draw. Independent posterior draws yield the usual rank reference law; dependence must be accounted for when calibrating the diagnostic. For discrete test quantities or ties, randomized ranks or another prespecified tie rule is required. Departures from expected rank uniformity under the assumed generator can reveal algorithm or implementation problems, but the check does not validate the scientific model as nature’s generator (Talts et al., 2018; Säilynoja et al., 2026).

Table 25.5. Open-set adequacy and none-of-the-models triggers.

Trigger	Signal	Status consequence
Posterior predictive failure	key held-out features outside replicated data	model inadequate for tested claim
Residual structure	systematic error by site, endpoint distance, device, or treatment	missing rival or observation process
Calibration failure	probabilities or intervals unreliable in critical strata	model confidence cannot carry verdict
Open-set anomaly	protected data unlike all candidate worlds	none-of-the-models status considered
Flexible reference dominance	nonmechanistic model predicts much better	model set may lack mechanism

Trigger	Signal	Status consequence
New model entry	independently motivated generator with fresh predictions	new benchmark version before claim update

25.5.3 — Holdout Anomaly Tests

Holdout anomaly tests ask whether protected synthetic or empirical features fall outside the behavior of all candidate models. They are not used to crown a winner. They are used to detect that the model set may be incomplete (Stanford, 2006).

The holdout units must respect dependence. Person, site, endpoint window, device version, and time segment should not leak across training and evaluation in ways that make anomaly detection look better than it is. Random observation-level splits are not acceptable for this purpose.

Anomaly tests can use proper scores, posterior predictive tail probabilities, learned low-dimensional summaries, and prespecified feature distances. Flexible methods are allowed as detectors, but their interpretive status remains limited unless they become specified generative models with fresh predictions.

A useful example is a new site whose observation shutdown policy differs from development sites. A closed-set model may force the site into a known class. An anomaly test may reveal that the entire observation process is outside the trained envelope.

Anomaly detection should be calibrated on synthetic open-set worlds. Otherwise it may either flag everything unusual or miss exactly the strange cases it was built to find.

When a holdout anomaly is severe, the result should become a protected-theory warning, not a public curiosity. The correct output may be No adequate estimate, no verdict, and a benchmark update.

Near-miss generators should preserve familiar marginal curves while introducing a scientifically relevant difference in the joint observations. The benchmark tests whether that observable difference can be detected. If two generators induce exactly the same law for all permitted observations, no anomaly detector can distinguish them from those observations alone; report structural nonidentifiability and identify what additional measurement or assumption would be required (Vehtari et al., 2017; Yao et al., 2018; Stanford, 2006).

Holdout anomaly tests should be cited by artifact version, protected split, discrepancy family, calibration procedure, and decision rule. The result should show whether all offered models missed the same structure rather than merely ranking them. Open-set inadequacy requires an executable trail because the least bad score is otherwise easy to mistake for adequacy (Vehtari et al., 2017; Yao et al., 2018; Stanford, 2006).

25.5.4 — Flexible Reference Models

Flexible reference models are useful because the world may be more complex than any mechanistic candidate. Gaussian processes, splines, state-space learners, ensemble predictors, and other nonparametric baselines can reveal whether mechanistic models are leaving predictable structure behind (Vehtari et al., 2017; Yao et al., 2018).

These flexible models should not receive interpretive authority by default. A neural network that predicts terminal windows well has not discovered the latent ledger. A nonparametric smoother that matches variance compression has not identified reserve coupling. It has found predictive structure that mechanistic models must explain or concede.

The benchmark should use flexible models as baselines for held-out prediction, calibration, residual analysis, and anomaly detection. If a flexible reference greatly outpredicts all mechanistic models, the model set may be inadequate even if one mechanistic model beats another.

Overfitting remains a danger. Flexible references require nested tuning, protected holdouts, regularization, calibration, and transport stress. Otherwise they become another way to preserve the appearance of performance without scientific meaning.

The report distinguishes predictive performance from the explanation assigned to it. A flexible reference can set a performance benchmark and suggest improvements to generator design. The empirical claim tested determines how that comparison contributes to the broader research program.

Equal treatment protects both sides. It prevents the PTVC candidate from defeating weak models and prevents flexible prediction from masquerading as philosophical explanation.

Open-set testing must work on synthetic worlds in which none of the offered models is true before further data are sought from people or sites. Failure to recognize that condition means the pipeline can convert any dataset into a winner. The humane

scientific choice is to repair the test rather than expand observation (Vehtari et al., 2017; Yao et al., 2018; Stanford, 2006).

The release record for flexible reference models must state the consequence of failure before the check is run. Depending on the role of open-set adequacy and none-of-the-models, failure may trigger a narrower estimand, expanded rival envelope, redesigned observation plan, No adequate estimate status, artifact withdrawal, or retirement of a route. In flexible reference models, a check constrains interpretation only when its possible outcomes carry prospectively specified consequences (Vehtari et al., 2017; Yao et al., 2018; Stanford, 2006).

25.5.5 — None-of-the-Models Verdict

None-of-the-models is a formal benchmark outcome. It means that, under a qualified analysis, no candidate model meets the declared adequacy criteria, including calibration and held-out prediction standards, for the target claim. It is not a rhetorical concession. It is a planned scientific status (Yao et al., 2018).

The verdict should be triggered by prospectively specified adequacy conditions: severe posterior predictive misfit, poor calibration across critical strata, failure on protected holdouts, or flexible references revealing large unexplained structure across all declared candidates. Failure of required open-set recovery thresholds instead blocks qualification of the affected analysis. The rule must be known before the benchmark runs.

A none-of-the-models result can preserve value. It may show that observation artifacts dominate, that endpoint definitions are too

weak, that treatment pathways need explicit modeling, or that the model class is missing a major mechanism. The right conclusion is not ‘nothing was learned’. It is that the current model set should not carry the claim.

The None-of-the-models verdict identifies the current model set as inadequate for the tested question. It directs the next stage toward a broader or revised set of candidates and a new comparison under declared criteria.

None-of-the-models should remain an honorable outcome. A field that can say every model failed is less vulnerable to confirmation pressure than a field that always announces the best available story.

An open-set verdict invites new models to enter through the same qualification and comparison requirements as the existing candidates.

A none-of-the-models verdict should record the exact triggers, affected target, failed adequacy checks, and conclusions that are blocked. It should also identify whether the next action is new generator design, a narrower estimand, additional calibration, or no further human study. The status must remain machine-readable so that downstream summaries cannot silently replace it with the least bad candidate (Vehtari et al., 2017; Yao et al., 2018; Stanford, 2006).

The none-of-the-models rule should be evaluated against the counterfactual closed-set verdict. Reviewers should see which candidate would have been crowned solely because the analysis lacked an open-set outcome and why that label is misleading. The

safeguard succeeds when it converts forced certainty into an explicit inadequacy result (Vehtari et al., 2017; Yao et al., 2018; Stanford, 2006).

25.5.6 — New Model Entry Rules

Model entry requires independent motivation and fresh predictions. Sources include critics' mechanisms, systematic misfit, changed measurement technology, or formal amendments (Stanford, 2006; Vehtari et al., 2017).

The package includes a generative specification, observation rules, parameter budget, plausible ranges, expected signatures, recovery plan, computation, and public status. Changes to the hypothesis or candidate model follow the versioning and review procedures in Chapter 28.

Protected challenge sets separate explanation from prediction. A revision may explain the benchmark that inspired it, but predicts only when it succeeds on new data.

Entry rules also include removal. Models that repeatedly fail recovery, adequacy, or transport are narrowed or retired so the library does not become a museum of protected options.

Public language remains modest: a promising model is a candidate, not a rescue, and a formal amendment is a proposal, not a hidden update.

With open-set adequacy established, transport and stress tests ask whether recovery survives movement across sites, populations, instruments, and assumptions.

The public entry record names motivation, equations or algorithm, parameter budget, permitted observations, code, prospectively specified tests, and version, preferably before the protected benchmark opens.

Distinguish pre-holdout models from later additions. Record proposal, code, budget, access, benchmark date, and consequence rule; chronology guards against post hoc rescue (Vehtari et al., 2017; Yao et al., 2018; Stanford, 2006).

A flexible reference may predict better or reveal missed structure without earning causal or metaphysical interpretation. Prediction and explanation remain separate.

Before results, fix none-of-the-models thresholds for predictive misfit, calibration failure, residual structure, and holdout anomalies. Open-set safeguards cannot be improvised afterward.

A model invented after seeing the data remains exploratory until it makes fresh predictions; it cannot retroactively validate the old claim.

Open-set adequacy matters most when every candidate has a constituency. It prevents scientific familiarity, mathematical elegance, philosophical meaning, or computational prestige from being mistaken for completeness.

The none-of-the-models branch must change the study. If all mechanisms fail and a flexible reference exploits only site or device artifacts, the result is model-set inadequacy and the next action is construction or redesign, not a public winner.

25.6 — Transport and Stress Tests

Transport is where model recovery leaves the laboratory of its own assumptions. A pipeline may recover at development sites with familiar devices, diagnoses, endpoint rules, and missingness, yet fail when those conditions change (Arjovsky et al., 2019; Peters et al., 2016; Yao et al., 2018; Ovadia et al., 2019; Sagawa et al., 2020).

Stress tests vary site practice, population, instrument, prevalence, prior structure, missingness, noise, language, and development environment. Out-of-distribution behavior is reported as a target of inference rather than hidden inside an average score.

Transport failure is information. A model may work in hospice oncology and fail in sudden neurological injury, or work under one wearable version and fail under another. Scientific status follows that specificity.

25.6.1 — Site Shift

Site shift captures differences in care practice, staffing, recruitment, devices, charting, hospice philosophy, endpoint adjudication, and local norms. A model developed in one site may recover because it has learned that site’s observation regime rather than a general mechanism (Arjovsky et al., 2019).

The benchmark should implement leave-site-out and synthetic site perturbation. In leave-site-out evaluation, all data from a site remain protected until model selection and tuning are complete. In synthetic perturbation, site-level parameters are varied beyond observed development ranges.

A site shift example is a hospice program that removes devices earlier for comfort than the development sites. Apparent terminal calm may become a policy artifact. A model that treats device removal as random may fail transport, even if it performed well elsewhere.

Site-level stress should report prediction, calibration, recovery, and confusion. It should also report which variables would have been needed to transport better. That output informs the next protocol rather than assigning blame to the site.

The public verdict should not generalize beyond the transported domain. If the result is site-dependent, the claim becomes site-limited. That is narrower, but it is scientifically cleaner.

This rule respects institutions as contexts, not mere data factories. A site is part of the data-generating process.

Site-shift analysis should be reproducible through site-level manifests, protected holdout assignments, calibration procedures, and transport weights. A critic should be able to remove one site, change the target mix, and identify where the claimed advantage fails. Aggregated public data may be used when privacy prevents record-level release, but the transport calculation must remain inspectable (Sugiyama et al., 2012; Pearl & Bareinboim, 2014).

Site shift often hides inside a pooled success. A model may transport in average loss while failing calibration at sites with different care pathways, device practices, or sampling schedules. Site-level intervals, residuals, and mechanism checks should therefore accompany the pooled estimate, with narrowing when

the advantage is not stable (Sugiyama et al., 2012; Pearl & Bareinboim, 2014).

25.6.2 — Population Shift

Population shift includes age, diagnosis, disability, culture, language, trauma history, medication burden, cognitive state, socioeconomic context, and life stage. A model that recovers in one population may fail when the meaning and measurement of channels change (Peters et al., 2016; Yao et al., 2018).

The benchmark should vary population parameters and use held-out population strata where possible. It should test whether sign conventions, calibration, missingness, endpoint adjudication, and channel weights remain meaningful across groups.

A disability example makes the risk concrete. Low movement may mean fatigue, neurological impairment, comfort, device placement, or ordinary baseline. A model that learned movement as burden in one group may misread another group unless person-specific and group-specific calibration are built into the generator and fit.

Population stress also applies to culture and language. Report scales, expression norms, family involvement, hospice scripts, and willingness to decline measurement can vary. Treating those differences as noise may create unfair uncertainty transfer.

Transport should report where the model must abstain. A subgroup with inadequate calibration is not a moral exception. It is a scientific boundary.

The Law’s public claim cannot be widened by convenience. Human clinical evidence travels only through explicit transport assumptions, measurement invariance, and demonstrated recovery under relevant shifts.

A population-shift trace should state the training and target populations, inclusion rules, age, diagnosis, disability, language, culture, treatment, site, and observation differences that matter to transport. It should report where calibration or recovery failed and which conclusion was withdrawn. Without that record, “generalization” becomes an adjective rather than an empirical claim.

The population-shift audit should display the broad claim that would have been exported from the development cohort without reweighting, recalibration, or transport checks. It then shows how prevalence, covariate support, and mechanism mix alter the score and uncertainty. The difference is the empirical cost of pretending that one population stands for all (Sugiyama et al., 2012; Pearl & Bareinboim, 2014).

Table 25.6. Dependence-respecting holdout units for transport stress.

Holdout unit	Leakage blocked	What it tests
Leave-person-out	protects whole persons from train-test leakage	generalization across streams
Leave-site-out	protects sites from development leakage	transport across care regimes
Leave-device-version-out	protects instrument versions from leakage	version and calibration robustness

Holdout unit	Leakage blocked	What it tests
Forward-chain time folds	keeps future evaluation windows out of model fitting and tuning	temporal prediction and update discipline
Endpoint-threshold holdout	protects stopping decisions	prevents endpoint leakage
Out-of-distribution stress	synthetic shift beyond development range	narrowing or abstention under shift

25.6.3 — Instrument Shift

Instrument shift appears when devices, firmware, survey instruments, clinical templates, or data-processing pipelines change. The measured world can move even when the underlying process does not. A benchmark that ignores versioning can mistake engineering drift for biological or experiential dynamics (Yao et al., 2018).

The stress test should include leave-device-version-out evaluation, calibration-transfer simulations, feature-definition changes, sampling-frequency changes, and sensor quality variation. It should record whether recovery depends on a particular instrument generation.

A firmware update can alter artifact rejection, heart-rate variability estimates, sleep staging, or missingness labels. If that update occurs during a terminal study, the apparent trajectory may shift. The version field is not bookkeeping; it is part of the observation model.

Instrument stress should also test old data reprocessing. If a new pipeline changes historical values, the benchmark must decide

whether to freeze the old release, rerun all analyses, or label results as not comparable.

The decision rule is straightforward. A claim that fails under plausible instrument shift becomes instrument-limited or requires recalibration before interpretation.

Device qualification prevents instruments from being treated as transparent windows. Instruments witness imperfectly, and their imperfections travel into model recovery.

Instrument-shift testing should preserve device model, firmware, survey version, clinical template, preprocessing, unit conversion, calibration data, and missingness changes. The trace must make it possible to reproduce the point at which an apparently stable model ceased to transport. Instrument updates are part of the data-generating system, not clerical metadata.

Instrument shift can preserve a smooth trajectory while changing scale origin, sensitivity, lag, or floor effects. The ambiguity is especially severe when device replacement coincides with clinical decline. Bridge samples, calibration fixtures, and version-specific observation models should show whether the scientific conclusion survives the instrument change (Little & Rubin, 2019; Hernán & Robins, 2020).

25.6.4 — Prevalence and Prior Shift

Prevalence and prior shift affect model comparison when the base rates of generators, endpoint types, diagnoses, observation artifacts, or care pathways change. A model that looks plausible in a high-terminal-risk setting may behave differently in a broader life-course cohort (Arjovsky et al., 2019; Peters et al., 2016).

The benchmark should vary prior weights over generator families and simulate different prevalence regimes. It should report how posterior model probabilities, stacking weights, thresholds, and none-of-the-models decisions change when the prior landscape changes.

Prior shift can expose hidden favoritism. If the PTVC candidate is selected mainly because benchmark priors make rival artifacts rare, the conclusion depends on an assumption rather than data discrimination. That dependence should be printed.

The analysis should separate prior sensitivity from empirical separation. A strong design can withstand reasonable prior variation. A weak design may swing among models as priors move, indicating that the data are not carrying the comparison.

The report should not hide this behind a single default prior. It should state which priors are skeptical, neutral, expert-informed, or stress-test priors, and which conclusions survive each.

Prevalence shift reminds the reader that model comparison is not only about fitting curves. It is about what worlds the protocol considered possible before data arrived.

The report should state development and target prevalences, covariate support, prior model weights, and any reweighting or recalibration method, then show how model ordering changes across defensible target prevalences. Because prior shift can alter posterior probabilities without changing individual observations, a winner that depends on an unverified prevalence assumption remains transport-sensitive (Sugiyama et al., 2012; Pearl & Bareinboim, 2014).

25.6.5 — Adversarial Missingness and Noise

Adversarial missingness and noise stress the observation model deliberately. The benchmark should ask how bad observation can become before recovery collapses, and whether collapse is detected rather than converted into false support (Peters et al., 2016).

The stressors include state-dependent dropout, endpoint-dependent observation, device removal, staff cadence change, channel-specific sensor artifacts, floor effects, saturation, delayed reports, cultural nonresponse, and noise floors that are misestimated by the fitting model.

An adversarial test might remove high-burden observations near endpoints, increase noise when reserve is low, or make calm states more observable than distressed states. If the analysis then finds terminal neutrality, the benchmark has located a false-support pathway.

The model should also be tested for false defeat. Severe noise may hide a true reserve-coupled signature and lead to a wrong rejection. False support and false defeat both matter because both distort the claim status.

The output should be a map of safe, fragile, and invalid observation regimes. A universal exponent or universal claim is not acceptable when recovery is conditional on noise and missingness levels.

Adversarial missingness is where the chapter turns suspicion into design. It refuses to let bad observation become a quiet collaborator in overclaim.

Adversarial tests must expose the missingness generator, noise distribution, severity grid, and decision rule. Independent reruns must locate calibration failure or changed model ordering, including selective terminal dropout. Without these fixtures, robustness merely asserts what unobserved data would show (Little & Rubin, 2019; Hernán & Robins, 2020).

Audit the conclusion produced by treating selective disappearance as random noise. A shrinking terminal record may mimic latent contraction while unobserved cases show the opposite. Stress tests earn their place by overturning that favorable but unsupported verdict (Little & Rubin, 2019; Hernán & Robins, 2020).

25.6.6 — Transport Failure

Transport failure means recovery, calibration, or prediction succeeds locally but fails elsewhere. It bounds model use without necessarily defeating it (Yao et al., 2018; Arjovsky et al., 2019).

Classify failures by cause: site practice, population calibration, instrument version, prior shift, observation artifact, endpoint uncertainty, treatment pathway, computation, or open-set misfit. A classified failure is more useful than a vague loss.

The result should change claim status. A model transporting across hospice oncology but failing in sudden death cannot speak for sudden death. A model transporting across devices only after recalibration must require it before future use, and one failing across cultures cannot claim cross-cultural generality.

Transport failure also guides future research. It may identify missing covariates, needed calibration, alternative endpoints, or

rival mechanisms. Narrowing should be productive rather than shameful.

Public communication should say exactly what failed to travel. This prevents broad headlines from borrowing the authority of narrow success.

The next section gives critics a formal role in finding these failures before the project can turn them into private inconveniences.

Record transport findings with source and target environments, prediction or recovery criteria, sensitivity analyses, and consequences for use. Preserve both successful and unsuccessful transfers in the scientific record.

Fix the consequence of transport failure before testing. Depending on its role, failure may narrow the estimand, expand the rival envelope, redesign observation, trigger No adequate estimate, withdraw an artifact, or retire a route. Without a precommitted action, a diagnostic describes fragility but does not adjudicate it (Arjovsky et al., 2019; Peters et al., 2016; Yao et al., 2018).

Leave-site-out and leave-device-version-out tests directly ask whether a model learned general structure or a local operating regime. It may instead learn that one hospice records symptoms differently, one device handles skin contact differently, or one recruitment path selects less severe cases.

Prevalence and prior shift matter because model comparison can be fragile when base rates change. A rare endpoint pattern in one cohort may become common in another because of diagnosis mix,

medication practice, or site referral patterns. Scores should be evaluated under plausible prevalence shifts before public language broadens.

Transport stress also creates a humane No adequate estimate rule. If a model succeeds only in its development environment, later sites should not be asked to carry confirmatory language. Their role may be exploratory transport testing, not proof-bearing replication.

Test quiet contextual differences: reports before versus after medication rounds, device tolerance of motion, cultural expression of late distress, and diagnosis-dependent relations among sedation, wakefulness, and available reports. Ignoring them may recover the site rather than the process.

Name what failed to travel. Parameters may transport while model selection fails; calibration may survive while endpoint sensitivity fails; figures may resemble each other while predictive scoring collapses. Claims must specify what remains valid across contexts.

25.7 — Red Teams and Challenge Logs

Red teams are the social form of model recovery. They give organized standing to independent reviewers testing the pipeline before its public use. Reproducible challenges and documented consequences give this review its scientific value (Nosek et al., 2018; National Academies of Sciences, Engineering, and Medicine, 2019; UNESCO, 2021a; Munafò et al., 2017; Cogitate Consortium et al., 2025).

Challenge logs preserve the memory of those attempts. They record attack, severity, reproduction, response, unresolved status, code changes, reruns, and public-wording changes. A private patch without a record erases the path by which the program learned.

Adversarial governance specifies roles, bounties, exploit logs, patch rules, critic protection, and public challenge norms. It keeps criticism rigorous without making critics into enemies or turning participant data into spectacle.

25.7.1 — Independent Red-Team Roles

Independent red-team roles prevent one kind of expertise from standing in for all critique. A model red team attacks generators and identification. A measurement red team attacks channels, calibration, and missingness. An endpoint red team attacks stopping rules and alignment. A software red team attacks code, containers, and reproducibility. An ethics red team attacks participant burden and public misuse (Nosek et al., 2018).

The roles should be separated enough to avoid groupthink. A strong statistician may miss a palliative care pathway. A software auditor may miss a cultural reporting problem. A clinician may miss endpoint leakage in code. Each role carries a different map of failure.

Adversarial collaboration offers a tested social design for part of this work. Current methodological analysis emphasizes advance agreement on predictions, operationalizations, analysis rules, documentation, and neutral arbitration, while participants report that the process is demanding and more often clarifies boundary conditions than produces a simple winner (Ceci et al., 2024; Isch et al., 2025). For this program, that is a strength. Red teams should reveal where models diverge, where both fail, and what remains unresolved, not manufacture a public contest whose result was never scientifically defined.

The protocol should give red teams access to synthetic benchmarks, documentation, prospective specification plans, code, and non-sensitive artifacts before protected human data are interpreted. Sensitive data access requires restricted rules, but lack of access should not become a reason to avoid critique.

Red teams should be allowed to specify rival generators and failure tests. Their proposed tests should be recorded even when rejected, with reasons. A critique that does not change the benchmark may still reveal an assumption the public should know.

Independence does not require hostility. The best red team wants the science to be harder to fool. That motivation is compatible with skepticism, support, or uncertainty about the Law.

This structure prevents adversarial testing from becoming a personality contest. The attack is on the claim, the model, the code, or the wording, not on the worth of participants, critics, or authors.

Red-team preparation should include near-miss cases in which most prospectively specified assumptions hold but one decisive leakage, conditioning, or transport rule fails. These fixtures test whether critics and maintainers can locate the failure without being told which module contains it. A challenge process that succeeds only on conspicuous errors is not yet protecting the scientific boundary (Nosek et al., 2015; Munafò et al., 2017; Nüst et al., 2020).

Independent red-team findings should cite the challenge specification, submitted artifact, evaluation environment, response, and final disposition. The cited record should make clear whether the issue was reproduced, fixed, rejected, or left open. Adversarial review becomes science only when its outcome can be followed beyond the meeting room (Nosek et al., 2018; National Academies of Sciences, Engineering, and Medicine, 2019; UNESCO, 2021a).

25.7.2 — Challenge Bounties

Challenge bounties reward substantive counterexamples and reproducible flaws. They can help shift incentives away from applause and toward vulnerability. A bounty should pay for a

better rival, a reproducible code failure, a leakage demonstration, a calibration flaw, a harmful public wording risk, or an open-set world that defeats the current benchmark (National Academies of Sciences, Engineering, and Medicine, 2019; UNESCO, 2021a).

The bounty criteria should be public. A submission should specify the claimed flaw, the artifact affected, steps to reproduce, expected consequence, severity, and suggested repair when available. Vague denunciation is not a bounty claim, though it may still be a public-risk signal.

Bounties should not reward harassment, participant exposure, clinical intrusion, or sensational screenshots. The chapter's challenge system is scientific, not vigilante. Protected data, vulnerable communities, and research staff remain protected.

A strong bounty example is a critic who supplies a selection-conditioned diffusion that produces apparent endpoint concentration and beats the PTVC candidate under held-out prediction. The correct response is not defensiveness. It is to enter the rival, rerun the benchmark, and update claim status.

Funding and governance of bounties should be independent enough to avoid donor capture or founder protection. The rules should state who decides validity, how appeals work, and how conflicts are disclosed.

The bounty system makes losing useful. It turns the strongest criticism into a public service rather than a threat to identity.

Challenge bounties should first target code, synthetic fixtures, and public artifacts so that vulnerabilities can be found without increasing participant burden. Human or animal data should enter

only when the challenge cannot be resolved by less intrusive means and the expected scientific gain is specific. Adversarial rigor does not require adversarial treatment of participants (Nosek et al., 2018; National Academies of Sciences, Engineering, and Medicine, 2019; UNESCO, 2021a).

Challenge bounties can improve coverage while also rewarding conspicuous exploits over quiet structural defects. The protocol should credit reproducible scientific impact, protect low-profile submissions, and separate vulnerability discovery from public performance. A challenge that optimizes attention rather than model correction can create theater while leaving the benchmark weak (Nosek et al., 2015; Munafò et al., 2017).

Table 25.7. Red-team roles and attack surfaces.

Role	Attack surface	Possible output
Model red team	generators, priors, identifiability, rival envelope	new generator or narrowed claim
Measurement red team	channels, calibration, missingness, sign conventions	observation-model patch or No adequate estimate
Endpoint red team	stopping rules, alignment, leakage	endpoint rerun or exclusion of flawed result
Software red team	code, containers, splits, seeds, dependencies	patch, rerun, security update
Ethics/public team	burden, privacy, captions, vulnerable readers	wording change or artifact withdrawal

Equation 25.5, Challenge-log completeness condition.

$$C_k := (a_k, r_k, s_k, p_k, u_k)$$

$\text{Complete}(C_k) = 1$ iff a_k, r_k, s_k, p_k , and u_k are all present.

The fields record the attack or challenge, reproduction status, severity, patch or response, and public-status update. Role label: artifact-governance diagnostic. The tuple is not a statistical theorem; it is a reproducibility rule for adversarial challenge records.

25.7.3 — Exploit Log

An exploit log is the replayable record of how the benchmark was attacked. Each entry should include a stable identifier and version, submitter role, affected component and release, severity, reproduction status, exploit description, minimal reproducible fixture, expected and observed failure, response or patch, rerun and regression-test result, public-language implication, final disposition, and unresolved risk. A critic should be able to replay both the vulnerability and the claimed repair without relying on private correspondence (Nosek et al., 2015; Nosek et al., 2018; Munafò et al., 2017; Nüst et al., 2020; National Academies of Sciences, Engineering, and Medicine, 2019; UNESCO, 2021a).

The word exploit is deliberate but bounded. It means a route by which the pipeline, artifact, analysis, or public wording can be made to overclaim, underreport uncertainty, misclassify a rival, leak protected information, or mislead readers. It does not mean attacking persons.

Severity should be tied to consequence. A typo in a caption is minor unless it changes claim status. Endpoint leakage in the final challenge set is critical. A code path that tunes thresholds on

protected data is critical. A public figure that compresses none-of-the-models into support is high risk.

The log should distinguish reproduced, not reproduced, disputed, fixed, accepted risk, and retired entries. Not every challenge will be correct, but every substantive challenge should leave a trace.

A public version can redact sensitive details while preserving the scientific lesson. Restricted versions can contain code, data identifiers, or security details that would create risk if released broadly.

The exploit log is a memory against quiet self-protection. It lets the project improve without pretending it was always clean.

25.7.4 — No Private Patch Without Record

A discovered flaw that affects results or interpretation must be repaired through a versioned record naming what changed, why it changed, the affected releases and analyses, code or protocol changes, added tests, required reruns, invalidated results, and corrected or withdrawn artifacts. Preserve the pre-patch results and verdicts so reviewers can trace changes in leakage, recovery, model ordering, or public status (Nosek et al., 2015; Nosek et al., 2018; Munafò et al., 2017; Nüst et al., 2020; National Academies of Sciences, Engineering, and Medicine, 2019).

The rule should apply to code, equations, synthetic generators, preprocessing, figures, tables, threshold choices, and public summaries. It should also apply to errors that hurt the PTVC candidate. Correction is not only for flaws that protect the theory.

There may be security exceptions. A vulnerability that exposes sensitive data may require delayed disclosure or restricted details. Even then, the existence of the issue, the affected releases, and the resolution status should be recorded in an appropriate layer.

This rule gives the scientific program a visible conscience. It lets trust be rebuilt through correction rather than maintained through concealment.

25.7.5 — Critic Protection and Nonretaliation

Critic protection is a scientific requirement when a project has public identity, community interest, or donor attention. A critic who finds a real flaw should not be treated as disloyal, hostile, or morally suspect. The benchmark needs their pressure (National Academies of Sciences, Engineering, and Medicine, 2019).

Nonretaliation rules should cover publication, community moderation, access to artifacts, bounty eligibility, and public response. A critic can be wrong, sharp, or inconvenient without losing standing. Abuse and harassment can be moderated, but substantive criticism should remain protected.

The protocol should separate adjudication from public popularity. A challenge is assessed by reproducibility, relevance, severity, and effect on claims, not by whether supporters like the submitter.

Critic protection also protects the project. If critics fear retaliation, flaws move underground, and public artifacts become more brittle. A project that supports serious critique strengthens its scientific independence and public trust.

Critic-protection procedures should leave a versioned, inspectable record of the challenge, evidence, reproduction status, response, patch or nonpatch decision, confidentiality option, conflict or retaliation concern, response time, and appeal route outside the challenged team. Later claims of an open challenge culture should cite that operating record (Nosek et al., 2015; Nosek et al., 2018; Munafò et al., 2017; National Academies of Sciences, Engineering, and Medicine, 2019; UNESCO, 2021a).

25.7.6 — Public Challenge Without Theater

Public challenge can strengthen the program, but debate-as-verdict, humiliation clips, pile-ons, scoreboards, and winner-loser framing replace method with spectacle. Public artifacts should distinguish submitted challenge, reproduced flaw, unresolved dispute, resolved patch, and claim-status change rather than slogans such as proved or destroyed (UNESCO, 2021a; Nosek et al., 2018).

Challenges belong first to executable artifacts and bounded questions. Synthetic fixtures, thresholds, rival envelopes, and caption drafts let critics test the benchmark without exposing participants, families, clinicians, sites, or private records. A failed benchmark is never permission for personal endpoint testing, harm, clinical delay, or public scoring.

When the method is nonseparable or unrecoverable, more intimate data cannot substitute for missing analysis. The challenge must improve the model before it enlarges participant burden (National Academies of Sciences, Engineering, and Medicine, 2019).

Staged disclosure, neutral replication, and visible status changes keep preliminary exploits and institutional rebuttals from becoming personality contests. The aim is a reproducible path from objection to correction, not humiliation (Nosek et al., 2015; Munafò et al., 2017).

Red teams should work before artifacts become costly to change, and mature logs should preserve unresolved entries without treating them as scandal. Some attacks await a stronger simulator; others expose wording risk rather than model error.

Public challenge without theater is not timidity. It is the courage to make the evidence trail stronger than prestige while keeping vulnerable people outside the spectacle.

25.8 — Code, Containers, and Reproducible Artifacts

For a computational benchmark, reproducibility means a critic can identify the exact code, data layer, synthetic generator, environment, prospective specification, decision thresholds, and release artifacts that produced a result. It also means sensitive human data remain protected rather than sacrificed to openness (Sandve et al., 2013; Boettiger, 2015; Wilkinson et al., 2016; Nüst et al., 2020; Peng, 2011; Wilson et al., 2017).

The artifact structure has six linked layers. Versioned source and release identities connect claims to code. Containers and environment files preserve execution context. Synthetic fixtures and unit tests protect formulas and transformations. Machine-readable prospective specifications bind code to decisions. Restricted and public layers balance reproducibility with privacy. Retirement and security rules make correction durable.

The section closes the chapter by turning answerability into a file system, a release practice, and a public discipline. The book supplies the scientific meaning. The artifacts let others test whether the machinery actually does what the book says it does.

25.8.1 — Versioned Source and Release IDs

Versioned source connects a published claim to exact code. A model-recovery result should cite a release ID, commit hash or equivalent, generator version, analysis version, decision-threshold version, and artifact manifest. Without that chain, a result cannot be reproduced with confidence (Sandve et al., 2013).

The release ID should appear in tables and benchmark reports, not only in a repository. If a figure changes because code changes, the figure receives a new release reference. If a generator changes, affected recovery results are flagged.

Versioning should cover notebooks, scripts, data dictionaries, container files, prospective specification files, synthetic fixtures, random seeds where appropriate, and rendered public artifacts. A polished chapter figure should be traceable to the code that created the underlying benchmark.

The release practice should avoid raw links in manuscript prose. The book can name the artifact class and release structure, while actual distribution belongs to governed publication channels and repositories.

A versioned release also protects against accidental canon drift. A public summary cannot quietly update a model assumption while still claiming the authority of an older benchmark.

This is a humble rule with large consequences. Exact source identity lets criticism land on an object rather than a memory.

Release identifiers should be tested against near-identical artifacts whose bytes, dependencies, source data, or frozen assumptions differ consequentially. The audit must detect when one human-readable title points to scientifically noncomparable executable states; checksums, manifests, and semantic-version notes must recover the exact state cited by each result (Nüst et al., 2020; Wilkinson et al., 2016).

25.8.2 — Containers and Environment Files

Containers and environment files preserve computational context. A benchmark may depend on probabilistic programming versions, numerical libraries, random number generators, plotting code, compilers, operating systems, and hardware assumptions. Without environment capture, reruns can fail or subtly differ (Boettiger, 2015; Wilkinson et al., 2016).

A container specification should include language versions, package versions, operating-system base, external dependencies, and commands to run the benchmark. Environment files for lighter workflows should be paired with lock files when possible.

Containers do not solve all reproducibility problems. They can become insecure, outdated, or impossible to run on future systems. The artifact plan should therefore include hashes, archived images, human-readable environment descriptions, and periodic rebuild tests.

The benchmark should include a minimal smoke test and a full challenge run. A critic should be able to run a small fixture quickly, then run the larger benchmark with documented compute needs.

Computation time belongs in the report. A method that recovers models but requires unrealistic resources may not be suitable for the planned research program or for independent replication.

Computational humility becomes concrete when rerunning is treated as part of a claim’s vulnerability.

Containers and environment files are qualified on synthetic fixtures before restricted empirical data are introduced. A reproducibility failure at that stage stops deployment and triggers correction without exposing additional participants. Technical preparation is part of minimizing research burden (Sandve et al., 2013; Boettiger, 2015; Wilkinson et al., 2016; Nüst et al., 2020).

Containers reduce environmental drift but do not eliminate it. Base images can disappear, hardware or numerical libraries can change behavior, and hidden network calls can break a claimed offline run. Validation across clean environments and archived dependency layers is needed before reproducibility is declared (Nüst et al., 2020; Wilkinson et al., 2016).

Table 25.8. Reproducible artifact layers.

Artifact layer	Contents	Scientific function
Source release	exact code, generator version, analysis version	reproduce the benchmark that produced a claim
Container/environment	dependencies, operating system, commands	rerun without invisible software drift
Synthetic fixtures	small known cases and edge cases	test formulas, transforms, leakage, and signs
Machine-readable prospective specification	locked decisions, thresholds, holdouts, status labels	compare executed analysis to declared plan
Restricted layer	sensitive empirical data and site-specific details	protect participants while preserving audit route

Artifact layer	Contents	Scientific function
Retirement record	superseded, deprecated, withdrawn, archived status	keep old artifacts from speaking with current authority

Equation 25.6, Release identity.

$$R = (G, M, O, D, T, S, V)$$

Role label: reproducibility manifest. In this tuple, G identifies the generator release, M the fitted-model and analysis release, O the observation-system specification, D the data or synthetic-fixture release, T the decision-threshold specification, S the protected-split and seed specification, and V the software environment and manifest version. A result without a release identity cannot be fully reproduced or challenged under the standards established here.

25.8.3 — Synthetic Fixtures and Unit Tests

Synthetic fixtures are small known datasets designed to test formulas, transformations, edge cases, and failure routes. Unit tests check that the code implements the declared model rather than a convenient approximation. They are where mathematical care becomes executable (Wilkinson et al., 2016).

Fixtures should include clean reserve-coupled data, OU data, bridge data, observation shutdown, missingness patterns, device version changes, endpoint uncertainty, extreme noise floors, and open-set misspecification. Each fixture has expected outputs or acceptable ranges.

Unit tests should check sign conventions, time alignment, endpoint independence, leakage prevention, train-test splitting, posterior predictive generation, SBC ranks, proper scores, and

figure-building data. A single sign error can convert burden-increasing into restorative signal.

The benchmark should include tests that are expected to fail when a known exploit is inserted. For example, a leakage fixture should show inflated recovery if protected endpoint thresholds leak into training. This makes the test suite adversarial, not merely confirmatory.

Wholly artificial fixtures can normally be released after a disclosure-risk check. Fixtures calibrated from sensitive participant or site data require review of what their parameters and outputs could reveal. A synthetic label alone does not establish that a release contains no private information.

Executable checks show whether the declared machinery runs as specified and make the implementation independently inspectable.

Synthetic fixtures and unit tests should record the target invariant, expected pass or failure, edge cases, software version, and responsible maintainer. Fixtures must include adversarial examples that break convenient assumptions, not only examples that demonstrate success. Their role is to make regression visible before a new release reaches empirical data.

Synthetic fixtures and unit tests should state the scientific error that would survive if each test were removed. A sign inversion, stale seed, endpoint leak, wrong likelihood, or broken missingness branch can otherwise generate a convincing benchmark result. The test suite is informative when its failure

modes map to concrete false conclusions (Nüst et al., 2020; Wilkinson et al., 2016).

25.8.4 — Machine-Readable Prospective Specification

Machine-readable prospective specification connects analysis code to declared decisions. It records generators, priors, endpoints, observation models, inclusion rules, thresholds, holdout units, tuning rules, none-of-the-models criteria, and public-status language in a form code can check (Nüst et al., 2020; Sandve et al., 2013).

Human-readable prospective specification remains necessary, but it is easy for prose to hide degrees of freedom. A structured file can specify which variables are locked, which margins are fixed, which windows are protected, and which choices require a new version.

The benchmark should automatically compare executed analysis with the protocol-fixed prospective specification. If code uses a different endpoint window, threshold, prior, exclusion rule, or holdout unit, the run is flagged rather than silently accepted.

Machine-readable prospective specification also helps red teams. A critic can ask whether the analysis matched the declared plan rather than relying on trust in a narrative report.

The file should include status labels. A result can be exploratory, recovery check, design-separability check, confirmatory benchmark, transport stress, or public artifact. Code should not let an exploratory run populate a confirmatory table by accident.

Claim-status discipline becomes a computational contract. The software should make it difficult for the analysis to become more certain than the plan allowed.

Machine-readable prospective specification should be tested against synthetic workflows before it governs a live study. If the encoded rules cannot reproduce the intended estimands, exclusions, stopping decisions, and verdict language, new participant data would enter a defective pipeline. Validation of the protocol object precedes recruitment (Sandve et al., 2013; Boettiger, 2015; Wilkinson et al., 2016; Nüst et al., 2020).

25.8.5 — Restricted and Public Layers

Reproducibility must be balanced with privacy and data dignity. The benchmark should separate public synthetic layers, restricted empirical layers, secure metadata layers, and public result summaries. Openness is not a license to expose participants, families, clinicians, or sites (Sandve et al., 2013).

The public layer should include synthetic generators, fixtures, model code, benchmark specifications, non-sensitive challenge logs, and reproducible figures built from synthetic data. The restricted layer may include protected empirical data, site-specific sensitive parameters, access-controlled validation outputs, and security details.

Restricted access should have governance: application criteria, data-use agreements, audit logs, role-based permissions, retention limits, incident response, and participant or site rights where appropriate. These details will be developed more fully in the governance chapters, but the benchmark cannot ignore them.

The public should not be asked to trust a black box. When empirical data must remain restricted, synthetic fixtures, red-team logs, independent audit summaries, and reproducible artifact manifests become especially important.

A public artifact should never imply that the benchmark is less uncertain because the private layer exists. Restricted evidence remains subject to the same model recovery, adequacy, and verdict rules.

This layered approach keeps the scientific program answerable without turning vulnerable lives into open data.

Public and restricted layers should cite one versioned release manifest stating which data, code, fixtures, parameters, outputs, and logs are available at each access level; why any restriction applies; and which results cannot be independently regenerated. It should record privacy review, security controls, reproducible public fixtures, and a route for qualified reanalysis. Restriction may protect people; it may not conceal an unfavorable result, and its remaining limits should be machine-readable (Sandve et al., 2013; Boettiger, 2015; Wilkinson et al., 2016; Nüst et al., 2020).

25.8.6 — Artifact Retirement and Security

Artifacts age: dependencies break, containers become insecure, devices change, models retire, and public wording becomes misleading after new benchmarks. Every artifact should therefore carry a status such as active, superseded, deprecated, withdrawn, security-restricted, or historical, with a reason, affected claims, replacement when available, and date (Boettiger, 2015; Wilkinson et al., 2016).

Security incidents are scientific events because compromised dependencies, leaked restricted files, stale figures, or invalidated assumptions can preserve a reproducible but wrong result. Triage, temporary access limits, patching, reruns, public notice, and durable archives must identify what future readers may still trust.

Retirement preserves history without leaving the retired object authoritative. The archive records the version, reason, affected conclusions, replacement or absence of one, security action, and public correction notice. Credentials, containers, datasets, and outputs that cannot be maintained safely should not remain silently callable.

Figures and public summaries follow the same rule. A shareable graphic should be tied in the reproducible record to its generator, fitted-model version, holdout split, threshold set, and status, so visual elegance cannot keep a superseded result alive.

Synthetic fixtures are the safest public entry point. They let critics test sign conventions, leakage guards, endpoint independence, model recovery, calibration, and figure scripts without exposing participant data. Machine-readable prospective specification further prevents exploratory thresholds, post-result holdouts, or mismatched generator versions from entering confirmatory outputs. Public fixtures should also include deliberately failing cases so critics can verify that safeguards and rejection paths activate when they should.

The artifact standard supports three reproducibility depths: public regeneration of tables from synthetic data, authorized rerun of restricted analyses in a controlled environment, and future

rebuilding from pinned dependencies and environment files. Each depth has a distinct privacy boundary and audit purpose. A reproducibility claim should name which depth was achieved, preventing synthetic regeneration from being mistaken for independent reproduction of restricted human analysis.

Model recovery is ready for replication infrastructure only when its worlds are hard, its failures visible, its artifacts open to challenge, and its corrections durable. That is the boundary between a computational promise and a scientific system independent sites can carry forward. Durable artifacts should include correction history so a later site can reproduce the current system without unknowingly reinstating a retired bug or model version.

Part VIII — Replication, Verdicts, and Scientific Updating

A scientific claim begins to mature when it leaves the conditions that first made it persuasive and enters the hands of independent teams free to test it without protecting its reputation. Earlier Parts defined PTVC, separated its layers, built measurement and endpoint gates, proposed humane studies, and gave serious rivals room to win. Part VIII asks whether any resulting evidence can travel across teams, sites, instruments, populations, and public summaries without changing what it means (Center for Open Science, 2025; Nosek et al., 2018).

The first discipline is vocabulary. Computational reproducibility asks whether declared data and code regenerate a reported result. Analytic robustness asks how much the conclusion depends on defensible analytic choices. Replication asks whether new evidence supports the same bounded claim, and transport asks where that result continues to hold. Large-scale metascience now examines these properties separately because each requires a different record, comparison, and verdict (National Academies of Sciences, Engineering, and Medicine, 2019; Miske et al., 2026; Aczel et al., 2026; Tyner et al., 2026; Brodeur et al., 2026).

In research on lived experience, context is part of the object. A hospice network, sleep laboratory, community clinic, research hospital, and longitudinal cohort may use the same nominal instrument while differing in language, medication, staffing, referral pathways, device firmware, family involvement, and observation loss. More sites improve inference only when those differences are measured, governed, and allowed to narrow the claim.

The aim is comparability without forced sameness. Common objects, bridge samples, translation review, calibration, site supplements, and transport estimands can earn comparability while preserving legitimate local difference. When the bridge fails, no-pooling is a substantive finding about comparability.

Part VIII also gives every finding an address. A result may bear on representation, an instrument, an endpoint rule, a candidate route, a rival comparison, a reference class, a transport claim, or the terminal target itself. It changes only the component reached through the declared dependency chain, and no favorable downstream result repairs an upstream gate that failed.

That discipline makes support and defeat equally informative. An instrument can become scientifically useful without being mistaken for access to the latent ledger. A candidate mechanism can retire without settling every target branch. A verified counterexample can defeat the exact universal branch it reaches, while an unidentified endpoint can make No adequate estimate the most rigorous result.

Institutions carry replication, but no institution confers truth. Site qualification, independent analysis, rival stewardship, endpoint adjudication, repositories, incident systems, negative-result rights, and correction records belong to the inferential architecture. They distribute the doors through which evidence can enter, challenge, narrow, or defeat the program.

The work also has a human infrastructure. Coordinators, clinicians, data stewards, translators, participants, families, and local communities carry harmonization and correction. Burden

limits, fair credit, referral routes, privacy controls, withdrawal, debriefing, and stop authority belong inside validity because an exhausted, coerced, or unsupported research system cannot produce trustworthy evidence.

Open science joins inspectable claims to protected people. Protocols, code, metadata, model cards, provenance, and public status records can be shared, controlled, or restricted according to purpose and risk. Raw terminal recordings, clinical notes, family speech, identity-linked trajectories, and sensitive device streams may require governed access. Reproducibility requires a reconstructible research record, including disclosed use of rapidly changing artificial-intelligence tools, not the conversion of private life into public material (Grant et al., 2026; Feuerriegel et al., 2026).

Chapter 26 builds the multisite research system. It separates protocol-fixed decisions from public preregistration claims, qualifies sites and devices, tests harmonization, models heterogeneity, distributes analytic authority, governs repositories, records incidents, protects staff and participants, and keeps negative results publishable. Replication becomes inspectable infrastructure rather than ceremonial repetition.

Chapter 27 governs what accumulated evidence is permitted to mean. It maps findings to components, distinguishes replication states, gives favorable results bounded language, preserves inconclusive and unusable evidence, and separates principled narrowing from rescue. Mechanisms may retire, rivals may dominate, and the strong form may be defeated without allowing any result to outrun its design.

Chapter 28 gives scientific correction a durable route. Versioned claim, model, evidence, and artifact registers preserve what changed and why. Dissent and external challenge remain reviewable; root-level questions return to *The Law of Fairness*; approved corrections propagate through the series, websites, diagrams, protocols, and public replies so that technical correction reaches every active surface (Committee on Publication Ethics, 2025; Crossref, 2025).

Chapter 29 keeps the program open after publication. It orders unresolved theorems, identification problems, first study families, simulation gates, value-of-information choices, release conditions, pause routes, redesign duties, and stop rules. Publication becomes the beginning of answerable testing and durable correction.

This structure sustains a rigorous hope. A narrower claim that survives is more valuable than a universal claim protected by ambiguity. A null replication with complete records is more useful than a favorable result whose adverse sites vanished inside a pooled mean. A visible correction is stronger than a beautiful artifact left wrong because it has already traveled far.

Part VIII closes the volume by building a research system in which every component can be challenged, reproduced, narrowed, corrected, or retired. Independent teams gain standing; local differences acquire scientific meaning; negative evidence receives a durable home; participants and staff retain enforceable protections; and every public claim remains tied to a versioned evidence record. The Part's central achievement is not a verdict, but a way to keep every verdict answerable.

Chapter 26 — Multisite Replication and Research Systems

Independent replication reveals which findings extend beyond the conditions of the first careful study. A palliative unit may have exceptional documentation, a research hospital may use unusually stable devices, a community clinic may recruit through stronger family networks, and a translated measure may carry meanings the originating team never tested. Replication begins by identifying which features of the original environment made the result possible (Nosek et al., 2018; Wilkinson et al., 2016).

Chapter 26 treats replication as scientific infrastructure. Similar-looking data from several institutions become stronger evidence only when the question, protocol, local adaptations, observation model, analysis route, and publication rights are fixed at the appropriate time. Site disagreement remains visible because it may be the most informative result in the network.

The distinction matters because careless success can damage an ambitious claim. Endpoint leakage, device drift, post-outcome model changes, local scripts, unmodeled attrition, or unpublished deviations can create apparent replication while widening confirmation bias. The network exists to discover which component travels, where it fails, and how narrowly the evidence permits it to be stated.

Site qualification is an evidentiary gate, not a prestige badge. A qualified site shows that its staff can carry the protocol without displacing care, that devices and firmware are traceable, that consent and language practices fit the population, that data flows are auditable, and that stop authority can actually be used. A site that cannot protect the people or the object remains outside the pooled confirmatory analysis.

Harmonization is the central technical problem. The same field name, wearable, survey item, or clinical code does not guarantee the same measurement object. Translation, medication, firmware, workflow delay, disability, and local response practice can alter what a channel means, so bridge samples and context-specific qualification may be required before pooling.

Site effects become evidence about scope. A signature present in one care regime and absent in another may reveal measurement failure, a clinical mediator, device instability, transport failure, or a narrower reference class. Site-level results that expose those differences can be more informative than a precise pooled estimate that conceals them.

Transport requires its own estimand. It asks which result moves from the study sites to a declared target setting under explicit assumptions about population, intervention, measurement, endpoint, and observation. Generalization is therefore a testable claim with a target population, a transport bridge, and conditions that may fail.

Repositories are scientific instruments, not storage closets. Final cleaned files cannot reveal which device version produced a signal, which transform was applied, what a participant withdrew, how translation changed, which container generated a figure, or which analysis version entered the public summary. Data dictionaries, provenance, access tiers, code and model registries, retention decisions, deletion events, and correction links make the result reconstructible.

Human infrastructure belongs inside the validity model. A night-shift nurse adding observations, a coordinator explaining consent during family crisis, a translator resolving an affective term, and a technician repairing a firmware failure all shape fidelity. Staffing ratios, workflow displacement, emotional strain, fair credit, participant support, family explanation load, debriefing, and stop authority are scientific operating conditions.

Incident systems preserve moments when the research object changes. A breach, device failure, safety complaint, protocol drift, mistaken endpoint classification, or delayed correction can alter what the evidence means. Logging, triage, independent response, reanalysis, and public linkage turn those events into scientific memory instead of reputational secrets.

Negative-result systems prevent the archive from becoming selectively favorable. Replication disappears when only harmonized sites, cooperative devices, successful instruments, or analyses in which rivals lose remain visible. Null, adverse, suspended, unusable, and Rival-favored outcomes need publication rights and persistent identifiers so later synthesis can distinguish learning from selection.

A worked design follows a four-site terminal-telemetry replication spanning an academic palliative unit, a community hospice, a rural clinic using another vendor, and a non-English-speaking care network. Each site contributes a distinct context and a distinct way the claim could fail. The consortium succeeds scientifically only when those differences are declared before outcome inspection and remain visible after analysis.

The result is an operational blueprint rather than a runnable protocol. It identifies what qualifies a site, which adaptations require logging, when pooling is prohibited, how analytic and adjudicative roles separate, who protects participants and staff, how incidents alter status, who controls repository access, and who corrects the public layer. Every major function receives an explicit owner, record, and review route.

The multisite architecture stops before verdict issuance. Its task is to create the conditions under which support, Reference-class narrowed, Model-ambiguous, Rival-favored, Route-failed, No adequate estimate, or defeat can become trustworthy. A false claim can be exposed without spectacle, a narrower component can remain honestly narrow, and a promising result stays inside scope until independent teams have tested it.

26.1 — Multisite Preregistration and Registered Reports

A multisite study begins with a shared decision object, not with enrollment. The core protocol fixes the scientific question, site supplements expose local implementation differences, and Registered Reports or another outcome-independent design review tests the method before anyone knows whether the result favors PTV, a rival, or no adequate model. Current protocol, reporting, and good-clinical-practice standards reinforce prospective specification, participant protection, reliable records, and transparent reporting (Chan et al., 2025; Hopewell et al., 2025; International Council for Harmonisation, 2026; Grant et al., 2026).

Terminal and longitudinal studies contain legitimate local differences in consent timing, language review, staffing ratios, device placement, family-contact rules, clinical referral pathways, and data-transfer constraints. Scientific comparability does not require hiding those differences; it requires fixing them before outcome inspection, recording their rationale, and preventing them from becoming convenient post hoc explanations, exclusions, or rescue devices.

Preregistration is a public-record claim, not a synonym for early intention. A protocol or analysis plan may be protocol-fixed or prospectively specified without being publicly preregistered. When a timestamped external registry record with a persistent identifier exists, the manuscript cites that record and identifies the estimands, endpoint windows, missingness rules, rival set,

decision thresholds, deviations, and public-language ceiling it fixes (Nosek et al., 2018; Grant et al., 2026).

Registered Reports add a distinct publication safeguard. Design and analysis receive peer review before results, and publication remains protected when the accepted route and quality conditions are followed. Null, Rival-favored, Model-ambiguous, and No adequate estimate outcomes then remain eligible for publication because the result was not known when the design received in-principle acceptance.

A multisite charter therefore identifies the common scientific question, each site's context of use, minimum shared measures, local adaptations, burden thresholds, independent analysis route, access tiers, incident escalation, and publication commitments before outcome inspection. This versioned structure lets later reviewers determine whether apparent replication answered one question or several shifting ones.

Table 26.1. Multisite charter fields that must exist before recruitment.

Charter field	Minimum content	Why it matters
Scientific component	The exact component claim, estimand, endpoint window, and rival matrix	Prevents a site from testing a different object under the same title
Context of use	Population, setting, language, device, cadence, care regime, and intended inference	Defines where the result can and cannot travel

Charter field	Minimum content	Why it matters
Site qualification	Staffing, training, calibration, consent route, support plan, and stop authority	Makes feasibility a scientific gate
Analysis version	Primary, secondary, exploratory, and rival analyses with thresholds	Protects confirmatory status from post hoc drift
Burden and incident rules	Participant, family, staff, safety, security, and deviation triggers	Keeps harm and workflow pressure inside the record
Publication rights	Null, negative, unusable, and rival-winning outcomes protected	Prevents suppression of inconvenient evidence

Table 26.2. Site qualification checklist.

Qualification object	Required evidence before activation	Failure consequence
Staff training	Role-specific training log, endpoint-language practice, consent rehearsal, incident escalation, and burden-stop authority	Site remains in shadow mode or cannot enroll high-risk windows
Device readiness	Hardware version, firmware version, calibration fixture, artifact profile, backup plan, and replacement route	Device channel excluded or site limited to nondevice analyses

Qualification object	Required evidence before activation	Failure consequence
Protocol fidelity	Dry-run record, synthetic-case walkthrough, timing check, missingness code practice, and amendment procedure	Site cannot contribute confirmatory data until corrected
Participant support	Consent route, withdrawal path, referral resources, after-hours contact, and nonparticipation care separation	Enrollment pauses until support is real rather than promised
Family and caregiver load	Contact limits, explanation schedule, bereavement timing, bystander consent screen, and opt-out path	Affected family-facing measures are suspended until the failed protection is corrected and the measures are requalified
Stop authority	Named staff with authority to pause recruitment, pause collection, quarantine data, or escalate incidents	Site cannot operate endpoint-adjacent protocols

Site qualification establishes whether an institution is prepared to supply observations for confirmatory research. The checklist covers participant and staff burden, device reliability, clinical complexity, and endpoint-adjacent procedures. Qualification findings are recorded with clear requirements for initial approval or requalification.

Table 26.3. Replication types and status effects.

Replication type	What it asks	Possible status effect
Direct replication	Can the same protocol, estimand, and observation model reproduce the component result under qualified site conditions?	Strengthens or weakens the specific component under that context of use
Conceptual replication	Does a different operational route recover the same component pattern without sharing the same measurement artifact?	Supports construct breadth only if the new route has its own rival matrix
Multisite replication	Does the pattern survive across qualified sites with site effects modeled rather than ignored?	Tests robustness and identifies scope limits or site-conditioned claims
Adversarial replication	Does the component survive when critics and rival stewards help specify models, thresholds, and failure routes?	Raises trust if it survives or forces narrowing if rivals win
Transport replication	Does the result travel to a new population, device regime, language, care setting, or sampling cadence?	Extends scope only under explicit transport assumptions and successful invariance checks

Replication type	What it asks	Possible status effect
Invalid or unusable replication	Did the design, harmonization, safety, or data quality fail before interpretation is possible?	Produces an infrastructure finding, not support or defeat of the component itself

The replication type identifies what was retested: a design in similar settings, a concept with a different method, or a prediction challenged by an independently developed alternative. Report the resulting scope and any qualification needed for the next extension.

The status consequence is declared before public release. A strong direct replication must not be advertised as universal transport, and failed harmonization must not be reported as defeat of the target when it establishes only that the measurement or implementation bridge failed. The table therefore requires the replication type, object, reference class, and transport scope to be named before the result is summarized.

26.1.1 — Shared Core Protocol

The shared core protocol fixes the minimum design every site implements before local adaptation. It identifies the common estimand, eligibility rule, observation window, measurement channels, endpoint proxy, missingness categories, safety gates, and primary comparison; otherwise, sites can agree on a headline while estimating different objects (Chan et al., 2025; International Council for Harmonisation, 2026).

Eligibility, cadence, endpoint proxies, channels, analysis families, burden stops, data fields, and status labels are frozen here, while

permitted local deviations are routed to site supplements. This division lets later reviewers determine whether a difference arose from context, implementation, or an altered scientific question.

A community hospice and a research hospital both use the same endpoint window but have different nursing documentation systems. The contrast shows that replication depends on implementable common rules, not merely on agreement with the headline model.

A protocol is too loose when every site can later claim to have followed it while estimating a different object. If protocol looseness is not named, it will be absorbed into site freedom and interpreted only after the outcome is known (Chambers, 2013; Scheel et al., 2021).

The core protocol should be narrow, versioned, and difficult to reinterpret after the first interim pattern appears. A narrow, versioned protocol preserves interpretability even when the common result becomes less dramatic.

The shared core creates a clean audit question: did every reported result answer the protocol's declared question? That trace allows later evidence synthesis to distinguish genuine replication from an institutionally convenient change of target.

26.1.2 — Site-Specific Supplements

A site supplement describes how the common protocol is instantiated in one setting, including any adaptation required by law, language, care workflow, infrastructure, or participant burden. Without that record, multisite variation is uninterpretable because the same nominal procedure may not represent the same

intervention or observation (Chan et al., 2025; International Council for Harmonisation, 2026).

It records population and referral pathways, diagnosis mix, care regime, device availability, language, jurisdiction, staffing, family-contact practice, and known feasibility limits. Reproducibility of implementation requires another team to distinguish mandatory, discretionary, and prohibited local choices without reconstructing them from memory.

Consider a rural hospice with intermittent connectivity and an urban hospital with continuous monitoring. The supplement should show whether differences in completeness or timing arise from clinical conditions, infrastructure, or departures from the common protocol, rather than leaving those causes to post hoc interpretation.

Local variation becomes dangerous when it is treated as invisible nuisance and then confused with support, nonreplication, or harm. At that moment, the program should stop upgrading the finding and classify the source of difference (Scheel et al., 2021; Nosek et al., 2018).

The supplement should make local adaptation honorable only when it is declared before it matters. Protection comes from rules that change permissions and labels when local conditions change, not from cautious wording alone.

The remaining issue is transport. Site adaptation is defensible only when the record shows which assumptions were preserved, which changed, and why the resulting evidence may travel.

26.1.3 — Registered-Report Review

Registered-Report review moves the central design judgment to a time when the result is unknown. Reviewers can challenge separability, burden, missingness, endpoint independence, rival coverage, and public-status wording before those choices can be influenced by an observed pattern (Chambers, 2013; Scheel et al., 2021; Center for Open Science, 2025).

The review record should preserve the submitted protocol, reviewer objections, author responses, in-principle acceptance, and any approved amendment. A later auditor can then distinguish a study that followed its accepted design from one whose publication commitment no longer covers the reported analysis.

A journal agrees to publish a carefully designed test even if the result is null or favors a Brownian bridge. That commitment changes analytic incentives before data collection and keeps publication from depending on a preferred outcome.

Outcome-dependent publication pressure remains a threat even in a well-governed network. The publication commitment should therefore extend to null, rival-favored, inconclusive, and unusable outcomes, provided the accepted protocol and quality conditions were met (Center for Open Science, 2025; Nosek et al., 2018).

Review before results should protect the value of a clean loss as much as a clean support pattern. The network must be free to discover that its own architecture is not yet sufficient.

The study answers its promised question, not its preferred later story. Outcome-independent review makes replication a test of that question rather than a contest for an attractive result.

26.1.4 — Primary and Secondary Analyses

Primary estimands, secondary analyses, exploratory diagnostics, and post hoc visualizations receive distinct preregistered labels, each with a date, owner, version, status, and rule for reopening the classification (Chan et al., 2025; Hopewell et al., 2025; Nosek et al., 2018).

A striking subgroup may appear only after the first pooled analysis. The primary-secondary boundary must route that finding to a new prospectively specified confirmatory analysis rather than convert it into a retroactive center of the study.

An exploratory discovery can inherit confirmatory language simply because the pattern is striking or comforting. In a multisite network, that inflation can be mistaken for replication when the apparent coherence is actually produced by unmodeled local practice (Center for Open Science, 2025; Chambers, 2013).

Discovery remains legitimate only when its label travels with it. At this point in the architecture, institutional design determines whether unexpected variation becomes a new question or is shifted onto staff and participants as unexplained work.

The record must separate findings that may alter component status from those justifying another prospective test. Otherwise, the network creates apparent cumulative evidence without independent confirmation.

26.1.5 — Deviation and Amendment Log

Every protocol change belongs in the scientific record. Even a harmless local deviation across hospitals, hospices, remote

programs, or multilingual clinics can alter consent, timing, observation, or endpoint meaning (Nosek et al., 2018; Center for Open Science, 2025).

The log records when and why the change occurred; the affected sites, measures, and participants; the reviewing body; and whether reanalysis is required. It permits transparent adaptation without allowing adaptation to become an unnamed cause of support or failure.

A firmware update that changes sleep-state classification midway through recruitment can reshape two sites without misconduct. The safeguard is to record the altered observation process and protect analysts from a falsely uniform dataset.

A result weakens when staff remember a change that the analysis package omits. The defect is localized, its consequences estimated, and the affected component narrowed or rerun rather than concealed in a pooled estimate (Chambers, 2013; Scheel et al., 2021).

Amendments must be visible enough that no reader has to infer them from drifting outputs. Dated records keep participants, staff, and families from carrying ambiguity merely so the claim appears cleaner.

Replication is an auditable history, not a polished endpoint detached from its making. Trust grows when disagreement is easier to inspect than suppress.

26.1.6 — Publication Independent of Outcome

Institutions commit to publication before results are known. This covers nulls, Rival-favored outcomes, failed instruments, and No adequate estimate under protocol-fixed quality conditions (Center for Open Science, 2025; Chambers, 2013).

The charter, funder agreement, and journal route protect adverse or unusable results, harmonization failures, and ethics suspensions. They specify amendment authority, review triggers, and visible disputed exceptions.

If observation shutdown explains terminal concentration better than the candidate, the result remains publishable under the same quality criteria as a favorable result. Suppressing it would turn a scientific comparison into a selective record.

Narrative-driven suppression is a governance failure, not a participant or hypothesis failure. Preserve findings and narrow supported status (Scheel et al., 2021; Nosek et al., 2018).

Publishing adverse evidence is a duty, not a reputational liability; retaining it protects participants, sites, and critics.

Fix questions, log amendments, and protect publication so comparability tests need not trust consortium memory.

26.2 — Harmonization Without Forced Sameness

Harmonization earns comparability only to the extent that shared meaning has been demonstrated. It begins with a common core while preserving legitimate differences in language, care, culture, devices, disability, and local workflow. A variable is shared when its meaning, unit, timing, context, and missingness behavior support the declared estimand, not merely when its column name matches (Fortier et al., 2011; American Educational Research Association et al., 2014; Wilkinson et al., 2016; International Test Commission, 2018).

This is why measurement invariance belongs before pooling. If a self-report item shifts meaning under translation, if a wearable channel behaves differently across skin tone or movement capacity, if a clinical record field changes with staffing practice, or if a distress marker is altered by medication, then a pooled estimate may become an artifact of harmonization failure. The data may look aligned while the construct has moved.

The analysis distinguishes common data elements from common meaning. A common data element is a field. Common meaning requires context-of-use evidence, bridge samples, linking models, translation review, device calibration, and declared uncertainty. Some fields can be harmonized fully. Some can be harmonized partially. Some should remain local and never enter a pooled confirmatory model.

Forced sameness transfers interpretive work to local staff, translators, patients, families, and disabled participants, then treats the resulting mismatch as error. A fair multisite design

records that load and preserves local meaning instead of demanding conformity to a shape designed elsewhere.

A good harmonization plan is both modest and sharp. It states which variables are common, which are linked, which are local, which require bridge evidence, which are excluded from pooling, and which failures narrow the claim. It lets a dataset travel only as far as its construct evidence travels.

Table 26.4. Harmonization and invariance plan.

Object	Evidence required	Permitted outcome
Common field	Same unit, source type, timestamp, missingness code, and transform	Full pooling only after meaning is also supported
Local field	Site-specific validity with declared use	Local analysis or qualitative interpretation
Bridge variable	Overlap sample, device crosswalk, translation comparison, or linking model	Linked analysis with uncertainty or no-link decision
Device version	Calibration record, firmware log, artifact behavior, and leave-version-out test	Version-specific model, bridge, or exclusion
Language version	Translation review, cognitive interview, cultural review, response-pattern check	Linked, local, revised, or withdrawn item

Object	Evidence required	Permitted outcome
Failed invariance	Declared failure mode and affected estimand	No pooling by administrative convenience

Equation 26.1. Candidate linking model for site-qualified measurement.

$$D_{\text{link}} \left(P(Y_{ij} \in \cdot | \eta_{ij}, s, d), P(Y_{ij} \in \cdot | \eta_{ij}, r, d) \right) \leq \varepsilon_{\text{link}}.$$

26.2.1 — Common Data Elements

A common data element is a field with declared units, timing, source, missingness code, and permitted values. Without a common-data-element boundary, identical field names can conceal incompatible measurements (Fortier et al., 2011; American Educational Research Association et al., 2014). In Equation 26.1, i indexes persons, j indexes the item-or-occasion unit declared by protocol, s is the candidate site, r is the declared reference site, and d is the device or instrument configuration; η_{ij} is the common latent construct value, D_{link} measures discrepancy between the two conditional measurement distributions, and $\varepsilon_{\text{link}}$ is the allowed discrepancy; the latent scale, discrepancy rule, and tolerance are protocol-fixed before pooling.

The data dictionary assigns each field a definition, unit, time basis, source, permissible transformation, missingness code, sensitivity tier, and responsible owner. Those semantics must be reproducible at another site without guesswork about an apparently familiar label.

Two sites may both report sleep interruption while one uses self-report and the other actigraphy. The common-data-element record must retain that distinction, specify whether a bridge is available,

and prevent the shared field name from concealing incomparable observations.

False comparability begins when identical column names are mistaken for common meaning. The program should suspend pooling, identify the semantic or measurement mismatch, and state what additional bridge evidence would be required (Wilkinson et al., 2016; International Test Commission, 2018).

Common fields must carry source and context, not merely labels. The safeguard is a schema that constrains permissible interpretation, not a general declaration of caution.

A data dictionary is a scientific object, not an administrative spreadsheet. It should expose the semantic and operational assumptions that must hold before a variable can cross a site boundary.

26.2.2 — Local Measurement Qualification

Local qualification asks whether a measure behaves adequately in the site's declared context of use, not whether the site can operate the device. Because qualification determines whether observations can enter a pooled or transported estimand, it is part of the scientific design (American Educational Research Association et al., 2014; International Test Commission, 2018).

Pilot reliability, calibration transfer, missingness, participant feedback, device tolerance, and workflow checks should be reported with their acceptance criteria. The resulting record should make clear why a measure was qualified, conditionally qualified, or excluded at that site.

A translated calm item is interpreted as politeness rather than felt relief in one setting. The response has changed because the social act changed, so translation review belongs in measurement qualification rather than cosmetic editing.

If local meaning or performance remains misaligned, pooling is not a neutral default. The defensible result may be a site-specific instrument, a bounded linking model, a separate stratum, or exclusion from the common estimand (International Test Commission, 2018; Fortier et al., 2011).

Qualification should happen before the variable receives confirmatory weight. Excluding an unqualified variable is therefore evidence of discipline, not a failure of ambition.

Local qualification turns harmonization from assumed sameness into earned comparability.

26.2.3 — Bridge Samples and Linking

Bridge samples answer a bounded linking question between instruments, languages, devices, or workflows. Their overlap design specifies what is linked, in which population and context, and with what uncertainty. A bridge that expands whenever comparability fails becomes a rescue device rather than a measurement study (Wilkinson et al., 2016; International Test Commission, 2018).

Linking models estimate transformations, uncertainty, and bias using participants or records measured under more than one regime when ethically feasible. Each measurement bridge requires a version, owner, calibration sample, uncertainty record, and rule for requalification.

During a device migration window, a subgroup may complete both the old and new diary formats. The bridge sample must remain small, consented, and necessary, so dual measurement does not become an unacknowledged burden imposed for administrative convenience.

A cross-site bridge becomes misleading when wide uncertainty is presented as exact conversion. Network scale can then imitate replication even though the common metric is being manufactured by an untested link (Fortier et al., 2011; American Educational Research Association et al., 2014).

A responsible linking output reports uncertainty, nontransportable regions, and no-link zones. These limits determine which observations may enter a common analysis and which must remain site-specific or partially identified.

Only the portion that survives the bridge evidence should enter a pooled estimate. Everything else remains a local finding, a sensitivity analysis, or a new research question rather than being absorbed into the appearance of replication.

26.2.4 — Partial Harmonization

Some variables can be harmonized only partially, and that status must be declared before pooling. A common label may conceal different clinical, cultural, or device meanings across research hospitals, community hospices, remote-monitoring programs, and multilingual clinics (International Test Commission, 2018; Fortier et al., 2011).

The harmonization plan distinguishes a shared core, variables linked with uncertainty, site-specific measures, and observations

reserved for local or qualitative interpretation. This architecture preserves useful local information while preventing an invalid common scale from becoming the price of consortium membership.

A respiratory feature may link across devices while an agitation field remains inseparable from local charting culture. That asymmetry is evidence about the measurement system. The protocol should preserve it in the analysis and the release record.

The result loses warrant if analysts discard meaningful local data or force it into an invalid common metric. The affected component should be reported separately, narrowed, or treated as nontransportable instead of being smoothed into a pooled estimate (American Educational Research Association et al., 2014; Wilkinson et al., 2016).

Partial harmonization protects local signal without upgrading it to pooled status. The decision to link, stratify, or abstain should be visible in the record rather than hidden inside a final model.

The result can now say what traveled and what remained local. That distinction makes heterogeneity an interpretable limit on scope.

26.2.5 — Translation and Cultural Review

Translation and cultural review preserve constructs rather than word forms. The record identifies what was translated, adapted, cognitively tested, rejected, and approved before site outcomes reveal which wording is favorable (Fortier et al., 2011; American Educational Research Association et al., 2014).

Panels should include language experts, clinicians, community advisors, disability perspectives, and field staff, with recorded authorship, revision authority, adjudication criteria, and unresolved disagreement. A burden term may carry family-duty or religious meaning in one language and elicit a different social act despite appearing lexically equivalent.

When wording changes pressure or response process, the defect belongs to measurement and transport rather than culture or character. The instrument is adapted, the link narrowed, or a no-link region declared; untranslatable constructs remain visible rather than being forced into a pooled score (Wilkinson et al., 2016; International Test Commission, 2018).

Cultural review should make meaning more visible. Its decisions are part of the scientific record because they determine whether common-looking measures are actually commensurable. Documenting translation choices and unresolved concepts helps later sites distinguish true cultural differences from instrument noninvariance.

26.2.6 — No Pooling by Administrative Convenience

Administrative convenience is not comparability. Pooling is allowed only after declared invariance, device-bridge, support, and transport gates make the combined estimand interpretable; the plan states when site-specific reporting replaces a common estimate (American Educational Research Association et al., 2014; Wilkinson et al., 2016). A harmonization decision should record which parameters were linked, which remained site-specific, and which comparisons were prohibited.

When funders expect one headline despite failed bridges, the scientific response is a qualified common result beside incompatible site results. Forcing them together turns administrative preference into an undeclared model and hides the defect from the main analysis (International Test Commission, 2018; Fortier et al., 2011). Presenting incompatible results beside the common estimate can reveal whether the pooled signal is robust or driven by a subset of sites.

No pooling is a valid result. It preserves where comparability ended and lets heterogeneity reveal measurement drift, transport boundaries, care-regime interactions, or distinct processes requiring their own tests. No pooling can also improve the next design by identifying the exact bridge or site condition that must be validated before combination becomes legitimate.

26.3 — Site Effects, Heterogeneity, and Transport

Heterogeneity is where a multisite study discovers the limits and transport conditions of its own claim. Site differences can arise from population, care practice, device configuration, laboratory procedure, observation intensity, law, language, or referral. The analysis treats those differences as possible effect modifiers, measurement failures, or scope boundaries rather than noise to erase (Gelman & Hill, 2007; Bareinboim & Pearl, 2016; Stuart et al., 2011).

A hierarchical model can help, but only if it is interpreted honestly. Partial pooling is not a machine for dissolving dissent. It estimates site-level variation while borrowing strength under assumptions. If those assumptions fail, the model may make an outlying site look like noise rather than a boundary. Accordingly, the analysis treats heterogeneity as possible scope evidence.

The 2026 SCORE results also show why site and method variation should be interpreted rather than averaged into one credibility score. A claim may be computationally reproducible from its original files, analytically fragile under other defensible specifications, and only partly replicable in independent data; another field may show stronger reproducibility while still carrying transport limits. Each pattern points to a different repair, including provenance reconstruction, specification review, direct replication, or reference-class narrowing (Miske et al., 2026; Aczel et al., 2026; Tyner et al., 2026; Brodeur et al., 2026).

Transport is different from replication. A result can replicate in the development network and still fail to transport to another

population, diagnosis, age group, language, care regime, device version, or sampling cadence. Transport requires a target population, covariate structure, measurement invariance evidence, treatment regime assumptions, and a reason to believe the mechanism should apply across contexts.

The multisite system identifies where a component result transfers and where a new qualification study is required. Extensions from oncology to dementia, pediatric settings, other species, or artificial architectures each specify their own measurement and bearer-classification questions.

The section's central promise is therefore restrained: heterogeneity is not a public relations problem. It is information about the boundary between an observed pattern and the conditions under which that pattern can be responsibly named.

Equation 26.2. Candidate hierarchical site model.

$$\hat{L}_{ijsvt} = \mu + a_i + b_j + c_s + d_v + x_{ijsvt}^\top \theta + \varepsilon_{ijsvt}$$

Equation 26.3. Transport estimand under declared target population.

$$\psi_T := \int m(x) dP_T(x), \quad w(x) := \frac{dP_T(x)}{dP_S(x)},$$

$$P_T \ll P_S.$$

26.3.1 — Hierarchical Site Models

Hierarchical site models specify how person, site, workflow, device, population, and calendar variation enter the analysis. Because that structure controls pooling and shrinkage, it is declared and tested as part of the generative model rather than added after a surprising site result appears (Gelman & Hill, 2007;

Bareinboim & Pearl, 2016). In Equation 26.2, i indexes person, j indexes workflow, s indexes site, v indexes device or version, and t indexes observation occasion or calendar time; a_i , b_j , c_s , and d_v are their declared hierarchical effects, θ is the covariate coefficient vector, and ε_{ijstv} is the residual term. In Equation 26.3, $m(x)$ is the conditional estimand function, P_S and P_T are the source and target covariate laws, and w is the Radon–Nikodym transport weight; if P_T is not absolutely continuous with respect to P_S on the analysis support, that weighting route is unavailable.

The model record should explain which effects are fixed, random, partially pooled, interacted, or excluded, and why. It should also state the site sample sizes and assumptions that make each level estimable, so later analysts can reproduce the hierarchy rather than merely the final coefficient table.

One site may show strong variance compression while another retains substantial dispersion. A pooled average could erase that boundary and turn a scope result into a misleading global pattern.

Partial pooling can obscure a genuine boundary when a site differs systematically from the network. In that case, a site-conditioned estimate, transport analysis, or explicit nonpooling decision is more informative than a cosmetically stable network average (Stuart et al., 2011; Fortier et al., 2011).

Site terms should be reported as possible scope evidence. Variation among sites can then reveal where a claim travels and where it stops rather than being treated as a nuisance to suppress.

A reader can see whether the component claim is network-wide or site-conditioned. Hierarchical modeling turns heterogeneity into a scientific result rather than a defect to be averaged away.

26.3.2 — Care and Workflow Effects

Care practice can shape observations that resemble psychological dynamics. The analysis isolates workflow contrasts, records their generating processes, and keeps clinical variation out of a generic site effect. Otherwise, a pooled model can misname a care difference as a Law-specific signal (Bareinboim & Pearl, 2016; Stuart et al., 2011).

The design records sedation norms, pain-management routes, visit schedules, family access, documentation habits, and staff ratios. Each care-workflow variable requires a time window, owner, definition, provenance, and rule for remeasurement.

A site with proactive symptom management may record fewer distress reports near endpoint than a site with late medication adjustment. Workflow contrasts belong in the study record, but care decisions remain clinically governed and never contingent on research participation.

Include care-workflow variables in the model so that differences in clinical practice can be separated from the proposed latent dynamics (Fortier et al., 2011; Gelman & Hill, 2007).

Workflow variables should enter the analysis before mechanism language does. Medication practice, staffing, visit timing, family involvement, device use, and referral patterns can change what is observed and which continuations remain available.

The analysis must be able to distinguish a humane clinical practice effect from a Law-specific signal. When it cannot, the appropriate result is a care-regime boundary or model ambiguity, not a stronger claim produced by network scale.

26.3.3 — Device and Laboratory Effects

Hardware, software, preprocessing, and calibration can create site signatures resembling substantive effects. Replication therefore needs a versioned device and laboratory record; a shared product name does not ensure a shared observation process (Stuart et al., 2011; Fortier et al., 2011).

For every site, the record identifies device model, firmware, sensor placement, sampling rate, artifact filters, laboratory procedure, and preprocessing version. Those fields make technical variation analyzable instead of allowing it to appear later as unexplained heterogeneity.

Suppose a wearable update changes motion-artifact removal during the final month of recruitment. The study has changed even if every operator followed instructions. The update should define a new device regime, trigger bridge checks, and remain visible in every pooled or transported result.

Apparent variance compression or failure loses force when it can be manufactured by a device change. The affected observations should be quarantined, bridged with explicit uncertainty, or reported separately, and the component claim should be narrowed if the technical break cannot be repaired (Gelman & Hill, 2007; Bareinboim & Pearl, 2016).

Leave-device-version-out prediction should be part of evaluation whenever firmware, sensors, or preprocessing may alter the observation law. A pooled device effect cannot substitute for demonstrated transport.

Evidence may cross a device boundary only after the declared bridge survives held-out testing. Until then, device-specific results remain device-specific.

26.3.4 — Population and Referral Effects

Population and referral effects begin before enrollment. Catchment area, referral criteria, clinician practice, insurance or access constraints, family capacity, and self-selection determine which streams reach a site and therefore which target population the site can represent (Fortier et al., 2011; Gelman & Hill, 2007).

The design models referral pathways, diagnosis, prognosis, socioeconomic access, language availability, caregiver presence, prior treatment, and selection into research. The sampling record should identify who defined eligibility, who may revise it, and how referral disputes affect scope.

A palliative unit enrolls people with stable family advocates while a safety-net hospital sees late referrals and fragmented records. The resulting reference class has changed through referral and retention, not through biology alone.

Without referral modeling, sample composition can be mistaken for biological universality. When referral structure produces the pattern, the claim must remain conditioned on the population and care pathway that generated it (Bareinboim & Pearl, 2016; Stuart et al., 2011).

Transport claims should name the populations actually represented and the populations that remain outside support. Scope becomes more credible when its exclusions are explicit.

26.3.5 — Transport Estimands

Each transport estimand fixes population, setting, care and device regimes, endpoint window, and inference before evidence crosses contexts (Gelman & Hill, 2007; Bareinboim & Pearl, 2016).

The record shows which differences were adjusted, ignored, unsupported, or assumed stable. Transport is an auditable inferential route, not rhetorical extension of a local success.

Moving a hospice telemetry model into home monitoring changes population, cadence, medication, caregivers, and endpoint structure. Declaring those changes makes transport testable.

Results beyond context are labeled extrapolation, carry transport uncertainty, and withhold broader claims when overlap or invariance is inadequate (Stuart et al., 2011; Fortier et al., 2011).

Transport requires covariate support, measurement comparability, and sensitivity to unmeasured context. Failure identifies the boundary the next design must address.

A transported finding and a question exposed by failed transport remain separate states.

26.3.6 — Heterogeneity as Scope Evidence

Heterogeneity can reveal dependence on measurement, diagnosis, care, device, culture, or an ordinary rival, defining the scope of later claims (Bareinboim & Pearl, 2016; Stuart et al., 2011).

Site differences are classified as measurement failure, mechanism boundary, rival advantage, care-regime effect, or unresolved disagreement under a rule staff apply and critics audit.

If a minority site favors a Doob-transform rival, its observation process and rival fit remain in the principal result rather than disappearing for narrative cleanliness.

An adverse site triggers narrowing, reanalysis, quarantine, or withdrawal under protocol-fixed criteria, not selective exclusion (Fortier et al., 2011; Gelman & Hill, 2007).

Site estimates, prediction intervals, and explanations remain visible beside the pooled result under independent oversight.

26.4 — Independent Replication Roles

Independence in replication is a distribution of roles, information, incentives, and decision rights. A different institutional address does not by itself create independence. The design separates theory stewardship, implementation, data custody, analysis, rival advocacy, endpoint adjudication, ethics review, and public communication so that one group cannot control the full evidentiary chain (Mellers et al., 2001; Nosek & Errington, 2020).

The role architecture gives scientific pressure a lawful destination. The originating team supplies theory, code, assumptions, and clarification; implementing sites carry the protocol; staged analysts receive governed data; rival stewards strengthen alternatives; endpoint and ethics reviewers protect high-risk classification; and conflict disclosures expose funding, authorship, advocacy, and institutional stakes.

Independence separates the responsibilities that shape an inference. Endpoint leakage, analysis leakage, funding pressure, authorship incentives, public reputation, and advocacy identity can influence interpretation. Distributed authority makes favorable results more credible by giving alternatives and possible failure routes independent evaluation.

Adversarial replication belongs here as a contract rather than a performance. Critics specify rivals and failure tests before benchmark release, independent sites retain publication rights, and negative results do not require permission from the originating team. Funding protects adverse findings rather than only approved extensions.

A replication system with independent roles also protects people. When endpoint classification is disputed, when a family feels pressured, when a site is overburdened, or when a data incident occurs, there must be a body with authority to suspend, narrow, or disclose without asking the theory's advocates to approve the discomfort.

Table 26.5. Independent-analysis workflow.

Workflow stage	Who sees what	Purpose
Fixture verification	Analysis team receives synthetic fixtures and known-answer cases only	Confirms code, formulas, and container behavior before real data access
Quality and missingness review	Data quality team sees site-coded data without outcome interpretation	Detects unusable channels, timing failures, device drift, and missingness patterns
Primary blinded analysis	Blinded analysts receive locked analysis dataset with masked site identities where feasible	Runs declared estimands without narrative and endpoint leakage
Rival model analysis	Rival stewards receive the same observation model and access constraints	Gives alternatives a fair chance under identical data conditions
Staged unblinding	Independent adjudication body releases site, device, and endpoint labels in predeclared order	Tests whether interpretation changes when context is revealed

Workflow stage	Who sees what	Purpose
Public interpretation review	Release group sees results, deviations, incidents, rival outcomes, and correction obligations	Converts record into status-labeled public language without upgrading claim status

The workflow matters because independence can be lost in small leaks. A message about which site had the most public attention, which family withdrew data, which device failed, or which endpoint window was controversial can shape analytic choices before anyone calls it bias. Staged access gives the analysis enough information to be correct while withholding enough context to keep the result from becoming a story too early.

Table 26.6. Adversarial replication contract.

Role	Protected right	Boundary
Originating team	Clarify theory, code, fixtures, and assumptions	Does not own replication outcomes or unblinded interpretation
Implementing site	Report feasibility limits, deviations, and local harms	Does not alter confirmatory estimands silently
Blinded analyst	Execute primary and rival analyses under staged access	Does not receive endpoint or site narratives before declared gates
Rival steward	Strengthen serious alternatives and publish their performance	Evaluates models independently of personal or institutional loyalty

Role	Protected right	Boundary
Endpoint and ethics review	Suspend, quarantine, or narrow evidence	Does not become public verdict authority over persons
Independent funder or sponsor	Support adverse and null publication	Does not upgrade public language by funding the work

26.4.1 — Originating Team

The originating team supplies the formal object, code, assumptions, synthetic fixtures, and clarification history, but it does not own the replication verdict. Separating authorship from adjudication prevents theory knowledge from becoming outcome control (Mellers et al., 2001; Nosek & Errington, 2020).

Versioned specifications, known failure conditions, analysis notes, and test fixtures should enter an independent repository before unblinded replication results are available. The record then shows what the team committed to and which later clarifications changed implementation.

The original modelers may answer a site question about endpoint windows while remaining shielded from unblinded outcomes. The clarification is logged, distributed to every affected site, and assessed for whether it changes the protocol-fixed analysis.

Clarification becomes steering when the team can infer which answer protects its model or when only favorable sites receive interpretive help. Such contact should trigger disclosure, sensitivity analysis, or a status reduction rather than being folded into vague implementation uncertainty (Ioannidis, 2005; Center for Open Science, 2025).

Originating-team contact should therefore be outcome-shielded, time-stamped, and reviewable. The purpose is not distance for its own sake, but a visible boundary between legitimate clarification and adaptive rescue.

This arrangement keeps replication connected to the theory without making it dependent on the theory's authors. The originating team can explain the claim, while independent implementers, analysts, rival stewards, and reviewers determine what the evidence permits.

26.4.2 — Independent Implementing Sites

Implementing sites carry the shared protocol through local staffing, law, culture, devices, care workflows, and participant needs. Their independence matters because feasibility limits and local departures change the scope of any apparent replication (Nosek & Errington, 2020; Ioannidis, 2005).

Each site signs a qualification record covering staffing, supervised training, calibration, consent routes, burden thresholds, stop authority, and the local conditions under which the protocol cannot be performed. Replication begins only when those conditions are operationally credible.

A small hospice may decline a sampling cadence that would displace nursing care. That refusal is not a defect to be hidden; it is evidence about the intervention's support and the settings in which the protocol can be conducted without transferring burden to staff or families.

If a site enrolls beyond its support capacity to satisfy network targets, the resulting data are compromised by the pressure the

system was designed to control. The protocol-fixed response is status reduction, reanalysis, quarantine, or withdrawal of the affected component (Center for Open Science, 2025; Mellers et al., 2001).

Site independence includes authority to reject unsafe feasibility demands and publish local limitations without penalty.

26.4.3 — Blinded Analysis Teams

Analysis teams receive data in stages that reduce endpoint and interpretation leakage. Without staged blinding, narrative knowledge can enter the analysis before formal comparison begins (Ioannidis, 2005; Center for Open Science, 2025).

The workflow separates data cleaning, quality review, primary analysis, rival analysis, and public interpretation through staged unblinding. The blinding log should show when each team gained access to site identity, endpoint labels, treatment or exposure information, and interim results, because those permissions shape the analyses that can remain independent.

Analysts run the prospectively specified model on site-coded data before learning which site had a public controversy. The coding sequence preserves blinding and prevents contextual knowledge from entering model comparison before the confirmatory analysis is complete.

Contextual leakage can enter the analysis through selective diagnostics or unexplained analyst judgment (Mellers et al., 2001; Nosek & Errington, 2020).

The final analysis should be challengeable as a route from data to conclusion, not merely reproducible as a numerical output. That distinction gives later evidence synthesis a record of how the result was made.

26.4.4 — Rival Model Stewards

Serious rivals need representation by people allowed to make them strong. Without rival stewardship, the network can appear adversarial while protecting the favored model (Center for Open Science, 2025; Mellers et al., 2001).

Rival stewards prospectively specify adaptation, homeostatic, bridge, frailty, sedation, observation-shutdown, predictive-control, and selection models with the same data access and tuning budget afforded to the focal route. Their specifications must support independent implementation and identify which PTVC-linked signature each rival can reproduce without the Law.

A rival steward may insist that a random-endpoint bridge remain a primary comparator when the originating team regards it as secondary. The adjudication record should preserve the disagreement, define the common scoring rule, and show whether any observed separation survives equal information and flexibility.

Rival comparison loses force when the Law competes only against alternatives designed by its supporters to be weak. The response is to strengthen the rival set and rerun recovery under equal information and flexibility, not to upgrade the favored result (Nosek & Errington, 2020; Ioannidis, 2005).

Rival stewardship should include code review, parameter ranges, diagnostic attention, and publication rights. The safeguard is genuine authority for rival teams to strengthen, test, and publish their models.

26.4.5 — Independent Endpoint and Ethics Review

Endpoint and ethics review remain independent of the discovery team. These reviewers decide what may be collected, which stop rules apply, and whether an endpoint classification is usable, thereby shaping the evidentiary object itself (Mellers et al., 2001; Nosek & Errington, 2020).

The file records evidence, unity and endpoint criteria, burden, family-pressure controls, dissent, recusal, and reasons for approval, restriction, or suspension so later decisions are auditable.

A family's withdrawal of final-week recordings changes both permission and endpoint coverage and is represented as an ethical and inferential event, not routine missingness.

The appropriate outcome may be withdrawal without penalty, No adequate estimate, or a narrower window even when retention would improve precision (Council for International Organizations of Medical Sciences, 2016; World Medical Association, 2024).

Endpoint review can halt classification or quarantine data when a cleaner label would exceed the evidence.

Participant protection and endpoint discipline are scientific preconditions, not team preferences.

26.4.6 — Conflict-of-Interest Disclosure

Conflict analysis identifies incentives that can shape interpretation, including funding, authorship, advocacy, prestige, and public identity. The record shows affected decisions and independent limits (Nosek & Errington, 2020; Ioannidis, 2005).

Disclosures name grants, donor commitments, intellectual property, authorship, public roles, prior advocacy, date, decision scope, reviewer, mitigation, and review trigger.

When a funder requests release before the disagreement appendix is ready, site leads enforce disclosure and recusal while shielding participants and junior staff from pressure.

Disclosure must change workflow when influence is plausible; otherwise it becomes an appendix while incentives continue to shape analyses, framing, and release timing (Center for Open Science, 2025; Mellers et al., 2001).

Mitigation can require recusal, staged access, independent review, or a documented reason to retain the role.

Coordination becomes replication only when dissent and adverse findings retain institutional standing.

26.5 — Repositories, Provenance, and Access

A repository becomes part of the inferential chain when it preserves the exact objects needed to reproduce, audit, reinterpret, or withdraw a result. Data dictionaries, provenance, code versions, containers, model cards, access decisions, retention rules, and correction links connect a public claim to the process that produced it (Wilkinson et al., 2016; Barker et al., 2022; Grant et al., 2026).

Scientific memory requires clear purpose limits when it includes sensitive material. The same system that allows a critic to inspect methods can expose clinical context, family speech, disability status, endpoint-adjacent recordings, or reidentification risk. The repository therefore separates public, controlled, and restricted layers and records why each layer exists.

Provenance makes the path from observation to result inspectable. A result records the source of each datum, its transformations, code and device versions, responsible role, quality flag, access tier, and reason for inclusion or exclusion.

Federated or distributed analysis can help when data cannot be pooled. It reduces transfer requirements and can respect legal or institutional boundaries. Harmonization, invariance, site qualification, and endpoint discipline establish scientific comparability, while separate checks establish security.

The section also protects record-regime separation. Research repositories are not civic records, government records, Workgame records, religious records, donor records, public archives, or Artificial Intelligence training corpora. The point of a repository

is to support scientific answerability, not to build a permanent cross-architecture dossier of persons.

Table 26.7. Data dictionary and provenance fields.

Field group	Required entries	Access tier implication
Identity and linkage	Pseudonym, site, visit, time, consent scope, withdrawal status	Restricted or controlled depending on reidentification risk
Measurement source	Instrument, device, firmware, reporter, clinical system, language version	Controls harmonization and bridge requirements
Transformation	Cleaning rule, artifact filter, imputation flag, model version, quality flag	Required for reproducible analysis
Provenance	Creator, reviewer, timestamp, software, container, release ID	Required for audit and correction
Sensitivity	Clinical, family, endpoint-adjacent, biometric, free text, location	Determines public, controlled, or restricted layer
Downstream use	Paper, figure, model card, public summary, participant return	Determines correction propagation

Table 26.8. Federated-analysis workflow and security gates.

Federated stage	Minimum scientific gate	Privacy or security gate
Local data preparation	Local dictionary, unit checks, missingness codes, device versions, and provenance map match the shared schema	Raw identifiers remain local and access is logged under site governance
Synthetic fixture run	Each site executes known-answer cases before touching sensitive data	Only synthetic records travel during code validation
Local model execution	Same container, same model version, same preprocessing declaration, and same failure flags are used	Outputs are reviewed for small-cell, leakage, and reidentification risk
Aggregation	Site-level estimates, uncertainty, convergence flags, and quality exclusions are combined under a declared meta-analytic model	No participant-level data leave the site unless separately approved
Central versus local sensitivity	Central pooled analysis, where lawful and ethical, is compared with federated estimates	Any discrepancy triggers access review and scientific reanalysis before public release

Federated stage	Minimum scientific gate	Privacy or security gate
Audit and retirement	Logs, release IDs, failures, and incident decisions are preserved for future reproduction	Deprecated code, compromised outputs, and unsafe artifacts receive retirement notices

Federated analysis provides an access architecture when legal requirements, trust, reidentification risk, clinical sensitivity, or community agreements favor local data control. Its scientific value depends on harmonization that makes the local estimates meaningfully comparable.

Federated work passes two independent gates. The scientific gate covers common schema, local measurement qualification, synthetic-fixture success, container equivalence, convergence reporting, and site-level uncertainty. The privacy and security gate covers local control of sensitive records, access logs, small-cell review, output inspection, breach response, and artifact retirement. Public claims require both.

A practical example shows why this belongs in the main text. A hospice network may be legally able to share model outputs but not raw final-week audio, device traces, or family notes. Another site may have community agreements that permit local analysis but not central transfer. The research system can respect those boundaries and still remain answerable if the code, fixtures, metadata, quality flags, and release identifiers are shared in a form critics can inspect.

Scientific comparability needs verification alongside privacy protection. Local sites may run nominally identical containers yet differ in preprocessing, time-zone handling, endpoint-window construction, or device-version bridges. The response is to align those operations or report estimates at the scope for which they are comparable.

A well-built federated workflow combines participant privacy with scientific accountability. Sensitive material stays local while shared methods, diagnostics, and release records permit independent review.

26.5.1 — Data Dictionary and Provenance

The data dictionary records what a field is and provenance records how it came to be. If data provenance is missing, the result can become unrecoverable before the final table is built (Wilkinson et al., 2016; Barker et al., 2022).

Each variable carries source, instrument, unit, timestamp, site, device version, transformation history, quality flag, sensitivity tier, and responsible owner. These fields form the chain of custody from observation to analysis and allow a later reviewer to determine whether two nominally identical values were actually produced in the same way.

An actigraphy-derived sleep feature is recomputed after a preprocessing update. Provenance must reveal that the derived variable changed, because the same field name now refers to a different transformation.

The final table reports the feature without its transform history. If transform history is not named, the discrepancy will be treated as

software noise or an irreproducible anecdote (National Institutes of Health, 2026a; National Institutes of Health, 2026b; Near et al., 2025).

Provenance should make reanalysis possible when any upstream object changes. Provenance preserves interpretability when a revised pipeline weakens or reverses the published estimate.

The provenance chain must carry a public claim back to its source records without exposing private content unnecessarily. Provenance and privacy are therefore designed together rather than traded against one another after collection.

26.5.2 — Public, Controlled, and Restricted Tiers

Access follows sensitivity and reidentification risk. Without access tiers, data circulation can widen privacy risk without increasing evidentiary clarity (Barker et al., 2022; National Institutes of Health, 2026a; National Institutes of Health, 2026b).

Public tiers may contain protocols, synthetic fixtures, code shells, aggregate results, and status labels; controlled tiers may contain vetted derivatives; restricted tiers hold identifiable or otherwise sensitive records. The access register should state the eligibility, purpose, approval, logging, retention, and revocation rules for each tier (National Institutes of Health, 2026b).

When a journalist requests raw final-week device streams after a public result, the decision turns on privacy, consent, reidentification risk, and scientific necessity, not on publicity value. A refusal or controlled alternative should be recorded so that access discipline remains visible rather than appearing as selective secrecy.

Openness becomes coercive when it pressures the consortium to release material whose sensitivity, reidentification risk, or consent basis requires restriction. The correct response is a more precise access tier and auditable review, not a weaker privacy boundary (Near et al., 2025; Rieke et al., 2020).

Access tiers should be declared before attention arrives. Protection depends on enforceable access controls and audit trails, not merely a careful privacy statement.

Transparency remains compatible with privacy because different objects travel through different access tiers. Public metadata, controlled data, executable code, and restricted human records need not share one door.

26.5.3 — Code and Model Registry

Stable identities for code and models are part of reproducibility. The registry binds each result to the executable analysis, software environment, dependencies, model card, test fixtures, and release identifier so a future analyst can reconstruct the pipeline instead of inferring it from prose (Near et al., 2025; Wilkinson et al., 2016).

The registry links the manuscript, public preregistration record when one exists, model code, containers, dependency files, model cards, data schema, and release identifiers. It also records deprecations, security patches, and environment changes that can alter output even when the analytic script is unchanged.

An analyst reruns the model six months later and obtains a different result because a package changed. The executable

environment has therefore altered the result-producing object even though the statistical code looks unchanged.

If a public figure cannot be reproduced from its recorded environment, the figure is not merely inconvenient. It should be quarantined from active use until the code path is restored, independently rerun, and reconciled with the published result (Rieke et al., 2020; Wilkinson et al., 2016).

Every released claim should name the exact artifact set that produced it. That provenance makes the claim auditable, reproducible, and correctable when one element changes.

The registry turns reproducibility from a slogan into an executable, versioned relationship among the claim, code, model, data schema, and environment.

26.5.4 — Retention and Deletion

Retention policy must define a bounded scientific and legal purpose rather than promise permanent accumulation. Durability, participant rights, deletion obligations, provenance needs, and future reproducibility have to be reconciled before records are stored, not after a request for removal arrives (Near et al., 2025; Rieke et al., 2020).

The plan defines retention periods, withdrawal routes, deletion feasibility, derived-data handling, legal holds, and public correction when data are removed. Each retention rule requires an owner, legal basis, review date, deletion route, and exception record.

A participant may withdraw permission for a sensitive audio channel after the study closes. Data stewards must follow the protocol-fixed withdrawal and deletion route while stating honestly which copies, derivatives, or lawful retention duties prevent complete erasure.

Consent cannot be treated as frozen merely because analysis has begun. New uses, new linkage, longer retention, wider access, model training, and public release may exceed what participants were told even when the repository remains technically secure (Wilkinson et al., 2016; Barker et al., 2022).

Retention rules should be understandable before enrollment and enforceable after publication. They should identify deletion limits, archival duties, derived-data treatment, withdrawal consequences, and the conditions under which a new use requires renewed review or consent.

Scientific memory remains accountable only when people can understand what persists, what can be withdrawn, and what cannot be recalled from already completed analyses. An archive without those boundaries becomes a record system with no meaningful exit.

26.5.5 — Breach and Vendor Risk

Third-party services are part of the evidence path. Cloud providers, device vendors, identity systems, analytic platforms, backup services, and model hosts can alter access, provenance, availability, and reproducibility, so their roles must be governed as scientific dependencies (Rieke et al., 2020; Wilkinson et al., 2016).

The threat model names each vendor, credential path, export route, backup medium, subcontractor, and failure mode. It also states which raw-to-derived mappings must remain recoverable if a service changes terms, closes, or suffers an incident.

Suppose a wearable vendor disables a data-export route during follow-up. Even perfect local compliance cannot repair the lost provenance after the fact. The incident should trigger a documented continuity plan, a scope review, and, when necessary, suspension of the affected analysis.

Vendor fragility undermines warrant when reanalysis needs an unavailable raw-to-derived mapping. Isolate the damaged component and narrow its scope rather than preserve it through pooled assumptions (Barker et al., 2022; National Institutes of Health, 2026a; National Institutes of Health, 2026b).

Vendor contracts should require exportability, incident notice, deletion support, and provenance preservation. Repository reliability includes the exit path, because a program cannot remain correctable if its records are trapped.

26.5.6 — No Operational Record Merger

Keep research records separate from civic, religious, governmental, Workgame, archival, donor, and ordinary-life records. Establish purpose limits, access controls, retention, and deletion before secondary reuse is proposed; later promises cannot fully undo a merged dossier (National Institutes of Health, 2026b; Barker et al., 2022).

Separate operational records, research records, public summaries, model-training corpora, and participant communications by

purpose and access. Register each regime's owner, permitted links, and authority to reopen them.

A public dashboard team asks to reuse study metadata to illustrate country readiness. Without a new authority and consent basis, that reuse converts a research record into an operational dossier and changes the purpose for which the data were collected.

Research participation silently becomes civic visibility. That purpose migration is a governance failure, calling for separation, deletion where feasible, and a documented purpose-limit incident rather than wider use (National Institutes of Health, 2026a; National Institutes of Health, 2026b; Near et al., 2025).

Purpose separation should be enforced in schema, contracts, access logs, and public wording. Record separation protects participants while preventing administrative reuse from becoming unconsented inference.

26.6 — Staff Burden and Participant Support

Replication depends on people whose labor is easy to hide. Coordinators, clinicians, translators, data stewards, technicians, participant advocates, and family-facing staff determine whether the protocol can be carried without degrading care or distorting the observation process. Staffing, training, workload, emotional strain, fair credit, referral capacity, and stop authority therefore belong inside the validity model.

Staff capacity is part of measurement design. It shapes fidelity, missingness, timing, quality flags, incident detection, consent quality, family communication, and dropout. Delicate research tasks need protected time and support within the shift. The study should budget attention as carefully as it budgets sensors.

Participant support has a different danger. Help should not be conditioned on research participation, and research participation should not become a disguised route to care. If the program detects distress, confusion, device burden, family pressure, or clinical need, the referral pathway must operate without turning the person into a better data source.

Family and caregiver burden matters because terminal, disability, and chronic-illness research often reaches beyond the participant. Repeated explanations, device troubleshooting, diary reminders, withdrawal decisions, and post-study summaries can fall on relatives or caregivers. Those tasks are part of the observation process. They cannot be hidden in a consent form.

Humane operation is a validity condition. A study that exhausts staff, pressures families, or turns support into dependence cannot

responsibly produce a clean public status. The scientific record therefore shows how people were protected while evidence was gathered.

Table 26.9. Operational burden metrics that affect validity.

Metric	Local measure	Scientific consequence
Staff time	Minutes per participant per shift, after-hours work, rework episodes	Predicts fidelity drift and missingness
Staff distress	Debrief requests, ethical concerns, role reassignment, sick leave signals	Triggers support and possible suspension
Care displacement	Missed or delayed care task, interrupted clinical action, urgent override	Marks data as ethically and scientifically suspect
Participant observation load	Device wear time, diary prompts, interview length, withdrawal requests	Alters sampling and missingness model
Family or caregiver load	Proxy reports, troubleshooting episodes, repeated explanations	Changes feasibility and consent quality
Credit and authorship	Named contributions, site outputs, community review, data-curation work	Prevents extraction of invisible labor

26.6.1 — Research Labor and Training

Research labor includes expertise, time, emotional work, translation, technical troubleshooting, and ethical judgment. A multisite protocol cannot assume that attendance at a training session makes those capacities interchangeable across settings (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, 1979; Council for International Organizations of Medical Sciences, 2016).

Training should cover protocol logic, endpoint caution, consent, device handling, data-entry standards, incident triggers, family communication, and stop authority, with supervised practice and periodic refresh. The record should show competence in the actual tasks, not merely completion of a module.

A new coordinator given a complex endpoint script without supervised practice may improvise in ways that change recruitment, explanation, and classification. The failure is systemic even when the coordinator acts conscientiously; the protocol has asked for judgment it did not prepare or support.

When staff improvise explanations that alter who enrolls or how people respond, the result no longer represents a common procedure. The network should record the divergence, assess its effect, and narrow or rerun the component instead of burying the change in a pooled estimate (World Medical Association, 2024).

Protocol fidelity begins with people who understand the purpose and limits of the work they are asked to do. Compliance without comprehension can reproduce forms while losing the scientific object.

26.6.2 — Clinical Workflow

Clinical workflow is a scientific constraint because study tasks can displace care, alter timing, and change who remains observable. Enrollment, reporting, device placement, interviews, and incident follow-up must therefore fit around clinical duties rather than compete with them (Council for International Organizations of Medical Sciences, 2016; World Medical Association, 2024).

Workflow analysis maps when observations occur, who performs them, what clinical duties compete, and which tasks stop during care pressure. The workflow record should identify clinical ownership, research handoffs, suspension triggers, and unresolved staff objections.

A nurse is asked to collect a nonurgent research measure during a pain-management crisis. Repetition can turn a small research request into assumed clinical duty, shifting burden toward staff and patients at the moment care should dominate.

Research presence quietly becomes another load on an already strained shift. Once research work displaces care, the protocol has crossed its burden boundary and should pause, narrow, or suspend while the incident is recorded (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, 1979).

Care interruption should be a protocol deviation and a potential suspension trigger. Care-first suspension protects participants and staff while preventing workload from being hidden inside study success.

The program earns data only when care remains prior in the actual workflow. A protocol that succeeds by displacing attention from participants has failed its own validity test.

26.6.3 — Participant Support and Referral

Participant support must remain available without creating dependence on continued research participation. Distress escalation, clinical referral, device-off options, explanation, and ordinary care access should protect the person rather than reward data completion (World Medical Association, 2024).

The protocol specifies who responds to distress, how referrals occur, what support continues after pause or withdrawal, which research staff may interpret findings, and where ordinary care remains independent of the study. These routes are part of validity because they shape participation and missingness.

A participant may keep wearing a burdensome device because the study team has become the only reliable source of explanation. That dependence should trigger support transfer and a renewed participation choice, not be treated as evidence of willingness or adherence.

Support becomes coercive when access to explanation, referral, or ordinary resources appears contingent on remaining observable. The remedy is to separate support from data collection, record the resulting missingness honestly, and reduce the claim if the supported sample changes (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, 1979; Council for International Organizations of Medical Sciences, 2016).

Referral and explanation should continue when a participant pauses or withdraws. That continuity makes exit real and prevents welfare provisions from functioning as retention incentives.

Participant welfare is not a means of preserving data density. Skipped measures, device-off periods, withdrawal, and burden stops remain legitimate outcomes even when they reduce precision or end a planned analysis.

26.6.4 — Family and Caregiver Burden

Families and caregivers may carry the practical labor of observation through reminders, translation, device troubleshooting, proxy reports, transportation, and withdrawal decisions. Their burden may affect participation and data quality; this protocol therefore requires that it be recorded and minimized (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, 1979).

The protocol tracks the frequency and duration of those tasks, who performs them, what support is available, and which thresholds suspend research demands. A burden measure that cannot be collected without creating more burden should be replaced by a lighter and more defensible record.

A daughter managing medications may also be asked to complete repeated proxy diaries. Her exhaustion is not an invisible implementation detail; it can alter timing, content, and dropout, and it should never be transformed into apparent participant neutrality.

When caregiver exhaustion becomes missingness and is treated as random loss, the analysis erases the reason the data

disappeared. The affected component should be reanalyzed under informative missingness or withdrawn if the relational burden cannot be represented (Little & Rubin, 2019).

Family-burden thresholds need relief routes, substitution rules, and authority to stop requests. Scientific authority is weakened, not strengthened, when a clean figure depends on unpaid relational labor that the protocol never counted. Making that labor visible improves the observation process and prepares the analysis for staff dissent and moral distress.

26.6.5 — Moral Distress and Debriefing

Staff can experience distress when research meets terminal care, vulnerability, conflict, or public stakes. If moral-distress routes are missing, staff silence can shape the record before any inferential audit detects it.

The support system should provide debriefing, escalation, role reassignment, counseling access, and nonretaliation for ethical concern. Recording uptake, delays, and unresolved distress matters because staff strain can affect retention, consent practice, endpoint judgment, and data quality.

A coordinator worries that a family feels watched but fears being seen as obstructing the study. Staff psychological safety therefore affects whether an ethical concern ever reaches the formal record.

Silence may be mistaken for protocol fidelity when staff lack safe dissent routes. If moral distress is not nameable, silence can be misread as consent to the protocol and confidence in the data.

A research system that responds to staff concerns supports both staff agency and scientific reliability. Moral distress, workflow displacement, and unsafe workarounds should reach people with authority to change or stop the protocol.

26.6.6 — Fair Credit and Authorship

Multisite labor should not be extracted invisibly. Without a credit boundary, invisible labor becomes part of the hidden infrastructure of replication (Council for International Organizations of Medical Sciences, 2016; World Medical Association, 2024).

Credit rules should cover site investigators, coordinators, data curators, technicians, translators, community advisers, security staff, and contributors to null or negative results. A contributorship matrix can make the actual work visible, distinguish authorship from acknowledgment, and prevent small sites from disappearing behind the coordinating center (Brand et al., 2015).

When a small site supplies the harmonization insight that makes the network interpretable, relegating that contribution to a footnote distorts the scientific record. Authorship and credit review should follow declared contribution criteria and include an appeal route for overlooked labor.

The labor system is inequitable when prestige flows upward while burden, translation, troubleshooting, and emotional work remain local. Credit and resource decisions should expose that distribution before it becomes an authorship dispute or a source of silent protocol drift (Brand et al., 2015; National Commission

for the Protection of Human Subjects of Biomedical and Behavioral Research, 1979).

Authorship and acknowledgment should match intellectual and operational contribution. Fair credit requires contribution rules with consequences, not ceremonial acknowledgments.

Scientific fairness includes the coordinators, clinicians, translators, analysts, and caregivers who make evidence trustworthy. Their labor and judgment belong in the design rather than in acknowledgments alone.

26.7 — Incident, Audit, and Negative-Result Systems

An incident system records events that change safety, data meaning, protocol fidelity, access, or public interpretation. Breaches, device failures, consent disputes, endpoint-classification errors, unplanned deviations, burden stops, and correction delays receive a common triage route without being collapsed into one severity score.

Deviation logs, ethics events, data incidents, null results, replication disagreement, and audit trails therefore belong inside the main scientific record. They should not be hidden in appendices or transformed into generic assurances. A multisite program without incident architecture will eventually improvise under pressure, and improvised correction is often too late for participants and too convenient for the favored claim.

Negative and null results need special protection. A site may find no terminal concentration, no variance compression, no reserve-coupled signature, stronger adaptation, stronger bridge behavior, or uninterpretable missingness. Those outcomes are not merely absent support. They are records that may narrow, defeat, or redirect component claims.

Replication disagreement also deserves structure. A majority result cannot erase a minority site if the minority site has better endpoint independence, better device fidelity, a different population, or stronger rival discrimination. The disagreement may be the scientific finding.

Audit readiness is the final test. The record must reconstruct what was planned, what happened, what changed, who approved it,

which data were affected, what reanalysis occurred, which public claims changed, and what remains unresolved. If that reconstruction is impossible, the program has asked the public to trust memory rather than evidence.

Table 26.10. Incident, audit, and negative-result matrix.

Event	Immediate action	Evidence-status consequence
Protocol deviation	Log, classify severity, notify review role	Reanalysis, exclusion, downgrade, or local-only use
Endpoint leakage	Freeze affected analysis, assess contamination	Repeat blinded analysis or mark unusable
Ethics incident	Support participant, pause affected procedures, independent review	Suspend site, revise protocol, or withdraw evidence
Security incident	Contain, notify, audit access, quarantine data	Reanalyze, restrict, correct, or retract
Null result	Register, publish, compare rivals, assess quality	No support, rival pressure, narrowing, or inconclusive status
Replication disagreement	Preserve site-level result and minority interpretation	Scope restriction or new mechanism test

26.7.1 — Scientific Deviation Audit

Scientific deviations are departures from protocol, code, endpoint definition, analysis version, or data-processing route. If deviation auditing is missing, local changes can alter the evidence long before a pooled model reveals heterogeneity (Ioannidis, 2005).

The deviation audit records severity, affected units, timing, discovery method, decision owner, reanalysis requirement, and public-status effect. Linking each deviation to the analyses it can influence allows reviewers to distinguish implementation drift from substantive heterogeneity.

A site changes the order of self-report items after complaints about fatigue. Even a small ordering change can alter reactivity and missingness in a vulnerable window, making the observation process site-specific.

Classifying deviations by their inferential consequences preserves interpretability even when a deviation weakens the pooled result.

A result should retain the history of deviations, incidents, repairs, and unresolved questions that shaped it. This record lets later reviewers reconstruct what the analysis learned from each change.

26.7.2 — Ethics and Safety Incidents

Ethics incidents include pressure, excessive burden, consent confusion, care displacement, distress, or bystander harm. Without incident categories, safety failures can be absorbed into generic implementation noise (World Medical Association, 2024).

Ethics and safety incident procedures should specify immediate response, suspension authority, participant support, independent review, notification, and communication. The incident file must show what happened, which protections were activated, what

evidence became unusable, and how the site or network changed afterward.

If a family says the study feels like it is watching for death rather than supporting care, the response cannot be reduced to a communications problem. The network should pause the affected procedure, review consent and burden with independent clinical and ethics authority, and distinguish a correctable design failure from an activity that should stop.

Consent cannot close the issue when participants or families experience the study as intrusive, confusing, or displaced from care. The system must treat that concern as safety and validity evidence, with authority to pause, support, and review rather than dismiss it as misunderstanding (World Medical Association, 2024).

Ethical incidents should trigger review before scientific convenience enters. Safety depends on stop authority and incident response, not on a cautious tone in the protocol.

Participant dignity remains a condition of evidence usability. Safety or ethics incidents can invalidate an evidentiary route even when the data appear analytically valuable.

26.7.3 — Data and Security Incidents

Data and security incidents can change access, completeness, trust, and the validity of derived results. Incident handling is therefore part of the research record: containment, forensic review, variable quarantine, reanalysis, and public correction must be linked to the affected evidence rather than left in a

separate compliance file (National Institutes of Health, 2026b; Committee on Publication Ethics, 2025).

The plan preserves containment actions, notifications, access suspensions, forensic findings, compromised-variable flags, vendor decisions, reanalysis, and release effects. The incident record then shows exactly how the usable dataset changed and which dependent results lost, retained, or recovered status.

A staff credential is used to download restricted endpoint-window data from another site. Credential governance now determines lawful and scientific access to the endpoint record, so a security event can also become an evidentiary event.

A technically contained incident may still invalidate an analysis if the breach, outage, or vendor failure altered completeness or provenance. The defensible outcome may be suspension of an affected variable, site, or release until the incident has been adjudicated and the analysis rerun (National Institutes of Health, 2026b; Committee on Publication Ethics, 2025).

26.7.4 — Negative and Null Result Registry

A negative-result registry has one narrow job: give null, adverse, and unusable findings a durable, searchable home. It should capture the tested object, protocol version, reference class, failure mode, and public status without converting a difficult outcome into silence or narrative repair (Committee on Publication Ethics, 2025; Center for Open Science, 2025).

The registry records hypothesis, site, sample, data quality, rival fits, missingness, deviations, interpretation, and publication

status. Each negative-result entry requires a stable identifier, protocol link, status label, access rule, and correction route.

A well-powered Registered Report may produce a null after strong harmonization. Registry staff publish that result without forcing sites to defend a scientifically informative outcome as an institutional failure.

A null result should not be relabeled inconclusive merely because it disappoints the preferred narrative. Its classification must follow predeclared quality, power, measurement, and separability criteria rather than institutional appetite (Ioannidis, 2005; Franco et al., 2014).

Those criteria should distinguish an informative null, an underpowered estimate, a failed instrument, a nonseparable model comparison, and an ethics-limited study. The status determines what enters synthesis and what kind of redesign is justified.

Future syntheses need separate counts for clean negative findings and unusable findings. If both disappear into a generic inconclusive category, the network will repeatedly rediscover failures it already paid to learn.

26.7.5 — Replication Disagreement

Disagreement among sites may be the central result rather than a defect in replication. It can expose a transport boundary, a hidden observation difference, a care-regime effect, or a rival that fits one context better than another (Center for Open Science, 2025; Ioannidis, 2005).

The record should preserve majority and minority interpretations, site estimates, rival fits, sensitivity analyses, and unresolved adjudication. Agreement is not the default destination; an auditable account of disagreement is.

Suppose two sites reproduce compression while a third site with stronger endpoint independence does not. The third site should receive more scrutiny, not less, because its design may reveal that the apparent replication depended on endpoint coupling elsewhere.

A pooled estimate loses force when an adverse site is averaged away to protect a clean public sentence. The disagreement remains visible, and the claim narrows or the model changes according to the protocol-fixed rules (Franco et al., 2014; Fanelli, 2012).

Replication disagreement should remain visible until a mechanism, measurement difference, or scope condition explains it. Pooling is not an explanation.

Dissent that survives the final model makes scope more honest. The disagreement record should show what each site observed, what was comparable, and what remains unresolved.

26.7.6 — Audit-Ready Research Program

An audit-ready program can reconstruct a result without relying on institutional memory or personal assurances. Required artifacts, retention periods, responsible owners, and recovery tests should be specified in advance, because missing provenance discovered after publication may make an otherwise attractive result unauditable (Sandve et al., 2013).

The archive links protocol versions, amendments, consent templates, access logs, code releases, containers, data dictionaries, incidents, analyses, and public statements. The audit manifest should identify artifact owners, version authority, reopening triggers, and unresolved reconstruction gaps. A missing owner or reopening trigger should itself count as an audit defect because it leaves future correction without accountable authority. The manifest should also preserve dependency links among artifacts, so a later correction can identify which analyses, figures, or public statements inherited authority from a superseded object. This makes provenance actionable rather than merely historical.

A critic tries to reproduce a figure two years after publication. If the code environment, transform history, or dependency versions have disappeared, the figure has outlived the evidence needed to reconstruct it. Long-term reproducibility requires preservation of executable environments or an independently documented migration path, not code files alone. Reconstruction should begin from the archived inputs and declared environment rather than from a later analyst's memory of how the pipeline probably worked. A successful rerun should reproduce not only the image but also the intermediate quantities and version identifiers on which the published result depended.

If an environment file, device log, or exclusion script is missing, the affected figure cannot be treated as reproducible. It should be quarantined while the environment is reconstructed; if independent rebuilding fails, the figure and any dependent claim require correction or withdrawal (Committee on Publication Ethics, 2025; Crossref, 2025). Quarantine should extend to

downstream derivatives whose validity depends on the missing artifact, not just the visibly affected figure. The dependency record should therefore identify which conclusions can survive independently and which remain suspended until reconstruction succeeds.

Independent dry runs should test audit readiness by exposing missing artifacts before a public claim depends on them. Dry runs should include a person unfamiliar with the originating workflow, since tacit knowledge is itself a reproducibility dependency. The dry run should start from the archived manifest rather than from informal help by the original team, and any required undocumented intervention should be logged as a reconstruction defect. Repeated dry runs can also reveal whether later software or infrastructure changes have silently broken an otherwise complete archival package.

Public release can now be treated as a controlled transformation from record to claim. Every compression step should preserve the tested component, reference class, uncertainty, and correction route. A release manifest can make that transformation auditable by linking each public object to the analysis version and evidence packet from which it was derived. The manifest should also record the transformation that produced each public table, figure, caption, or summary, allowing reviewers to trace a simplified artifact back to the exact result it represents. If the underlying analysis changes, that dependency map identifies which public objects require review rather than relying on memory or broad manual searches.

26.8 — Public Release and Correction

Public release is a scientific act because public language can change the perceived status of the evidence. A release packet therefore binds the result to its component, reference class, context, rivals, uncertainty, access conditions, participant communication, persistent identifier, correction route, and hostile-crop review before high-reach language appears.

Public release remains status-labeled. The main sentence states the tested component, the relevant population or setting, the result, and any limitation that changes its meaning. The accompanying record supplies instrument and endpoint versions, rival analyses, heterogeneity, access conditions, and the correction route. A short surface is acceptable when its central claim remains accurate without the longer record.

Donor and media pressure receive a local boundary here because attention can alter scientific language. A preliminary result may sound more certain in a fundraising deck than in a paper. A null may disappear from a website because it is not inspiring. A correction may be delayed because it weakens a public narrative. Public release requires rules that remain stronger than excitement.

Participant communication deserves its own channel. People who contributed data should receive outcomes in language that is accurate, respectful, and not psychologically burdensome. They should not receive an individual ledger verdict, a spiritual interpretation, a prediction about endpoint neutrality, or a request to become a public example. Return should serve dignity, not publicity.

Publication of evidence and revision of the claim register are separate acts. A research system may release, correct, retract, withdraw, or label scientific results; it cannot silently rewrite the formal root, authorize an applied title, or open a transition gate. Those actions require their own governed routes.

Table 26.11. Public release label fields.

Release field	Required statement	Forbidden compression
Component tested	Which measurable component was studied	The Law is proven
Context of use	Population, site type, device, language, care regime, endpoint rule	Applies to all conscious streams
Replication state	Direct, conceptual, multisite, adversarial, transport, or failed	Independent confirmation without qualification
Rival status	Which rivals were compared and which remain viable	Rivals were defeated if they were not tested
Negative evidence	Nulls, failed sites, unusable data, deviations, incidents	Clean pattern with adverse evidence hidden
Correction path	Repository release ID, correction contact, retraction trigger	Permanent public certainty

26.8.1 — Embargo Until Required Review

Preliminary findings should not outrun the reviews that give them meaning. Site quality, harmonization, primary analysis, rival analysis, incident review, participant communication, and public

wording all need to close before a high-reach release (Committee on Publication Ethics, 2025; Crossref, 2025).

The embargo is therefore tied to specified review gates and an expected decision date. It protects the evidentiary record while preventing secrecy from becoming a tool for indefinite delay or narrative control.

A striking interim pattern may circulate among donors before blinded rival analysis is complete. Once attention enters the analytic room, choices about diagnostics, exclusions, and wording can become responsive to a story that has already begun to travel.

The result loses warrant when public attention shapes interpretation before the record closes. The remedy is to document the leak, repeat the affected analysis under protected conditions where possible, and reduce the status when independence cannot be restored (Center for Open Science, 2025).

Public trust sometimes requires patience while a claim finishes being checked. A release that outruns endpoint review, privacy review, or site reconciliation creates a public artifact the evidence cannot yet carry.

26.8.2 — Status-Labeled Release

A status-labeled release states the evidentiary object before interpretation begins: tested component, reference class, uncertainty, unresolved rivals, replication state, and correction route. These labels should be fixed in the release record and placed next to the public artifact, not added after attention rewards

stronger language (Crossref, 2025; Center for Open Science, 2025).

The release label states what was tested, where it was tested, what did not replicate, what rivals remain, and what correction path exists. The release register should identify the sentence owner, status source, correction trigger, and history of disputed wording.

A graphic shows terminal concentration but omits that two sites failed device harmonization. The image has retained the status of the headline while shedding the limits that made the finding accurate.

The public sees a clean pattern that the underlying record does not support. The graphic must be corrected or withdrawn and the failed harmonization limits restored to every active destination (Committee on Publication Ethics, 2025).

Status labels should be adjacent to the artifact, not buried elsewhere. Adjacent status labels protect readers by preventing a detached image from carrying more warrant than the study earned.

Status-labeled release makes the result understandable without manufacturing certainty. It preserves the difference between a component finding, a route verdict, and a whole-claim conclusion.

26.8.3 — No Donor or Media Upgrade

Fundraising and media attention cannot change scientific status. Every donor summary, media abstract, website, caption, and social excerpt should be checked against the same versioned

result record used for the technical report (Center for Open Science, 2025).

Communications review should compare each public claim with the tested component, scope, uncertainty, remaining rivals, replication state, and correction route. The public surface must preserve the route by which the sentence earned its warrant.

Suppose a sponsor asks to describe a partial replication as the first proof of the Law. The correct response is not a softer synonym for proof, but a component-specific statement that names what replicated and what remains unresolved.

When money upgrades the sentence while the data remain unchanged, the release has become a funding artifact rather than a scientific artifact. The overstatement should be blocked, corrected, and recorded as a public-risk incident (Committee on Publication Ethics, 2025; Crossref, 2025).

Release language should be fixed before donor packaging and revised only through the same correction process that governs the scientific record. This prevents access, prestige, or urgency from creating a second and stronger claim register.

Public communication can invite support for research by describing the question, current findings, and next study. Scientific status follows the evidence-review process.

26.8.4 — Correction and Retraction

Public error requires visible repair. A correction or retraction changes the status of every surface that carried the affected claim,

not only the paper in which the defect was discovered (Committee on Publication Ethics, 2025).

The correction plan identifies papers, repositories, code, websites, figures, captions, summaries, model cards, donor materials, and downstream citations, assigns an owner to each, and records completion. A process that cannot be executed and audited across those surfaces is not yet a correction system.

Suppose a later audit finds that a device-version bridge was invalid in a published figure. The technical explanation, revised analysis, participant communication, and public graphic all need coordinated repair; the burden cannot be shifted to one site or one reader to reconstruct.

Correcting the paper while leaving the public graphic online preserves the error where it has the greatest reach. The graphic should be relabeled, quarantined, or withdrawn, and every active citation to it should point to the correction (Crossref, 2025; Center for Open Science, 2025).

A correction record identifies the project-controlled surfaces updated, the known external reuses notified, and the copies that could not be recalled or corrected. A durable notice should remain available so readers encountering older material can find the current status.

26.8.5 — Participant Communication

Plan participant and family communication prospectively: return can create burden, false meaning, or participation pressure (National Academies of Sciences, Engineering, and Medicine, 2018).

The protocol fixes timing, optionality, plain language, study-level findings, limits, incidents, support routes, withdrawal implications, correction notices, and questions. Communication stays nonindividualizing absent a clinically authorized route.

Never send bereaved families summaries resembling verdicts on a loved one's inner life. Tone and timing add research burden; distress after return is not hostility to science.

Participants deserve clear findings and limits, with the freedom to decide whether and how they discuss their involvement publicly.

26.8.6 — Release Is Not an Update to the Claim Register

Publication does not change the formal series. A release may enter review, but publicity cannot revise root definitions, applied authority, religious doctrine, law, or transition timing (Crossref, 2025; Center for Open Science, 2025).

Each release names the tested component, review owner, untouched claims, and public limits. A favorable multisite result updates only the evidence register; broader scientific, applied, spiritual, legal, or transition changes need separate review.

Freeze and correct unsupported publicity upgrades; return evidence to human change control (Committee on Publication Ethics, 2025).

Chapter 27 — Evidence Accumulation and Defeat

Evidence becomes cumulative when each result can strengthen, qualify, or challenge the component it actually tests. Positive findings deserve clear recognition, mixed findings identify the next question, and adverse findings redirect work. An answerable evidence architecture gives every result an address, a justified scope, and a defined consequence for scientific status (Mayo, 2018; Lakatos, 1978).

Evidence attaches only to the component a design can reach. A hospice study may inform terminal concentration in one clinical context without speaking for childhood, nonhuman animals, dreams, artificial systems, or the strong latent universal branch. A horizon task may pressure a candidate scheduling model without changing the endpoint claim, while a failed wearable pipeline may retire one instrument version and leave the lived target untouched.

Methodological trustworthiness and eventual factual correctness are distinct. A result can later prove wrong yet remain trustworthy when the question was clear, the study was evaluable, error controls were visible, and the public sentence matched the evidence. A favorable result can remain untrustworthy when those conditions fail, even if later work happens to point in the same direction (Nosek et al., 2026).

Evidence accounting is noncompensatory. Strong replication cannot repair invalid measurement, a beautiful model cannot repair endpoint leakage, public interest cannot repair rival inferiority, and a large sample cannot repair a wrong estimand. Necessary dependencies are conjunctive, so one blocked gate can cap the entire downstream claim.

Narrowing is a central scientific skill, but not every successor is a narrower form of the same claim. A smaller reference class or domain may narrow scope; a change from exact scalar closure to a vector, finite-band, probabilistic, or route-level target creates a non-equivalent successor with a new identifier, assumptions, and decision rule. Progress depends on naming that change and preserving the failed predecessor.

Every evidence state receives usable language. Preliminary component support, replicated support, Route-favored, Model-ambiguous, Rival-favored, Open-set inadequate, Reference-class narrowed, No adequate estimate, route retirement, and theory-level defeat occupy different axes rather than one prestige scale. Each conclusion carries its own next step and public sentence.

The stakes appear in ordinary research work. A statistician may find heterogeneity hidden by a pooled estimate, an endpoint reviewer may discover outcome leakage, a family advisory group may hear an overclaim in a summary, and a rival steward may recover the data better than the focal model. In an answerable system, those findings change status before release instead of becoming cleanup after the announcement.

Dissent remains part of the evidence record because scientific judgment cannot be delegated to one equation or one committee. Minority reports, appeals, external challenges, and later reconsideration preserve observations that a majority may have missed. The architecture records disagreement while maintaining a decision deadline and a defined reconsideration route.

Defeat is reported without spectacle: it changes the scientific claim, not the standing of participants or the obligations owed to them. The verdict belongs to the model and claim, not to the people who supplied the evidence.

Scientific memory must operate at component scale. Earlier Parts asked how to measure, model, compare, and replicate; the evidence record now states what was tested, what was not, which dependencies failed, what rivals explained better, which claims narrowed, and which public artifacts changed. Without that memory, later researchers can repeat the same overclaim in more polished language.

The result is verdict discipline rather than verdict theater. A mature record may say that one component is replicated, another remains Model-ambiguous, a third has No adequate estimate, a fourth is Rival-favored, and the strong form has not moved. That mixed state is precise when each conclusion follows a declared gate. The mixed record should be preserved without forcing a single overall score, because different components may justifiably move in opposite directions.

The program becomes stronger by losing locally, recording the loss, and changing course. A smaller true claim outranks a universal claim protected by ambiguity. A retired mechanism outranks a rebranded failure, and a public correction outranks a silent rewrite that preserves prestige while shifting the scientific burden. Local losses also reduce future burden by preventing repeated investment in bridges or mechanisms that have already failed adequate tests.

Chapter 27 supplies the rules by which evidence accumulates and updates the status of claims, routes, mechanisms, and reference classes through support, narrowing, suspension, retirement, or defeat. It governs future abstracts, figures, interviews, donor pages, public replies, and cross-book references by forcing each sentence back to the component and evidence packet that earned it. No result may travel farther than its design. This traceability allows later public language to strengthen when evidence improves and contract when it weakens without rewriting the history of either change.

27.1 — Evidence Attaches to Components

An evidence system begins by giving every result an address. Representation, measurement, bearer classification, endpoint adjudication, formal realization, route, signature, rival comparison, replication, transport, and public language remain separate nodes connected by explicit dependencies. A finding changes only the node it reaches and the downstream claims licensed by that node.

The following map connects findings developed earlier in the book with the comparisons they make possible. It also identifies the units to track when combining results across studies.

Table 27.1. Scientific findings and connected research questions.

Evidence family	Scientific contribution	Next comparison	Unit to track in synthesis
Mood and activity selection — Taquet et al. (2016, 2020)	Mood relates to subsequent activity selection, providing a basis for studying affect regulation in everyday life.	Compare predictions from current mood, activity opportunities, and prespecified affective-history summaries.	Participant and dataset; the reports share the smartphone cohort.
Temporal structure of mood — Keren et al. (2021)	A primacy model predicted mood better than recency alternatives in the tasks studied.	Compare primacy, recency, and cumulative-history models across tasks and timescales.	Participant sample and task.

Evidence family	Scientific contribution	Next comparison	Unit to track in synthesis
Biological cumulative responses — Gupta and Sontag (2025)	Integral-feedback and particular feedforward models made different predictions for cumulative dose–response shape.	Identify response patterns that distinguish specified models of accumulated affect.	Model architecture, input history, and output measure.
Sleep and emotional processing — van der Helm et al. (2011); Wassing et al. (2019)	Overnight changes in emotional responses connect affective adaptation with sleep and REM continuity.	Jointly model prior affect, sleep continuity, and subsequent emotional responses.	Participant cohort and sleep protocol.
Belief and allocation choices — White et al. (2019)	Reminders of karma or God increased generous allocations among corresponding believers in the experiments.	Compare predictions based on belief, social incentives, and affective history.	Experiment, participant sample, and belief group.

These connections support a coordinated research program: measure affective histories, specify competing predictions, and test which relations carry across settings. Joint analyses can account for shared participants and measurements while assessing how well each model predicts new observations.

The component graph is both a scientific and ethical safeguard. It keeps uncertainty from being shifted onto participants, critics,

later authors, or vulnerable readers. When a study reaches only one bridge, the public sentence remains on that bridge.

Table 27.2. Component evidence matrix for noncompensatory claim status.

Component	What evidence can update	Dependencies to verify
Representation	Scalarization, temporal additivity, origin convention, multidimensional alternatives.	Coherent representation before interpreting endpoint findings.
Measurement	Calibration, context of use, uncertainty propagation, and version performance for the candidate momentary-valence and interval-contribution estimators.	Instrument qualification alongside the formal realization.
Bearer and endpoint	Unity classification, stopping rule independence, open-channel windows, false endings.	Independent endpoint adjudication and qualified bearer classification.
Realization and mechanism	Reserve coupling, Queue, horizon, brain-body mediators, stochastic assumptions.	Connection between the tested mechanism and the specified target.

Component	What evidence can update	Dependencies to verify
Rival and consequence	Signature conjunction, Brownian bridge, adaptation, predictive control, selection, missingness.	Competitive alternatives evaluated under common comparison rules.
Replication and transport	Direct, conceptual, multisite, transported, leave-site-out, leave-device-out.	Heterogeneity and site-specific outcomes alongside the pooled estimate.

Equation 27.1 (component evidence graph):

$$G_{evidence} = (C, D, E, R, V)$$

Here C names components, D names dependencies among components, E names evidence records, R names rival states, and V names versioned public verdicts. The display records how scientific components, evidence, and decisions are connected.

Equation 27.2 (noncompensatory gate rule):

$$PublicStatus(C *) \leq Status(c), \text{ for every } c \in Dep(C *)$$

The preorder expresses a noncompensatory dependency rule: a downstream public status cannot outrun any failed prerequisite on a compatible status axis. Unlike verdicts remain separate, and the component states are not forced into a total order. A successful mechanism cannot repair failed measurement, and a favorable pooled result cannot repair endpoint failure.

A component graph gives specialists a precise place to contribute. Measurement researchers can examine calibration, palliative clinicians can evaluate endpoint windows, and statisticians can

assess transport. Each contribution can improve its component while leaving other questions available for separate review.

The graph is versioned because components change. A candidate instrument version, an endpoint rule, a reserve realization, and a rival matrix each have revision histories. If a later study cites a component without its version, the citation becomes ambiguous. Ambiguity is where unsupported status travel begins.

Dependencies should be marked as necessary, optional, or explanatory. Measurement validity is necessary for measured-ledger claims. A particular brain-body mechanism may be explanatory but not necessary for a consequence signature. A public artifact is not a scientific dependency, but it is a public-risk dependency because it can distort what the evidence means.

The graph also helps reviewers ask whether a result is adverse in the right place. A failed mechanism is not an adverse endpoint. A failed endpoint is not a failed measurement instrument. A failed measurement bridge is not evidence that lived experience has no structure. Precision prevents both inflation and despair.

One useful review habit is to require a result sentence before a conclusion sentence. The result sentence names the component and finding. The conclusion sentence says what changes. If the conclusion says more than the result sentence can carry, the status has drifted.

Accordingly, the component graph functions as a public-language instrument, not merely an internal database. It shows why one claim changed while neighboring claims did not. That visibility is part of the fairness of the science itself.

The component record includes a concise use-scope column specifying the permitted research context, affected decisions, and protected participant rights. This makes the operational boundary available where the evidence is used.

Component records contain unresolved dependencies in active voice. Instead of saying “measurement remains a limitation,” the status should say, “the candidate instrument version has not established sign validity in this context.” Active wording makes the blocker visible enough to govern later claims.

The same discipline applies to positive components. If endpoint adjudication is strong, say so plainly. If a rival matrix is unusually complete, say so plainly. Component discipline preserves excellence by locating it precisely rather than flattening it into caution.

In practice, the component graph becomes a table for line-by-line review. That review lets specialists resolve component scope before publication and gives readers a clearer account of what the evidence supports.

27.1.1 — Representation Component

The representation component asks whether the scientific object has been expressed in a form that can carry evidence at all. It covers scalarization, temporal additivity, origin conventions, sign conventions, and the decision to treat a stream as a path rather than as a collection of detached moments. If representation fails, later measurement may be precise but aimed at the wrong object.

A representation update evaluates whether the chosen formal language can express the target. Evidence may favor a richer

structure, separate dimensions, or a different sampling cadence for recovering a time-integral. These findings guide the next model and measurement design.

Consider a team that obtains reliable arousal data, tolerable sampling, and stable within-person response scales while valence origins vary across illness stages. The next representation study can examine state-specific calibration or a richer structure for that reference class.

A cleaner figure is not a reason to preserve an unidentified scalar. An investigator may keep the scalar because it makes the figure, narrative, or press release easier to present. The graph forbids that convenience. If the representation does not identify the quantity, a later endpoint pattern cannot rescue it. The public record must say that the tested scalar representation was not established for the declared context of use (Popper, 1959; Lakatos, 1978).

The status language should be exact. A representation may be supported, unresolved, narrowed, replaced by a multidimensional structure, or retired. It should not be called validated simply because downstream models fit. Fit can hide wrong meaning when the model absorbs representation error into nuisance parameters.

Carry forward the representation question: which experiential structure did the study model, and how was it connected to the observations?

27.1.2 — Measurement Component

The measurement component concerns the candidate momentary-valence and interval-contribution measurement stack, its context

of use, calibration evidence, uncertainty model, and version history. Declared channels, sign rules, missingness models, participant challenge rights, and transport evidence define how its estimates can be used (Popper, 1959).

Measurement evidence can improve wearable reliability, reduce recall bias through a better report schedule, or increase held-out predictive accuracy. Each gain strengthens a specific part of the observation process.

A concrete measurement case begins with a multisite candidate instrument version that performs well in cancer hospice settings but fails calibration in advanced neurological disease because speech loss, motor slowing, medication, and autonomic disturbance change channel meaning. The appropriate response is not to average the populations together, but to impose a context-of-use boundary and version note.

The danger is compensatory thinking. Researchers may say that the endpoint signature still looks favorable, so measurement limitations can be tolerated. The correct rule is the opposite. If the sign, scale, uncertainty, or missingness of the measured ledger is not valid for the tested context, then the target was not tested in that context (Lakatos, 1978; Manski, 2003).

Measurement status must therefore name version, population, setting, device, cadence, language, and intended inference. A result may support candidate instrument version 3.1 for comfort-first observational palliative research while saying nothing about ordinary life, employment, education, public administration, or private self-tracking.

The graph protects people as well as statistics. When measurement remains inside the declared research protocol, it leaves no eligibility decision, trust label, worth judgment, or care ranking behind. That boundary is part of the measurement component, not a decorative ethics note.

27.1.3 — Bearer and Endpoint Components

Bearer and endpoint components identify the continuing stream under study and its independently specified stopping rule. They state how person, body, record, report, device, and clinical-event information contributes to that classification (Popper, 1959; Lakatos, 1978).

Endpoint evidence updates a stopping rule only when that rule is independent of the ledger estimator. The endpoint cannot be defined as the moment the measured ledger appears neutral; it must use prospectively specified unity or consciousness-related channels that are not algebraically identical to the outcome. Otherwise neutrality is built into the definition rather than discovered.

If monitoring stops during sudden deterioration, the endpoint record should identify whether sedation, device tolerance, family burden, or another observation event explains the missing channel. Independent endpoint evidence determines the classification used for later analysis.

Endpoint adjudication is tracked separately from the study's stopping rule. A convenient final observation may end data collection while leaving the endpoint unresolved. The component graph records that distinction and identifies the additional

endpoint evidence required for terminal inference (Manski, 2003).

Bearer and endpoint status belong in the public record: which stream criteria were applied, what endpoint object was used, how uncertainty was carried, and which observations remained unavailable. That disclosure prevents a component result from being mistaken for direct access to a person's complete conscious history.

The strong form waits behind these gates. No amount of model fit should move it if the bearer or endpoint component remains unresolved. The endpoint firewall is not a preface. It is a dependency.

27.1.4 — Realization and Mechanism Components

Realization and mechanism components describe candidate dynamics for a formal boundary condition. Reserve coupling, scheduling routes, finite-horizon pressure, shadow costs, brain-body mediation, and stochastic process choices each supply structures that can be modeled and tested (Lakatos, 1978; Manski, 2003).

A reserve-coupled product model may predict variance compression in a specified window. The corresponding result evaluates that prediction and the measurement relation connecting latent burden to observed dynamics.

If variance compression appears only under a fitting window that also favors Brownian bridge models and observation-shutdown artifacts, the result identifies a model-confusion region. Recovery

analysis can then determine which measurements or windows would separate those explanations.

Rebranding a failed mechanism does not preserve its evidence. If the candidate scheduling model fails, the program may not quietly relabel ordinary avoidance as candidate scheduling behavior. If finite-horizon pressure fails, the program may not call every urgency effect a finite-horizon control signal. New mechanisms require independent motivation and new risk analysis.

Mechanism status can be supported, bounded, narrowed, suspended, retired, or replaced. A replacement record states what changed, what evidence motivated it, what new predictions follow, and which outcomes would challenge them.

Mechanisms can be refined or retired as evidence accumulates. Their lasting contribution is the sharper question, better instrument, or clearer prediction they leave for the next study.

27.1.5 — Consequence and Rival Components

The consequence and rival components ask whether the predicted observable structures appear and whether serious alternatives explain them as well or better. The relevant object is not a single impressive curve. It is the conjunction of signatures under the same observation constraints faced by the Law-candidate model and by its rivals (Manski, 2003).

A consequence may be terminal concentration, variance compression, reserve-linked contraction, endpoint independence, or a failure of ordinary first-moment explanation. But none of these alone is sufficient. Brownian bridges, Doob transforms,

adaptation, frailty, medication, terminal scripts, missingness, and selection can all mimic parts of the pattern.

A useful stress test is a pooled terminal dataset where the final estimated ledger values cluster near the neutral band. If data were aligned to death after the fact, if visits intensified near decline, if sedation removed high-variance observations, or if one site contributed most of the late windows, the apparent consequence may belong to observation and selection rather than to the Law.

Weak rivals make a favorable comparison scientifically uninformative. A chapter or protocol that gives the Law a flexible model and gives rivals caricatures has already failed the component. Rival seriousness is not generosity. It is identification. A weak rival matrix can manufacture support by making ordinary explanations look absent (Popper, 1959).

The status update should say which consequence survived which rival. A signature can be supported against adaptation and still unresolved against bridge models. A model can outperform frailty in one diagnosis and lose to medication-only decline in another. That granularity is the governing discipline.

The scientific dignity of the project depends on letting rivals win where they should. A rival victory is not a public-relations crisis. It is an accurate allocation of explanation.

27.1.6 — Strong-Form Component

The strong-form component concerns terminal neutrality for qualifying unified conscious streams. Its evaluation joins formal representation, longitudinal measurement, endpoint identification, and comparisons across reference classes.

Results bear on the strong form through explicit prediction and comparison. Replicated agreement across qualified components can strengthen a specified account; credible counterexamples can identify where its scope or assumptions require revision. The evidence graph makes these contributions assessable together. The graph should distinguish evidentiary dependence from thematic relation, preventing a nearby success from being counted as support for a component it does not test.

Put this rule against a decade of studies that support variance compression in some palliative contexts, defeat one candidate instrument version, retire one candidate scheduling model, and show strong rival performance in another diagnosis. The public summary maps those findings by component, population, and study design, making the advances and next questions visible together. The map should preserve study-level identifiers so readers can trace each status back to its evidence packet rather than rely on a synthesized reputation of the program.

Prestige contaminates review when the reputation of a team, site, journal, or sponsor changes how much adversity a result must survive. Once a program has enough technical machinery, people may begin to speak as though the strong form has been carried by the weight of the whole apparatus. The component graph prevents that drift. The strong form is not the sum of enthusiasm across components (Popper, 1959; Lakatos, 1978). Dependency weight should come from the logic of the claim rather than the prestige or volume of work surrounding a component.

Status language for the strong form must be conservative and explicit. It may remain hypothesized, under pressure, narrowed in

public interpretation, suspended from empirical verdict, or defeated under defined conditions. It should not be upgraded by applied coherence, public resonance, or institutional usefulness. Any stronger label should identify the specific dependency that changed and the evidence that justified the upgrade.

The strong-form component therefore sits last in the graph. It receives pressure only through dependencies that have survived. That order is not modesty; it is the price of making a universal claim without turning it into doctrine. Placing the strong form last also exposes where the chain remains incomplete instead of allowing completed lower-level work to create an illusion of closure.

27.2 — Sequential Evidence and Replication States

Using the reproducibility, robustness, replication, and transport distinctions established in Chapter 26, this section orders the evidence states that can change a claim: exploration, prospectively specified testing, public preregistration where actually deposited, direct or conceptual replication, multisite replication, transported replication, and sequential review (National Academies of Sciences, Engineering, and Medicine, 2019; Nosek et al., 2018; Klein et al., 2018; Bareinboim & Pearl, 2016).

The sequence prevents status from becoming a score. A component may have three promising signals and no adequate replication. Another may have one severe failure that blocks further public claim. The judgment is structured, but it is not arithmetic.

Table 27.3. Evidence states and the public language each state permits.

Evidence state	Scientific function	Permitted public language
Exploratory signal	Generates design questions and candidate signatures.	Describes an exploratory finding and motivates a prospectively specified comparison.
Prospectively governed single-study result	Tests one component under declared rules.	May update the tested component within its reference class.
Direct replication	Repeats the essential test independently.	May strengthen or weaken the same component claim.

Evidence state	Scientific function	Permitted public language
Conceptual replication	Tests the same component through different design logic.	May support robustness of the component, not identity of mechanism.
Multisite or transported replication	Tests heterogeneity and context of use.	May widen, narrow, or split the reference class.
Governed review	Integrates quality, dissent, rivals, and public correction.	May issue a status label with scope and reasons.

Equation 27.3 (sequential status update, human-reviewed):

$$S(c, t + 1) = J[S(c, t), e(c, t + 1), q(c, t + 1), r(c, t + 1)]$$

The symbol J stands for governed judgment, not a mechanical score. It receives the prior component status, a new evidence record, quality information, and rival-state information, then issues a versioned decision with recorded reasons.

Sequential evidence also needs a calendar. A result released before review has a different status from the same result after independent verification, data audit, and rival reanalysis. Time does not make evidence stronger by itself, but time allows the checks that prevent premature authority.

The sequence records movement in both directions. A component can move from exploratory signal to preliminary support and return to inconclusive after a failed replication. A model can move from promising to retired. A measurement version can move from local use to suspended use after device drift. Evidence, not institutional optimism or elapsed time, determines the direction.

The review unit is not a single paper but the evidence record for a component. Papers can contain multiple components, and one paper can support one component while defeating another. A sequential system that treats each publication as one point will blur the exact distinctions the evidence architecture is designed to protect.

Publication bias requires special attention because favorable results travel farther and are easier to remember. Null results, unusable studies, burden stops, and unpublished protocols can disappear unless the evidence system requires them. Sequential review asks not only what was published, but what was prospectively specified, publicly preregistered, attempted, stopped, or withheld.

The sequence also protects participants. If early studies repeatedly show nonseparability or unacceptable burden, the next stage may be redesign rather than more recruitment. Evidence accumulation should not become an excuse to ask vulnerable people for the same inconclusive data again.

In a mature program, status movement should be slower than public excitement and faster than institutional denial. It waits for verification without waiting forever after the evidence has turned. That timing is part of sequential scientific discipline.

Status movement requires prospectively specified stopping conditions. A component cannot remain preliminary forever because the next replication is politically inconvenient, and it cannot upgrade because time has passed. The record identifies

which evidence triggers upgrade, narrowing, suspension, retirement, or defeat.

Sequential review should also mark stale evidence. A measurement version tested under one device firmware, one care regime, or one diagnostic convention may become outdated. Staleness does not erase the study, but it changes the role the study can play in current status.

The evidence record for a component includes failed registrations and abandoned protocols. A publicly preregistered study stopped for ethical burden teaches something different from a design that was only privately drafted or never launched. Each history changes the burden and interpretation of the next study.

When new evidence arrives while public materials remain in circulation, the sequence includes an embargo policy for status claims. Internal analysis may proceed, but external language waits until the declared review gate is complete. This prevents half-reviewed results from becoming public certainty.

Independent reanalysis examines a predeclared family of analytically reasonable specifications rather than one critic-selected alternative. Multiverse and specification-curve methods reveal whether a status label depends on one defensible choice among many, while many-analyst designs expose how expert judgment contributes to dispersion. These approaches do not average truth into existence; they map analytic fragility that the evidence register must carry into later review (Steege et al., 2016; Simonsohn et al., 2020; Silberzahn et al., 2018).

A sequential system earns credibility by moving downward when the evidence requires it. Upward movement is trustworthy only when the same machinery can record analytic fragility, failed replication, stale instruments, burden stops, rival superiority, and status reversal.

27.2.1 — Exploratory Signal

An exploratory signal can reveal a bounded empirical pattern and help design a stronger test. It may arise from pilot data, retrospective records, qualitative observation, or existing measurements; simulation can separately reveal what a model predicts under stated assumptions. The report should identify the source, selection process, analytic flexibility, and uncertainty. Such findings contribute to discovery and identify the prospective comparison to run next (Chambers, 2013; Nosek et al., 2018; Lakens, 2017).

Record the signal's provenance, analytic degrees of freedom, selection routes, and plausible alternative explanations. Distinguish expectations stated before inspection from questions first suggested by the observations.

The contrast is clearest in a terminal dataset where late variance appears lower than early variance. The pattern may motivate a prospectively specified compression test, but it may also reflect more frequent visits near decline, medication changes, hospice admission criteria, or missing high-distress observations. Exploration should sharpen those alternatives rather than announce a finding.

Label an exploratory figure at its first release and link it to the analysis record. Readers can then follow how an initial observation develops into a specified prediction and independent test (Schönbrodt et al., 2017; Nosek et al., 2018).

Exploratory reporting should state the observation directly and label its status: for example, the analyzed sample showed a pattern that motivates a prospective comparison. The resulting hypothesis can then be stated with words such as suggests or motivates, followed by the comparison that would evaluate it.

An exploratory signal carries the program forward by identifying a question worth testing. Preserving its exploratory status gives that early insight room to develop while keeping later confirmation independently informative.

27.2.2 — Publicly Preregistered Single-Study Result

A single-study result that meets §6.7's public-preregistration standard has more authority than an exploratory signal because its promised path, deviations, and decision rule are independently inspectable; registration does not make the result true (Lakens, 2017; Schönbrodt et al., 2017).

The component updated by a single study is the component actually tested. A study may publicly preregister measurement invariance for one diagnosis and one device version, or one endpoint rule for one context of use; neither record updates every instrument or stopping classification.

Consider a single hospice protocol that tests equivalence of a declared measured estimand using a specified candidate instrument version during independently adjudicated open-

channel windows. A favorable result may justify preliminary component support for that candidate momentary-valence estimator-endpoint combination. It does not validate the strong form.

Changing a threshold after outcome inspection converts a confirmatory test into a rescue. Neutrality bands, endpoint windows, inclusion rules, and smoothing parameters may still be explored in sensitivity analysis, but the resulting claim no longer occupies the publicly preregistered single-study state (Nosek et al., 2018; Klein et al., 2018).

A single-study statement names the component, reference class, registry identifier, protocol and analysis version, deviations, comparison models, and uncertainty. These details let readers assess its contribution and plan replication.

A good single study creates a clear opportunity for independent replication, with the essential design preserved and both confirming and disconfirming outcomes able to inform the next step.

27.2.3 — Direct Replication

Direct replication repeats the essential test as closely as feasible while using an independent team, independent recruitment, and independent analysis controls. It asks whether the original component result survives when the social, coding, and analytic context changes. Here, direct does not mean identical in every detail; it means that the critical test is preserved (Schönbrodt et al., 2017; Nosek et al., 2018).

Replication evidence should include adherence to the original protocol, permitted deviations, device and software versions, participant burden, endpoint adjudication, and blinded analysis status. A study that changes the target must be identified as a new test. A changed design may qualify as conceptual or transported replication only when it still tests the same declared component and its relationship to the original test is explicit.

Consider a second team repeating a preterminal variance-compression test using the same candidate instrument version and endpoint rule at a new site. If it succeeds, the component gains credibility. If it fails under adequate conditions, the original result becomes local, fragile, or possibly false.

Replication is protected rather than severe when the favored component is insulated from adverse outcomes. A favored model can be protected by tuning the replication to the original site's quirks or by explaining every adverse result as implementation failure. Direct replication must permit the possibility that the original finding does not repeat (Open Science Collaboration, 2015; Klein et al., 2018; Nosek & Errington, 2020).

Only independent repetition under the essential design licenses replicated component support. The summary must identify the component, sites, prospectively specified target, any persistent preregistration records, common analysis, unresolved heterogeneity, and evidence state rather than treating replicated as a free-standing seal.

Direct replication is an act of respect. It says the finding matters enough to expose it to independent failure.

27.2.4 — Conceptual Replication

Conceptual replication tests the same component through a different design, measurement route, population, or mechanism. It is powerful because it asks whether the component is more than an artifact of one procedure. It is also risky because the design can drift away from the original object (Nosek et al., 2018; Klein et al., 2018).

A conceptual replication must name the invariant being tested. Is it the same consequence, the same measurement bridge, the same endpoint relation, the same rival defeat, or the same mechanism? Without that declaration, any loosely similar result can be folded into support.

Cross-method comparison becomes informative in testing the same narrowing of terminal variance through experience sampling, clinician-assisted reports, and passive physiological channels. Agreement across designs may strengthen a consequence component. Disagreement may reveal that one method captures arousal, another captures reportability, and neither alone captures measured burden.

Analogy becomes misleading when thematic resemblance is described as replication. A study that finds any repair, rebound, adaptation, or calmness is not necessarily replicating a Law-specific component. Conceptual replication must remain conceptual in the scientific sense, not associative in the rhetorical sense (Nosek & Errington, 2020; Lakens, 2017).

Conceptual replication requires public language that names both the invariant and the deliberate design change. A result that

survives a new population, instrument, or perturbation may strengthen transport of one component while leaving the original mechanism and endpoint bridge unresolved.

Conceptual replication broadens the question by changing the route. It should not broaden the claim by blurring the destination.

27.2.5 — Multisite and Transported Replication

Multisite and transported replication asks whether a component survives across sites, devices, languages, care regimes, diagnoses, cultures, and study teams. It is not merely more data. It is a test of context. Heterogeneity is therefore not a nuisance to be averaged away; it is one of the central findings (Klein et al., 2018; Fortier et al., 2011; Stuart et al., 2011; Bareinboim & Pearl, 2016).

Transported evidence must define context of use. A palliative oncology setting, a neurological ward, a sleep laboratory, a home-diary study, and an Artificial Intelligence-mediated archive do not share the same observation process. Replication across them requires measurement invariance, endpoint comparability, and rival envelopes appropriate to each context.

Transport is tested by a signal that repeats in two English-language hospice networks but fails in a multilingual setting where reports are mediated through family interpreters and different pain medication practices. The correct update may be transport failure, not global falsification and not global support.

A favorable pooled average can conceal site reversal, device-version failure, subgroup harm, or care-regime dependence. Prediction intervals, leave-site-out checks, and site-specific

reports must remain visible (Lakens, 2017; Schönbrodt et al., 2017).

Public language after transported replication should say whether the reference class widened, split, narrowed, or failed to transport. The phrase replicated across sites is incomplete unless the heterogeneity record travels with it.

Transport is where a theory learns humility. A claim that becomes smaller across contexts may become more useful because it finally names where it lives.

27.2.6 — Sequential Validity and Review

Sequential validity concerns how evidence is reviewed over time without letting repeated looks, changing thresholds, or accumulating public pressure distort the result. Statistical tools can help, including prediction intervals, sequential meta-analysis, calibration checks, and robustness summaries. But the judgment remains governed by humans who must record reasons, dissent, and scope (Jennison & Turnbull, 2000; Lakens, 2017).

A living evidence system should separate analysis updates from status updates. New data may update plots, posterior distributions, heterogeneity estimates, or model weights before the public status label changes. This prevents every interim fluctuation from becoming a headline.

Sequential review is tested by a series of three replications, one favorable, one mixed, and one negative under a new device version. Sequential review should not choose the most comforting interpretation. It should ask whether the component is version-

dependent, whether transport failed, whether the original mechanism is wrong, and whether the public label must narrow.

Review by momentum treats elapsed time and institutional investment as evidence for an upgrade. Once a program has a public identity, committees may feel that status should move gradually upward unless catastrophe occurs. That pressure is rejected. A single severe dependency failure can block an otherwise favorable accumulation (Schönbrodt et al., 2017; Nosek et al., 2018).

Sequential review should publish the rule by which evidence states are revised, the quality criteria applied, the dissent recorded, and the correction path for public artifacts. The result is not a score, but it is not private intuition either.

The sequence ends where judgment begins. Tools arrange evidence; people accept responsibility for language.

27.3 — Route-Favored, Partial, and Replicated Results

Positive evidence needs disciplined vocabulary. Calling every favorable result merely interesting prevents learning; calling every favorable result validation destroys scope. Component support, route preference, replication, convergent evidence, and target evidence therefore receive distinct meanings, thresholds, dependencies, and propagation rules.

The standard is generous to real findings and strict about scope. A component can be supported while another component blocks a wider claim. Convergence can matter without becoming universal discovery. The public statement must carry both truths.

Table 27.4. Positive status labels and their dependency limits.

Status label	Minimum condition	Required limitation
Preliminary component support	One adequate prospectively specified result for a declared component.	Names reference class, analysis version, and unresolved rivals.
Partial support	Some predicted structure appears while dependencies remain unresolved.	Lists adverse, missing, or untested dependencies.
Replicated component support	Independent direct or transported support.	Retains heterogeneity and site-specific failures.
Mechanism support	A candidate realization predicts better than declared rivals.	Does not support the strong form by itself.

Status label	Minimum condition	Required limitation
Convergent support	Different methods support the same component.	Requires shared target, not merely similar story.
No full-canon validation	A component succeeds but the series remains domain-separated.	Prohibits applied, legal, religious, or transition upgrade.

A worked result packet makes the vocabulary operational. Suppose a four-site study qualifies the candidate momentary-valence instrument in two sites, detects calibration drift at a third, and cannot adjudicate the terminal endpoint at a fourth because sedation and missingness exceed the protocol-fixed bounds. In the two qualified sites, a reserve-coupled candidate outperforms one ordinary regulator but remains indistinguishable from an endpoint-conditioned bridge under held-out scoring.

The correct record is mixed rather than averaged. Two qualified contexts may support the measurement component, the third yields Unusable evidence for the affected measurement estimand, and a fourth may suspend terminal inference. The route can remain Model-ambiguous while the strong target does not move. No pooled mean repairs blocked gates, and no favorable site speaks for an endpoint class it could not identify.

The public sentence names both the object and the limits: two sites reproduced a bounded measurement result, while device transport and terminal-endpoint prerequisites failed elsewhere, leaving the PTVC target unadjudicated. That sentence is less dramatic than a discovery claim, but more informative because

another team can reconstruct what succeeded, what failed, and what evidence would be needed next.

Positive language should be written so that it can survive hostile quotation. A sentence that says replicated support without naming component and scope will be cropped as validation. A sentence that says partial support while hiding the blocker will be cropped as evasion. The solution is not timid prose, but complete local prose.

The support label should include the result's dependency footprint. A measurement-supported component with endpoint unresolved has a different footprint from a mechanism-supported component with measurement unresolved. The reader should never have to infer which bridge remains open.

Quality governs interpretation as much as count. Three weak studies do not necessarily outrank one strong, publicly preregistered replication, and one strong study may still be blocked by a severe dependency failure. Positive evidence accumulates through quality-sensitive judgment rather than the emotional appeal of repetition.

A support statement should also identify the strongest surviving rival. If the result beats some rivals but remains unresolved against bridge or selection rivals, the public sentence should say so. Rival visibility prevents positive language from becoming an argument by omission.

The support vocabulary rewards good work. Bounded findings can earn real recognition without being inflated into support for the whole Law.

Every positive label carries a loss condition. Preliminary support states what replication failure would remove it. Partial support states which dependency must be resolved before the claim can expand. Replicated support states which heterogeneity or transport failure would narrow it.

Support language should also distinguish scientific excitement from public entitlement. Researchers may be excited by a clean component result. The public, however, is entitled to hear scope, uncertainty, and rival status in the same breath as the result.

When a component is supported, downstream chapters or public artifacts should not quote it without its qualifier. A graph label, caption, social excerpt, and donor paragraph must carry the component boundary. Otherwise the qualifier exists only for those who read the technical chapter.

The status record identifies who reviewed the positive label. A label that has not passed independent analysis, red-team review, and public-risk review does not enter high-reach summaries. The issue is premature authority, not secrecy.

Partial support can be more useful than broad support because it directs future work. It says where the bridge held, where it cracked, and where the next protocol should apply pressure. That guidance is lost when partial support is flattened into good news.

27.3.1 — Preliminary Component Support

Preliminary component support is the first positive label a result can earn after adequate prospectively specified testing. It is neither a consolation nor a promotional label. It means that one

component survived one serious test under declared assumptions (Open Science Collaboration, 2015; Camerer et al., 2018).

The label names the supported component: a measurement bridge, a terminal-window pattern, a rival-comparison result, or a mechanism prediction. Including the population, window, and analysis in the same statement gives preliminary support a precise and useful meaning.

The distinction is clearest in one high-quality study whose design was publicly preregistered and whose prespecified equivalence procedure yields a nonempty measured compatibility set lying wholly within the equivalence band for a declared estimand, using a specified candidate instrument version during independently defined open-channel windows for one diagnosis group. The public statement may report preliminary support for that measured-endpoint component in that context. It may not say the Law has been discovered.

Emotional acceleration occurs when a striking result moves through the status ladder faster than its dependencies can be checked. Supporters may hear preliminary as nearly proven, while critics may treat it as spin. The status record should therefore publish the exact tested component, the untested dependencies, the rival matrix, and the conditions that would reverse the label (Klein et al., 2018; Vehtari et al., 2017).

Preliminary support should travel with an expiration condition. It waits for direct replication, conceptual replication, or transported replication. If those fail, the label changes. It is not a permanent trophy stored from an early favorable result.

The dignity of preliminary support is that it lets science be hopeful without being careless. It gives the next study a reason, not a conclusion.

27.3.2 — Partial Support

Partial support recognizes that some predicted structure appeared while other dependencies remain unresolved, mixed, or adverse. It is more honest than either all-or-nothing support or total dismissal. Many serious programs live for a long time in this state (Camerer et al., 2018; Klein et al., 2018).

The label should name what is supported and what blocks expansion. A consequence signature may appear, but the mechanism may fail. A measurement version may work locally, but transport may fail. A rival may be beaten in one dataset and win in another. Partial support is not a vague positive mood; it is a structured partition.

Consider a study that estimates variance compression in a prospectively defined preterminal window but cannot adjudicate the later endpoint. If measurement is qualified for that window, the study may support the measured preterminal pattern while leaving terminal inference unavailable. If measurement also fails for the affected observations, those observations cannot support the pattern; report the qualified and unusable subsets separately.

Selective emphasis distorts accumulation by foregrounding favorable components and relegating adverse ones to technical margins. A public summary may lead with the supported part and hide the unresolved part in subordinate clauses. The blocker must appear in the same status statement as the support. The unresolved

dependency is part of the finding (Vehtari et al., 2017; Open Science Collaboration, 2015).

Partial support may justify continued research, narrower protocols, and careful public discussion. It does not justify applied authority, public scoring, personal endpoint testing, spiritual certainty, or legal transition of claim status.

Partial should sound precise rather than weak. It is the state in which science refuses to confuse a real piece with the whole.

27.3.3 — Replicated Component Support

Replicated component support requires independent evidence that the same component survives essential repetition. It is stronger than preliminary support because it has crossed the social and operational boundary between teams. Yet it remains component support, not whole-theory validation (Klein et al., 2018; Vehtari et al., 2017).

The replication record must include failures as well as successes. A component supported in four sites and failed in two is not simply replicated. It is heterogeneous. The public status may be replicated within a narrower reference class, replicated with adverse site exceptions, or not yet transportable.

Replication becomes informative when an endpoint-independent terminal concentration pattern repeats in two palliative networks but fails in a setting with different sedation practices. The finding may be replicated for certain care regimes and narrowed for others. The failure is not noise.

Replication synthesis reports heterogeneity alongside the pooled estimate. Prediction intervals describe variation relevant to a new site, while site-level analyses investigate differences in populations, procedures, and contexts. Together these results identify where component support transports and where further study is useful (Open Science Collaboration, 2015; Camerer et al., 2018).

The word replicated should never stand alone. A release must name what was replicated, by whom, under which protocol-fixed design and public registry record if any, across which sites or conditions, with what heterogeneity, and at which evidence state.

Replication gives a component more weight, but it does not make it weightless. It still carries assumptions, scope, and dependencies.

27.3.4 — Mechanism Support

Mechanism support concerns a candidate explanation, not the formal boundary condition. Reserve coupling, candidate scheduling-route dynamics, horizon pressure, interoceptive mediation, or a learning-rival comparison can be supported as mechanisms or defeated as mechanisms without settling the strong claim (Vehtari et al., 2017; Open Science Collaboration, 2015).

A mechanism earns support by predicting more than a generic pattern. It should identify a distinctive structure, a timing relation, a parameter recovery profile, a perturbation response, or a rival-discriminating residual. If it only redescribes regulation after the fact, it has not earned mechanism support.

A reserve-coupled realization earns support by predicting held-out variance compression and reserve-linked innovation amplitude changes while Brownian bridge and observation-shutdown rivals fail under the same observation model. Support belongs to that realization and context.

Mechanism results identify which tested routes explain the observations under the stated design and comparison conditions (Camerer et al., 2018; Klein et al., 2018).

Version mechanism support. Moving from finite-variation to stochastic reserve, or from scalar scheduling to partially observed control, requires a named version; earlier support does not automatically transfer.

Mechanisms serve testability by making claims vulnerable. Failed mechanisms should leave cleanly.

27.3.5 — Convergent Support Across Methods

Convergent support requires different measurement and study families to support one prospectively defined component, reducing dependence on any instrument, site, or analysis. Similar prose is insufficient: dream studies, terminal telemetry, horizon tasks, and longitudinal reports need declared bridges to the same target (Open Science Collaboration, 2015; Camerer et al., 2018).

Terminal variance compression might appear in active reports, clinician-assisted windows, and physiological residuals under one endpoint rule. Convergence strengthens when confounds differ; shared missingness or selection can create a common artifact.

The component graph must connect each method to the target, with its recall, device, clinician, and selection weaknesses explicit (Klein et al., 2018; Vehtari et al., 2017).

True convergence is compelling because the paths remain distinct until disciplined evidence shows where they meet.

27.3.6 — No Whole-Claim Validation

The Science of Fairness updates scientific components and their public descriptions. Applied titles use relevant findings through their own research, legal, practical, and interpretive processes (Camerer et al., 2018; Klein et al., 2018).

Multisite support applies to a named component, reference class, and method. Status labels must follow donor pages, graphics, summaries, and paired books to block prestige by association (Vehtari et al., 2017; Open Science Collaboration, 2015).

Component support, bounded replication, and narrowed evidence state preserve the contribution without validating the series, religion, transition, or political authority.

27.4 — Inconclusive and Unusable Evidence

Inconclusive and unusable evidence are different scientific states. Wide uncertainty may leave several values plausible; model nonseparability may leave several generators observationally equivalent; measurement or endpoint failure may block the target; and an ethical stop may make continuation unacceptable. Each state preserves different information and requires a different repair (Manski, 2003; Little & Rubin, 2019; Lakens, 2017).

The classification protects both directions of error: nondiscrimination is not promoted to support, and a failed design is not promoted to defeat of a target it never identified. The outcome belongs to the actual failure mode.

Table 27.5. Inconclusive and unusable outcomes.

Outcome	What happened	Correct update
Wide or mixed uncertainty	Intervals, posteriors, or sensitivity analyses fail to discriminate.	Inconclusive for the tested component.
Nonseparable models	Model recovery or design separability fails before inference.	No winner; redesign or narrower claim.
Measurement failure	Instrument sign, scale, missingness, or calibration fails.	Target untested in that context.

Outcome	What happened	Correct update
Endpoint failure	Stopping object is ambiguous, unavailable, outcome-contaminated, or incompatible with the declared endpoint branch.	Terminal inference suspended.
Ethical or burden stop	Study cannot proceed without excess burden or risk.	Stop or reduce observation; classify each affected inference under its remaining valid gates.
Public uncertainty	Evidence state is mixed or not yet reviewed.	Status-labeled uncertainty, no spin.

Use Table 27.5 together with §24.2's canonical No adequate estimate rule for the evidence-state definitions. This section focuses on the information each state preserves and the repair it requires.

Unusable evidence also needs respect. Data can be unusable for the intended inference and still ethically significant. A burden stop, a family-pressure incident, or a participant challenge may teach the program where measurement itself creates load. Those lessons belong in the record.

Reviewers distinguish ignorance from confusion. Ignorance means a component was not tested. Confusion means data were collected but cannot discriminate. Failure means the component was tested and contradicted. These states create different scientific obligations.

A generic call for more research is not enough. The public record identifies whether the obstacle was low power, nonidentification, missingness, heterogeneity, endpoint uncertainty, rival nonseparability, or protocol failure because each demands a different next step.

A high-quality inconclusive study can reveal how to strengthen the next test. It may identify a fragile signature, a measurement gap, or a participant-protection rule that needs refinement. Those findings improve the research program by locating the changes most likely to make subsequent evidence informative.

Uncertainty becomes a public object. It is not a private discomfort behind the scenes. When uncertainty blocks a claim, the block should be visible enough that later writers cannot step around it by accident.

A report of inconclusive evidence should include whether the component remains worth testing. Sometimes a better design is available. Sometimes the burden or identification problem suggests that the question should be left alone until methods change. This distinction protects participants from automatic repetition.

Unusable evidence should not be destroyed unless retention itself creates risk. The record may need to preserve metadata, stop reasons, and protocol lessons while minimizing or deleting sensitive observations. Data dignity and failure memory must be reconciled case by case.

A nonseparable model result should feed back into benchmark design. If real data could not choose among models, the next step

is not a larger sample by default. It may be a new observation channel, randomized cadence, better endpoint adjudication, or an admission that the component is not yet identifiable.

Measurement failure should also update consent materials. Participants should not be invited into a future study with language implying that the prior instrument worked. The burden of honesty begins before recruitment.

Endpoint failure should update care coordination. If terminal inference required more observation than comfort allowed, the next protocol should not simply ask harder. It should ask whether the terminal question can be answered without increasing the burden on dying people and families.

Uncertainty, handled well, is protective knowledge. It tells the program where not to promise, where not to recruit, and where not to draw the next public diagram.

Some evidence states are unanswerable rather than merely inconclusive. An unanswerable zone appears when the component cannot be tested under responsible conditions, when observation would create unacceptable burden, when the endpoint cannot be defined without circularity, or when the construct cannot be transported into the reference class without inventing what the study was supposed to learn. This status marks a boundary in instrument, ethics, or reference class; it is not a rhetorical refuge from defeat.

The evidence graph records unanswerable zones with the same seriousness it gives positive replications. The entry names the component, attempted design, reason the verdict cannot be

reached, ethical or measurement barrier, public consequence, and whether the block is temporary, design-contingent, or principled. A temporary block may await a less burdensome sensor or stronger translation method. A principled block may arise when the only route would manipulate suffering, pressure final reports, or convert private grief into research material.

The boundary becomes concrete in a terminal subpopulation whose only available observation windows occur during sedation decisions, family crisis, and communication loss. The program may care deeply about that reference class without pretending that the final open-channel window was observed. A similar boundary arises where terminal reporting would expose families to stigma or spiritual pressure; protected silence cannot be recoded as neutral missingness.

An unanswerable result identifies what the observations leave unresolved, such as affect during silence, the consequences of withdrawal, or endpoint classification. The analysis retains those uncertainties and describes the information needed for a later answer.

Public language for an unanswerable zone is plain: this component has no responsible verdict in this reference class under current methods. The record names whether the blocker is measurement, endpoint, missingness, burden, nonseparability, or open-set inadequacy. It does not call the result pending when no responsible design exists, and it does not call the target false when the target was never tested.

27.4.1 — Wide or Mixed Uncertainty

Wide or mixed uncertainty occurs when the data do not discriminate among the relevant possibilities. The signal may point one way, another sensitivity analysis may point another, and prediction intervals may remain too broad for status movement. This is an inconclusive scientific result (Manski, 2003; Little & Rubin, 2019).

The proper analysis should show where uncertainty enters: sampling variability, measurement error, missingness, endpoint ambiguity, site heterogeneity, prior sensitivity, model choice, or rival overlap. A single wide interval is less useful than a map of why it is wide.

Consider a study whose mean terminal estimate lies near the neutral band but whose equivalence interval crosses both meaningful positive and meaningful negative regions after missingness sensitivity. The result is not support. It is nondiscrimination under current measurement and observation assumptions.

A favorable center can hide wide uncertainty, reversals, and unusable cases. Readers may focus on the point estimate and ignore the width. The public label must therefore lead with uncertainty, not with the most attractive center (Lakens, 2017; Mayo, 2018).

Wide uncertainty can still teach. It may identify a needed cadence, a better endpoint window, a stronger rival benchmark, or a less burdensome design. But it does not move component support unless the decision rule declared that it could.

Inconclusive evidence is not a blank. It is a record of where the instrument, design, or reference class could not yet speak.

27.4.2 — Nonseparable Models

Nonseparable models occur when the analysis cannot distinguish candidate explanations under the available data. The Law-candidate model, a Brownian bridge, an observation-shutdown model, and a frailty-selection model may all reproduce the same measured trajectory. Model fit alone cannot decide among them (Little & Rubin, 2019; Lakens, 2017).

The separability problem should be addressed before human recruitment when possible. Synthetic challenges, parameter recovery, held-out prediction, and adversarial simulations should show whether the proposed design can recover the true generator under plausible conditions. If it cannot, real data will not rescue the comparison.

When reserve coupling and a random-endpoint bridge fit terminal concentration equally well after accounting for observation timing, report model nonseparability. The result identifies the contrast that a revised design needs to resolve.

Preference for a parsimonious story cannot decide between models that the design failed to separate. Analysts may choose the model that matches the theory and call the rival too artificial, or choose the rival and call the Law defeated. Both moves overstate the evidence if the design cannot separate them (Mayo, 2018; Manski, 2003).

The detachable sentence is: the models were observationally nonseparable under the declared design, so no mechanism winner

is reported. That wording protects the result from later compression into support for whichever model a reader already prefers.

A model that cannot be distinguished from a serious rival has not lost all value. It has lost the right to discriminate publicly until the design improves.

27.4.3 — Measurement Failure

Measurement failure identifies the target and context for which the instrument lacks a qualified estimate. The record specifies the relevant sign, scale, calibration, missingness, device, cultural, disability, medication, or channel issue and the validation needed to proceed (Lakens, 2017; Mayo, 2018).

A failed candidate instrument version should be retired, narrowed, or reworked without blaming participants. The problem may be the model's relation to lived experience, not the person's testimony. Measurement dignity means a nonstandard signal is not treated as deception or noise by default.

Measurement failure is unmistakable in an estimator that treats low movement and low speech as reduced distress in a neurological population where motor decline and communication impairment drive those channels. The instrument may falsely suggest neutrality. The correct update is measurement failure in that context.

Burying nuisance structure in a supplement does not repair the main inference. Teams may put the measurement issue in a supplement while the main text reports the desired status. The

measurement failure must appear in the same public status statement as the result (Manski, 2003; Little & Rubin, 2019).

Measurement failure can still produce useful component science. It may reveal channel limits, calibration needs, or protected contexts where measurement should not be attempted. Those findings should travel into future protocols.

The target remains worthy even when the instrument fails. A broken thermometer does not make fever imaginary; it makes the reading unusable.

27.4.4 — Endpoint Failure

Endpoint failure occurs when the stopping object is ambiguous, unavailable, outcome-contaminated, or incompatible with the declared branch. Chapters 7 and 13 define the branch taxonomy and random-endpoint conditions. A failed endpoint gate may preserve useful preterminal evidence, but it cannot adjudicate a terminal target outside the endpoint branch actually identified (Mayo, 2018; Manski, 2003).

Endpoint failure can arise through sudden death, resuscitation, sedation, terminal delirium, sensor dropout, family burden, delayed documentation, or post hoc endpoint selection. Each route should be coded separately because each implies a different repair or limitation.

Endpoint discipline is tested by a low-signal ending where the last usable candidate instrument window occurs forty hours before truth-level stream endpoint is clinically inferred. Treating that window as terminal would make the result cleaner and less true.

The endpoint component should suspend terminal inference and perhaps preserve only preterminal dynamics.

The final available observation cannot stand in for the truth-level endpoint merely because it is convenient. Analysts may be tempted to call the final available measure the endpoint measure. That move converts missingness into evidence. The endpoint firewall forbids it (Little & Rubin, 2019; Lakens, 2017).

The public account should distinguish an unavailable endpoint, unresolved timing, outcome-contaminated adjudication, false-ending risk, and failure of a declared branch-specific timing premise. Dependence alone is not endpoint failure when a state-coupled branch explicitly models it.

Endpoint failure is not defeat unless the endpoint was adequately identified and contradicted the claim. It is a refusal to pretend that a terminal question was answered when it was not.

27.4.5 — Ethical or Burden Stop

An ethical or burden stop occurs when a study cannot responsibly continue because the measurement burden, privacy risk, participant distress, family pressure, staff load, or clinical interference becomes too high. Stopping protects care. If a required gate fails, the affected evidence is Unusable; otherwise any consent-permitted analysis of retained data keeps the status supported by its validity, identification, and precision (Council for International Organizations of Medical Sciences, 2016).

The stop rule should be prospectively specified and operational. It should identify who can stop, which burden indicators trigger review, how withdrawal is honored, how family pressure is

handled, and how the resulting evidence state is labeled. A humane stop should not be improvised under crisis.

The ethical rule is tested by a terminal protocol where repeated prompts begin to distress participants or pressure families into interpreting final experiences. The correct action is to stop the measurement, classify the affected endpoint inference as Unusable if the stop causes a required endpoint gate to fail, and preserve care as the priority.

Participant burden is not an ordinary missing-data mechanism to be optimized away. If the reason observation stopped is that observation itself became harmful, imputing the missing path as though it were ordinary dropout hides the most important fact. The burden is part of the evidence state (Lakens, 2017; Mayo, 2018).

After an ethical or burden stop, public reporting must identify the procedure that stopped, the reason, and the data that remain usable. It must also record the participant or staff support that followed and the questions the program will no longer pursue in that form.

A science of fairness proves its seriousness by knowing when not to measure. Some unanswered questions are ethically better than answered ones.

27.4.6 — Public Language for Uncertainty

Public uncertainty language must avoid both promotional spin and false defeat. The public can understand uncertainty when it is explained as a precise evidence state. What destroys trust is not uncertainty itself, but uncertainty hidden until critics expose it

(Little & Rubin, 2019; Lakens, 2017). A stable vocabulary for uncertainty makes corrections less dramatic because the public has already been shown that inconclusive and unusable are legitimate outcomes.

The status statement should contain four elements: component, evidence state, scope, and reason. For example: measurement component inconclusive in a multilingual terminal sample because calibration and missingness sensitivity did not discriminate. That sentence is less exciting than a headline and more useful than a slogan. Adding the planned next action makes the status operational without implying that every uncertainty can or should be resolved immediately.

The uncertainty categories separate in a public website summarizing a mixed replication. The accurate label may be partial support for one terminal consequence, measurement failure in one subgroup, and rival dominance in one model comparison. A single green, yellow, or red icon would mislead. Component-level display can still be visually simple if each icon or line corresponds to a named claim rather than one aggregate project mood. A compact table can place the shared study identifier beside separate component outcomes, making disagreement visible without turning the entire project into one score.

Compressing mixed uncertainty into one status label destroys information the verdict needs. Donor pages, media summaries, diagrams, and social posts often shrink nuance into a mood. Public artifacts must preserve the component structure or refrain from release (Mayo, 2018; Manski, 2003). If compression cannot

preserve the distinction, a link to the full component table is not enough; the simplified artifact itself should not imply a unified verdict. When one component is corrected, the notice can identify the other components that remain unchanged instead of replacing the entire account with a new headline.

A public summary must name whether unusable evidence narrows, suspends, blocks, retires, or leaves the question unanswered. The summary should also identify whether the limitation comes from data quality, identification, model adequacy, or a genuine adverse result. An adverse result under valid prerequisites retains its adverse classification; it is not reclassified as unusable simply because the preferred account lost.

27.5 — Narrowing Reference Classes and Claims

Narrowing can preserve a true result only when the successor is explicitly smaller, independently motivated, and prospectively testable. A reduced population, time domain, or context may be a genuine reference-class narrowing; a change in representation, exactness, modality, endpoint, or target object creates a non-equivalent successor that must receive its own identity and decision rule.

A principled narrowing is predeclared or independently motivated, publicly labeled, testable in its new form, and connected to a mechanism or measurement reason. A degenerating narrowing follows failure with a smaller claim that predicts nothing new.

Table 27.6. Narrowing and successor routes and their required public correction.

Revision route	What changes	Public correction required
Population	Diagnosis, age, species, state, culture, or care regime.	Identify the old broader class and the new bounded class.
Temporal	Terminal claim becomes preterminal or window-specific.	Remove language implying endpoint coverage.
Representation	Scalar closure becomes multidimensional consequence.	Revise formulas, diagrams, and summaries.

Revision route	What changes	Public correction required
Endpoint	Universal endpoint becomes qualified stopping event.	State which endpoint decisions no longer travel.
Statistical	Pathwise universality becomes reference-class tendency.	Remove universal Law-language from empirical claims.
Public artifact	Graphic or guide overstates the old scope.	Replace, date, and preserve correction history.

Equation 27.4 (schematic rule for pure reference-class narrowing):

$$D_{\text{new}} \subsetneq D_{\text{old}}$$

$$\mathcal{P}_{\text{new}} = \mathcal{P}_{\text{old}}|_{D_{\text{new}}}$$

Here D denotes the declared reference-class domain and $\mathcal{P}$ the claim's prediction rule on that domain. Pure reference-class narrowing restricts the domain while keeping predictions for retained cases, target geometry, and the decision rule unchanged. Changes to representation, modality, endpoint, or target object require a non-equivalent successor and are outside this schematic rule. The new class is independently motivated, defined without inspecting favorable outcomes, and tested with a new transport or inclusion rule. Otherwise, post hoc exclusion becomes rescue.

Narrowing should begin with a comparison between the old claim and the new one. What population was removed? What endpoint was qualified? What temporal window was shortened? What representation changed? Without that comparison, readers cannot tell whether the program learned or merely moved.

Each narrowing should state its independent reason. A population may narrow because measurement invariance failed. A temporal window may narrow because endpoint identification failed. A representation may narrow because scalar additivity failed. A statistical claim may narrow because pathwise universality lacked empirical content. The reason is part of the narrowed claim.

A narrowed claim states new predictions and the outcomes that would challenge them. A sharper target makes the next test more informative.

Narrowing has downstream effects. Protocols, analysis plans, public graphics, cross-book references, donor summaries, media language, and future chapter summaries must all change. The correction burden belongs to the project, not to the skeptical reader.

A program may narrow more than once, but repeated narrowing should trigger review. At some point, the question becomes whether the remaining claim still carries the original empirical ambition or whether it should be reclassified as a different, smaller hypothesis. The no-rescue rule belongs here.

Transparent narrowing preserves the structure that evidence supports and gives it a clearer domain of use. Showing the old and new claims together lets readers see exactly what was learned.

Narrowing should include an audit of inherited language. The old wording may remain in introductions, captions, summary pages, social excerpts, conference slides, and earlier chapters. If those places are not corrected, the narrowed claim has not actually narrowed in public.

A narrowing register should store the old claim, new claim, evidence reason, date, reviewer decision, dissent, and affected artifacts. This may sound administrative, but it is how scientific memory prevents repeated overclaim. Without a register, narrowing becomes a whisper.

The distinction between reference-class narrowing and mechanism retirement should be preserved. A claim may hold only in one population because a mechanism operates there, or because measurement only works there, or because rivals differ there. The reason determines what can travel.

Narrowing should not be used to protect emotional language. If the universal claim narrows to a bounded empirical signature, public prose should stop sounding universal. The emotional register must shrink with the scientific claim.

The strongest narrowed claims often become more testable. A precise population, endpoint, representation, and statistical target can generate sharper protocols than the broad claim could. Narrowing can therefore increase scientific power while reducing public grandeur, provided the reduction remains visible enough that no one mistakes it for unchanged ambition.

27.5.1 — Population Narrowing

Population narrowing limits a claim by diagnosis, age, species, developmental stage, culture, state of consciousness, care regime, or other reference-class boundary. It is justified when evidence shows that a component holds in one population and fails, remains untested, or changes meaning in another (Bareinboim & Pearl, 2016; Stuart et al., 2011).

The narrowing must specify why the boundary matters. A diagnosis boundary may reflect medication, communication, disease trajectory, reserve dynamics, endpoint confidence, or measurement invariance. A cultural boundary may reflect language, reporting norms, family mediation, or care practices. Without a mechanism, population narrowing can become arbitrary rescue.

Consider support for one candidate instrument version in adult hospice oncology and failure in advanced dementia because bearer continuity, reportability, medication, and endpoint evidence differ. The correct update is not human evidence in general. It is a bounded adult oncology result with dementia-specific suspension or redesign.

Convenience slicing narrows the reference class after the result rather than through an independently motivated rule. After a broad study fails, analysts may search subgroups until one looks favorable. That subgroup can motivate exploration, but it cannot become principled narrowing without new justification and prospectively specified confirmatory work (Fortier et al., 2011; Lakatos, 1978).

Any public correction must name both the old reference class and the new one. It cannot quietly replace all conscious streams with certain adult terminal contexts as though the claim had always been that narrow.

Population narrowing is honorable when it protects truth from overreach. It becomes rescue only when it hides the distance between what was promised and what survived.

27.5.2 — Temporal Narrowing

Temporal narrowing limits a claim to certain windows, such as preterminal dynamics, post-event adjustment, sleep-related repair, or short-horizon control tasks. It may occur when terminal endpoint evidence fails but earlier dynamics remain identifiable and informative (Stuart et al., 2011; Fortier et al., 2011).

The key question is whether the temporal boundary is scientifically motivated before the result. A preterminal window may be justified by sampling cadence, reserve observability, medication stability, or ethical access. It is not justified simply because the terminal window failed.

Temporal narrowing is clearest in strong evidence for variance contraction in the last month of recorded clinical life, with unusable final open-channel windows due to sedation and endpoint ambiguity. The program may preserve a preterminal consequence claim while suspending terminal inference.

Retreating from a terminal claim to a preterminal one after failure is narrowing, not continued support for the original target. It should not retain the emotional force of terminal neutrality while abandoning the endpoint burden (Lakatos, 1978; Bareinboim & Pearl, 2016).

For a preterminal study, the release identifies its observation window, estimated dynamics, and the additional endpoint or route qualification needed for the next investigation.

Temporal narrowing can still be scientifically rich. A smaller window with clearer identification may teach more than a universal window defended by missing data.

27.5.3 — Representation Narrowing

Representation change creates a new target unless a proved bridge preserves the original object. Replacing exact scalar closure with a vector-valued structure, finite-band compatibility, variance compression, endpoint concentration, reserve-linked contraction, or a directional tendency is not merely a smaller version of additive PTV. Each successor requires its own identifier, assumptions, estimands, rival set, and decision rule, while the predecessor retains its original status (Lakatos, 1978).

A revised representation should have independent empirical motivation and testable consequences. If valence, arousal, pain, meaning, fatigue, and threat carry distinct predictive information in a reference class, a multidimensional structure can preserve that information.

A multidimensional study may show that physical pain, social fear, and existential distress behave differently near an endpoint, defeating the proposed scalarization in that context. The result can motivate a vector or set-valued successor and preserve valuable lived-experience science, but it does not count as support for the failed scalar branch.

Unannounced representation drift changes the object while preserving the appearance of continuity. If the public graphic still implies one closing line while the technical specification has moved to multiple noncollapsible dimensions, the program is misleading readers.

When representation changes, formulas, diagrams, summaries, and status labels change with it. Representation is not a footnote because it determines what counts as evidence.

Representation change is scientifically honest only when the formal object, equations, estimands, and public language all change with it.

27.5.4 — Endpoint Narrowing

Endpoint narrowing limits claims to specific qualified events rather than universal death-of-mind classification. It may be necessary when some endpoints can be independently adjudicated and others cannot. The narrowed endpoint becomes part of the claim, not a sampling detail (Lakatos, 1978; Bareinboim & Pearl, 2016).

A qualified endpoint might be an open-channel window before irreversible loss of unity, a clinically adjudicated consciousness transition, a terminal observation window under low-sedation conditions, or another prospectively specified stopping event. Each carries different authority and requires its own bridge.

The endpoint scope can be tested with a protocol that can identify terminal open-channel windows in gradual decline but not in sudden death. Evidence from gradual decline cannot be extended to sudden endings unless a separate endpoint model is built and tested.

Name the endpoint class in the main result sentence so that gradual decline, sudden endings, and other event types retain their observed scope (Stuart et al., 2011; Fortier et al., 2011).

A corrected endpoint claim names the qualified endpoint and removes universal phrasing from summaries. The phrase truth-level stream endpoint cannot imply that all endpoint classes were equally identified.

Endpoint narrowing keeps the endpoint firewall alive after data arrive. It prevents the most emotionally powerful word in the theory from outrunning the most fragile evidence.

27.5.5 — Statistical Narrowing

Statistical change also creates a new claim when it changes the quantifier or target geometry. Moving from set-universal exact closure to a reference-class tendency, from exact zero to finite-band concentration, or from terminal closure to a probabilistic signature does not preserve the original empirical target. The successor may be valuable, but it requires a new protocol, error guarantee, and status record (Bareinboim & Pearl, 2016; Stuart et al., 2011).

The strong latent form and the public empirical target must remain distinct. If empirical evidence supports a tendency in a measured reference class, the public claim should say tendency in that class. It should not imply that the latent strong form has been established.

A meta-analysis may find near-neutral concentration on average while some sites remain clearly adverse and the prediction interval is wide. The program may report that reference-class tendency and heterogeneity as a new empirical claim. It may not describe the result as pathwise or universal closure.

Changes in statistical scope should be reflected consistently in prose, formulas, targets, and verdicts. Expressions such as overwhelmingly tends, essentially closes, and in the limit each require the corresponding probabilistic or limiting statement. Explicit wording makes the revised claim available for precise evaluation (Lakatos, 1978).

The correction notice must distinguish the old claim strength from the new one. Pathwise, ensemble, and predictive-distribution claims are not interchangeable.

A statistical successor succeeds when it says exactly what the data support and leaves the original target available for independent rejection or suspension.

27.5.6 — Public Correction After Narrowing

A narrowing notice should identify the withdrawn scope and the corrected claim, update project-controlled high-reach artifacts, and notify known external reusers. The correction log records unresolved copies so that incomplete recall is visible rather than mistaken for unchanged scientific status (Crossref, 2025).

The correction should be dated, visible, and component-specific. Preserve old language in the record rather than erase it, so failure memory shows what changed and why.

Narrowing and rescue diverge when a visual explainer still shows a universal terminal curve after evidence narrows to one palliative reference class. Replace the image, archive it with a correction note, and cross-reference every reuse. The correction note should state the surviving reference class directly on the replacement

visual so old universal interpretation cannot reappear through cropping.

Quiet revision breaks the evidence-to-claim chain and makes readers reconstruct changes made for institutional comfort. A science of fairness cannot shift that burden outward (Lakatos, 1978; Bareinboim & Pearl, 2016). Version history should make narrowing visible at the point of use, not require readers to infer it by comparing editions.

Calm correction states what changed, what survives, what failed, and which language is retired; it avoids apologetic theater. A calm correction can also preserve confidence in unaffected components by separating the narrowed claim from the parts of the program that did not change.

27.6 — Mechanism Retirement and Rival Dominance

Candidate mechanisms remain useful only while they make recoverable, discriminating predictions. A route that fits after outcome-dependent tuning, survives only by changing its latent object, or loses repeatedly to equal-budget rivals must narrow, retire, or yield resources. Mechanism retirement protects the target from being fused to one favored story.

Rival dominance receives its proper scientific status. If adaptation, Brownian bridges, predictive control, safe reinforcement learning, frailty, observation shutdown, or selection explains the evidence better under fair comparison, the public status must change.

Table 27.7. Mechanism retirement and rival dominance matrix.

Object	Retirement trigger	What may survive
Reserve realization	Bridge failure, parameter nonrecovery, rival superiority, wrong variance pattern.	Formal question and general reserve measurement may survive.
Queue or horizon	Ordinary control explains priority, blocking, and repair signatures.	Behavioral task insights and burden analysis may survive.
Candidate momentary-valence estimator version	Calibration, sign, transport, or missingness failure.	Data dignity rules and revised measurement lessons may survive.

Object	Retirement trigger	What may survive
Rival dominance	Repeated superior held-out prediction and calibration by rivals.	Bounded components not explained by the rival may remain.
Replacement mechanism	No independent motivation or no new falsifier.	None; replacement waits for prospectively specified risk.
Useful component science	Law-specific interpretation fails but findings remain sound.	Clinical, measurement, or ethical insights continue with narrower labels.

Mechanism retirement requires a clean archive of what was promised. A model cannot be retired responsibly if no one can tell which predictions it made. Each mechanism should therefore have a versioned prediction sheet, rival matrix, parameter-recovery record, and public-risk note. Retirement then becomes a decision, not a mood.

Rival dominance should be announced with the same precision as support. The rival should be named, the component should be named, and the comparison should be described. Saying ordinary models explain it is too vague. Saying an endpoint-conditioned bridge with observation shutdown dominates a reserve-coupled candidate under the shared observation model is useful.

Retirement should not erase useful work. A retired mechanism does not invalidate every dataset, participant contribution, or method built around it; it changes the interpretation and public claim attached to those materials, and the record should preserve that distinction.

Replacement proposals should face a cooling period after defeat. Immediate substitution can be emotionally satisfying and scientifically reckless. A new mechanism should be motivated by independent theory or new data, not by the desire to keep old public language alive.

The public status of a retired mechanism should include a future-use rule. Can the old model be used as a simulation baseline? Can it appear in teaching as a failed candidate? Can its variables remain in exploratory analysis? Can it be cited in public summaries? These permissions should be explicit.

Mechanism retirement is an evidentiary decision about one declared route, not a euphemism for moving it into metaphor. When a prospectively declared route fails its recovery or signature criteria under an adequate design, its status is Route-failed. The record identifies the failed predictions, recovery results, equal-budget rivals, scope, and downstream artifacts that must change.

A retired mechanism should not be erased from educational materials. It can be taught as a candidate that made the theory vulnerable and then lost. That history teaches readers how the program protects itself from self-confirmation.

Rival dominance should update source priority. If mainstream models explain a component better, later chapters, summaries, and public artifacts should cite or describe those models as the leading explanation for that component. The Law-specific model should not remain first by tradition.

Mechanism retirement can create communication anxiety because mechanisms are memorable. Candidate scheduling language, reserve language, and horizon pressure may be easier for readers to remember than evidence-state language. The response is not to keep failed metaphors alive, but to replace them with clearer bounded explanations.

When a mechanism retires, dependent claims should be traced. A chapter, figure, or protocol that relied on the mechanism may also need revision. Retirement is not isolated if the mechanism served as a bridge for other statements.

Useful residual methods should be given new names when necessary. A protocol that began as a candidate scheduling-route test may become an urgency-control task or a burden-prioritization study. Renaming protects the result from carrying a retired interpretation.

Graceful loss is the governing standard. A Route-failed mechanism may leave the Law-specific framework and still leave behind knowledge good enough to keep.

27.6.1 — Reserve Realization Retirement

Reserve realization retirement occurs when the product model, its bridge to measured quantities, or its distinctive predictions fail under adequate testing. The reserve idea may be elegant, but elegance is not tenure. A realization that cannot recover parameters, survive rivals, or transport across contexts should be removed or narrowed (Palminteri et al., 2017; Chamberlin, 1890).

Retirement triggers include wrong variance exponents, unstable deconvolution, bridge failure, correlated observation artifacts,

rival dominance by Brownian bridges or frailty, and inability to identify reserve independently. Each trigger should be recorded because each teaches a different lesson.

Consider a benchmark showing that fixed and random endpoint bridges reproduce apparent compression under the same observation schedule, while reserve parameters are nonidentifiable across plausible noise floors. The product realization may be retired for that evidence family.

Once a reserve model fails, retaining reserve as an all-purpose metaphor conceals the retirement. If the realization no longer functions scientifically, the word reserve should not remain as a vague explanation for every contraction. The public record should say which reserve claim ended (Platt, 1964; Burnham & Anderson, 2002).

Retirement does not erase useful work. It may preserve clinical reserve measurement, stochastic modeling lessons, noise-floor analysis, and rival-comparison methods. What ends is the Law-specific interpretation of that realization.

Retiring a realization leaves a clear record for better models. Later chapters should identify the retired version and preserve its useful methods under their revised interpretation.

27.6.2 — Candidate Scheduling and Horizon Route Retirement

Candidate scheduling and horizon-route retirement occurs when ordinary planning, urgency, homeostasis, active inference, reinforcement learning, scarcity, or safe-control models explain priority, blocking, reactivation, discharge, or finite-horizon

effects without a Law-specific structure. The scheduling route is a candidate model, not an invisible actor that must be preserved (Chamberlin, 1890; Platt, 1964).

The retirement test should compare executable models under shared tasks. If ordinary harm avoidance or model-predictive control reproduces the signatures with fewer assumptions and better held-out performance, the candidate scheduling interpretation narrows or leaves the scientific layer.

Route retirement can be seen in a laboratory task where horizon-sensitive avoidance appears exactly as finite-horizon safe control predicts, with no residual priority structure unique to the candidate scheduling model. The behavioral result may still matter, but the retired scheduling mechanism does not own it.

Ordinary urgency must not be relabeled as candidate scheduling pressure merely to preserve a Law-specific interpretation. That move empties the construct of empirical content. If every priority shift is treated as candidate scheduling activity, the route cannot lose (Burnham & Anderson, 2002; Palminteri et al., 2017).

Candidate scheduling language exists to make burden-ordering testable enough that survival has meaning. When a scheduling or horizon route retires, the release should say which mechanism was tested, what failed, which ordinary explanations performed better, and whether any target-level question remains open.

27.6.3 — Candidate Instrument Version Retirement

Candidate instrument version retirement occurs when an instrument cannot identify, calibrate, transport, or ethically operate in its declared context of use. A version may retire

because of device drift, cultural calibration failure, disability bias, medication confounding, channel dropout, or participant challenge outcomes (Platt, 1964; Burnham & Anderson, 2002).

Retirement is version-specific. Candidate instrument version 2.4 may fail in one setting while another version remains under development elsewhere. The record does not treat the candidate momentary-valence estimator as one timeless instrument whose failures can disappear inside later versions.

Instrument retirement becomes unavoidable in a wearable-heavy candidate instrument version that performs poorly after a firmware update changes motion filtering and heart-rate variability estimates. Leave-device-version-out validation fails. That version should stop contributing to confirmatory evidence until recalibrated.

Silent recoding can salvage a dataset only by changing the object after the test. Teams may try to rescue the instrument by adjusting weights after outcomes are known. Such work may become exploratory re-estimation, but it cannot preserve the original confirmatory status (Palminteri et al., 2017; Chamberlin, 1890).

Public-facing text for a failed instrument should use the explicit verdict Unusable evidence, identify the context of use that failed, and state whether the failure is repairable or structural. It should not convert instrument weakness into ambiguity about the person.

Instrument retirement is one way the project protects persons from its own ambition. A failed measure should burden the protocol, not the participant.

27.6.4 — Rival Dominance

Rival dominance occurs when an alternative model repeatedly predicts, calibrates, transports, and explains the relevant component better than the Law-candidate model under fair comparison. It is not merely a rival doing well. It is the point at which the Law-specific interpretation no longer carries the best explanation for that component (Burnham & Anderson, 2002; Palminteri et al., 2017).

Dominance should be judged through held-out prediction, calibration, posterior predictive checks, model recovery, parsimony, robustness, transport, and absolute fit. It should also include whether the rival handles missingness, endpoints, device changes, and site heterogeneity without special pleading.

Rival dominance becomes clear in a combination of frailty, observation shutdown, and endpoint-conditioned diffusion that predicts terminal concentration and variance compression across sites better than the reserve candidate, while leaving no Law-specific residual. The component becomes rival-dominant.

Rival comparison is asymmetric when the favored model receives more information, flexibility, or interpretive charity. If rivals are tuned less carefully, denied realistic observation models, or excluded from certain diagnostics, dominance cannot be judged. Rival seriousness must come before rival victory (Chamberlin, 1890; Platt, 1964).

When a rival dominates, the public account should say that the named rival explains the named component better under the declared evidence set, while also stating what, if anything,

remains unexplained. This prevents both totalizing defeat language and denial of the rival's success.

Rival dominance is scientific progress. It identifies the explanation that currently serves the evidence best and gives subsequent research a stronger starting point.

27.6.5 — No Mechanism Substitution Without New Risk

A failed mechanism may be replaced only when the successor adds independent predictions, can lose to serious rivals, and carries its own public-risk review. Replacement is a new scientific commitment, not a costume change (Palminteri et al., 2017; Chamberlin, 1890).

The proposal states what the old route could not explain, why the successor is motivated before the new target result, how its variables are measured, which data distinguish it, and which public language it forbids. A vector reserve model, for example, must name its dimensions and a prediction that separates it from ordinary allostatic regulation.

Hidden variables, flexible priors, new regimes, or unmeasured states added only after failure are rescue unless they create fresh exposure to defeat. Added sophistication that merely shrinks the failure space is status pressure, not advancement (Platt, 1964; Burnham & Anderson, 2002).

The public record marks the superseded model, displacing evidence, successor scope, unchanged claims, and new risk. A good replacement makes the program more vulnerable and more informative.

27.6.6 — Preserve Useful Component Science

Useful component science may survive after a Law-specific interpretation ends: measurement can improve palliative research, missingness methods can protect participants, rivals can clarify terminal data, and failed mechanisms can leave valuable tools (Chamberlin, 1890; Platt, 1964).

Retired approaches can retain operational value. An instrument may reveal device bias, and a scheduling model may leave an effective burden-monitoring protocol. Recording those contributions preserves useful knowledge for later work.

Public summaries separate mechanism retirement from target defeat and reject both total collapse and automatic preservation of attached claims. Keeping useful science under the authority it earned lets truth and usefulness coexist (Burnham & Anderson, 2002; Palminteri et al., 2017).

27.7 — Theory-Level Defeat and Failure Memory

Theory-level defeat requires a stronger evidentiary route than failure of one instrument, route, or reference class. It occurs when a declared universal or branch-specific target is contradicted under its own prerequisites, or when repeated repairs remove the distinctive empirical content that made the target testable. The defeat record preserves the exact branch, evidence, assumptions, and successor consequences.

Defeat must be possible, explicit, and remembered. If defeat can always be renamed as refinement, the program has lost empirical content. If defeat is treated as disgrace, the program will avoid naming it. Defeat becomes a governed scientific outcome.

Table 27.8. Defeat and abandonment criteria.

Defeat route	Minimum condition	Required consequence
Credible counterexample	Well-identified stream and endpoint with robust terminal imbalance.	Pressure on universality and strong-form status.
Repeated conjunction failure	Distinctive signature conjunction repeatedly absent under adequate designs.	Escalation from component failure to program-level pressure.
Unresolvable identification failure	No empirically meaningful bridge can be justified under ethical constraints.	Suspension or withdrawal of public empirical claim.

Defeat route	Minimum condition	Required consequence
Persistent rival superiority	Serious rivals repeatedly dominate across component comparisons.	Retire Law-specific interpretation for those components.
Defeat statement	Review determines scope of withdrawal and surviving claims.	Public correction, status revision, and cross-artifact update.
Failure memory	Data, code, reasons, dissent, and corrections preserved.	Prevents future re-overclaim and repeated recruitment burden.

Equation 27.5 (empirical-content exhaustion test):

$$\lim_{k \rightarrow \infty} \Delta \text{Prediction}(k) = 0 \quad \Rightarrow \quad \text{rescue-versus-refinement review flag}$$

The display names the danger rather than proving a theorem. When each revision preserves the claim while adding no new discriminating prediction, the program should classify the move as rescue and apply theory-level pressure.

Theory-level defeat is branch-specific and explicit. A gate-valid counterexample defeats the exact universal branch it reaches; a repeated inability to identify the target may instead yield principled abstention or a smaller successor. The record distinguishes contradiction from nonidentification so neither is used to rescue the other.

A defeat review should include internal scientists, external critics, methodological specialists, participant or family representatives where appropriate, and public-risk reviewers. The question is not

who protects the project. The question is who can see the burden that insiders may miss.

Failure memory should preserve dissent on both sides. A minority report arguing that defeat is too broad can be important. A minority report arguing that defeat is too narrow can be important. Later researchers need to know what reasonable experts thought at the time, not only what the majority decided.

Defeat can also be partial by architecture. The strong form may be defeated while burden analysis remains useful. A mechanism may be defeated while a measurement lesson remains. A public empirical claim may be suspended while the formal hypothesis remains untested. The defeat statement should not oversimplify either direction.

The failure record should constrain future editions. A later chapter, public graphic, or speech should not revive defeated language unless it cites the defeat and explains a new, independently justified reason to reopen the question. This prevents the same public risk from cycling through new audiences.

The deepest purpose of failure memory is mercy toward the future. It stops future participants, researchers, readers, and critics from spending their lives reopening a door that evidence has already closed.

A theory-level review should ask whether the remaining claim still differs from serious rivals. If the surviving language merely says that conscious systems regulate, adapt, or avoid harm, the

Law-specific empirical content may be exhausted. The program should not preserve a distinctive name for an ordinary result.

Failure memory should include public artifact lineage. A cropped figure, simplified chart, or old explanatory video can continue teaching the defeated claim years after the paper has been corrected. The failure record should therefore track artifacts, not only studies.

A credible counterexample should be protected from sensationalism. The person or case should not become a mascot of defeat. The public statement should focus on the component and evidence route, with privacy and dignity preserved.

Theory-level defeat may require cross-book notices. Applied books should not silently keep language that scientific defeat has withdrawn. The science book does not govern those domains, but it does govern the scientific language they may borrow.

The failure memory should state whether reopening is possible. Some defeated claims may be reopened only by a new measurement bridge, new endpoint rule, or new independently motivated prediction. Others may be abandoned for the current edition. The distinction prevents endless revival.

Defeat is most credible when it is prepared in advance. A project that writes defeat criteria before it needs them shows that it cares more about truth than victory.

27.7.1 — Credible Counterexample

A credible counterexample is a well-identified case that directly pressures the universal structure of the strong claim. It requires a

qualifying stream, an independently adjudicated endpoint, valid measurement or other justified evidence, robust uncertainty analysis, and exclusion of major rival artifacts. It is rare because the burden is high (Popper, 1959; Lakatos, 1978).

The counterexample must reach the complete-stream latent residual through adequate representation, origin, routing, endpoint, missingness, and measured-to-latent guarantees. Checks should exclude artifacts that could create the apparent contradiction. Identifying the natural mechanism responsible for a valid nonzero residual is not an additional requirement for rejecting the exact universal branch.

Consider a qualifying stream with an independently adjudicated endpoint, context-qualified measurement, and a nonempty, truth-containing compatibility set for its complete-stream latent residual that lies wholly outside the prospectively fixed equivalence band. The set must account for the unobserved past, measured-to-latent uncertainty, informative missingness, and declared artifact checks. Such a case is adverse to that band claim and, when zero is excluded under the protocol-fixed inferential guarantee, to the exact universal branch, even if an ordinary rival explains the nonzero residual.

Counterexamples cannot be diluted by pooling them with favorable cases or by redefining the population after inspection. Claims that a case is anomalous, unrepresentative, or measurement noise must follow prospectively specified criteria. When those criteria are met, the counterexample enters failure memory and changes the declared branch (Mayo, 2018; Meehl, 1978).

A counterexample should be reported at the level it defeats: one reference class, branch, modality, route, or strong universal form. The release should also state what narrower claims remain logically available without implying that they have already earned evidence.

A universal claim gives credible counterexamples a decisive role. Specifying their requirements makes both the claim and its possible tests more precise.

27.7.2 — Repeated Conjunction Failure

Repeated conjunction failure occurs when the distinctive pattern that should separate the Law-candidate program from rivals repeatedly fails to appear under adequate designs. One absent signature may be local. Repeated absence across independent tests creates theory-level pressure (Lakatos, 1978; Mayo, 2018).

The conjunction matters because single signatures are often mimicked. Variance compression alone, neutrality bands alone, reserve correlation alone, or first-moment movement alone may be non-discriminating. The program asked for a structured combination. Failure of that combination is more serious than failure of one auxiliary detail.

Conjunction failure is exposed by a sequence of terminal protocols in which concentration appears only when endpoint-conditioned rivals also predict it, reserve-linked contraction fails, endpoint independence remains fragile, and held-out rival models outperform the Law candidate. The conjunction has failed.

A route-specific signature cannot substitute for the terminal target it was meant to inform. After one predicted structure fails, the

program may highlight a different pattern as though it had always been central. The original signature retains priority, and the status must change if the declared conjunction does not survive (Meehl, 1978; Oreskes et al., 1994).

When the distinctive conjunction fails repeatedly, the release should say that the protocol-fixed strong form is not supported and identify the adverse component. It should not replace defeat with a vague promise that a future version will surely work. A theory may survive by becoming smaller, but it may not survive by forgetting what it asked the world to show.

27.7.3 — Unresolvable Identification Failure

Unresolvable identification failure occurs when the program cannot give the public empirical claim meaningful content under ethical and measurement constraints. The problem is not merely lack of data today. It is the absence of a defensible route from observable quantities to the target component (Mayo, 2018; Meehl, 1978).

Identification failure can arise from an unstable origin, nontransportable unit, endpoint ambiguity, inseparable rivals, unmeasurable bearer states, or ethical limits on a necessary observation. The diagnosis should identify the affected component and observation route, and state which independently justified alternatives remain available.

A design requiring high-frequency terminal self-report may be unanswerable under present ethics when reporting would burden participants and passive channels cannot identify the required quantity. That conclusion limits the stated design. It directs work

toward a separately qualified measurement bridge and does not, by itself, establish permanent untestability of every PTVC branch.

New sensing methods can expand what research can observe. Proposals involving artificial intelligence, wearables, or brain decoding should specify the quantity to be identified and test its calibration across the intended settings. This turns technological promise into a researchable measurement claim (Oreskes et al., 1994; Popper, 1959).

When an empirical verdict is suspended, the public wording identifies the reason: No adequate estimate, unresolved model ambiguity, failed endpoint bridge, or open-set inadequacy. It also names the evidence needed to reconsider that status.

Unresolvable identification failure is not the same as defeat by counterexample. It is defeat of public empirical content unless a new, independently justified bridge is created.

27.7.4 — Persistent Rival Superiority

Persistent rival superiority escalates when ordinary models repeatedly outperform Law-candidate models across components, contexts, and held-out tests. A single rival victory can retire a mechanism. Persistent rival superiority can pressure the broader program (Meehl, 1978; Oreskes et al., 1994).

The rivals must be serious and implemented fairly. Adaptation, opponent processes, Brownian bridges, Doob transforms, predictive processing, homeostasis, safe control, frailty, observation shutdown, and selection must face the same observation model and endpoint constraints. Only then does superiority carry status force.

Persistent rival superiority appears in repeated superiority of endpoint-conditioned bridges and observation-gain models for terminal patterns, combined with adaptation models winning nonterminal repair dynamics and safe-control models winning horizon tasks. The remaining Law-specific residual may vanish.

Residual hunting treats whatever rivals have not yet explained as evidence for the favored theory. A small unexplained remainder matters only when it was prospectively specified, is robust to reasonable alternatives, and is large enough to discriminate among generators (Popper, 1959; Lakatos, 1978).

Theory-level reporting should specify which rivals dominate which components and whether any Law-specific discriminator remains. It should not imply that the formal question is untouched if the empirical program has lost the ability to distinguish it from ordinary explanations.

27.7.5 — Defeat Statement and Scope

A defeat statement specifies exactly what is withdrawn, what is narrowed, what remains unresolved, and what useful component science survives. It should be public, dated, versioned, and written in clear, direct language (Oreskes et al., 1994; Popper, 1959).

The statement should identify the defeated object: strong form, public empirical claim, component, mechanism, instrument, endpoint rule, reference class, or public artifact. It should also identify the evidence path that forced the change and the dissent recorded during review.

The defeat statement must survive a review board concluding that the reserve-coupled terminal signature program is defeated for adult hospice oncology because serious rivals dominate and reserve parameters are nonrecoverable. The statement should not say the entire series is false unless the evidence supports that scope.

A globally vague verdict protects institutional comfort because readers cannot tell what actually changed. The record must name the object, scope, evidence, reasons, consequences, and correction duties (Lakatos, 1978; Mayo, 2018).

A defeat statement identifies the scientific object affected and confirms continuing care commitments, dignity, legal safeguards, and the independent basis of useful applied practices.

A precise verdict preserves both the finding that changed the claim and the knowledge that remains valid.

27.7.6 — Failure Memory

Failure memory preserves data, code, protocols, model logs, review reasons, dissent, correction notices, and public-language changes. It prevents the same failed claim from returning in a new edition, a new diagram, a new donor page, or a new institutional setting without disclosure (Popper, 1959; Lakatos, 1978).

The memory should be searchable by component, version, reference class, endpoint rule, device, site, rival, and public artifact. Negative results need identifiers as durable as positive results. A durable record lets future optimism build on what has been learned, including the approaches that need a new justification before reuse. Searchable links between failure

records and successor work help prevent the archive from becoming a passive graveyard rather than an active design constraint.

Defeat and disappearance separate in a failed candidate instrument version whose invalid sign convention is later reused in a public graphic because the failure lived only in an old technical report. A failure-memory register would prevent that by marking the instrument and every dependent artifact. Artifact status should be machine-readable where possible so outdated objects can be flagged before republication or automated reuse.

An archive without consequences permits failed objects to remain active. Failure memory must constrain future language, protocols, and summaries while recording lessons and corrections without blame (Mayo, 2018; Meehl, 1978). The archive should also record when a later repair genuinely reopens a failed component, preserving both the original loss and the evidence that justified reconsideration.

27.8 — Care and Dignity After Scientific Change

Scientific status governs claims, not persons. This section defines the communication, correction, and care duties that remain active across every verdict.

Defeat is reported without mocking people who found hope in the hypothesis or implying that suffering becomes more or less real after an evidence update. The theory changes; the person's dignity does not.

Table 27.9. Care continuity after scientific status change.

Risk after status change	Local rule	Public consequence
Support moralizes suffering	Care remains immediate and independent.	Report the measured outcome without assigning moral purpose or morally owed payment to suffering.
Defeat humiliates participants	Participants are never the failed object.	Public statements blame no person or family.
Research variables escape	No score, rank, or eligibility use survives.	Constructs remain inside research governance.
Applied lens discarded	Burden analysis remains useful where ethically grounded.	Ordinary care and institutional repair continue.
Loss hidden or dramatized	Correction is calm, dated, and precise.	Public trust comes from visible change.
Grand claim shrinks	A smaller true claim is success.	Accuracy outranks grandeur.

Care continuity must be designed into communication before bad news arrives. A defeat statement written in panic can sound cold or defensive. A narrowed-status announcement written only for scientists can leave families, readers, and public supporters confused. The care language should be prepared as part of the status architecture.

The care rule also protects critics. People who warned about overclaim should not be blamed for the pain of correction. A fair science does not make skeptics carry the emotional burden of truth-telling. It incorporates their objections into review and remembers them.

Communities affected by research should receive explanations that respect their own stakes. A palliative site, disability community, language group, or clinical population should not learn that its data narrowed a claim through sensational media. Participant communication is part of dignity after scientific change.

No status change should create a demand for personal interpretation. A reader does not have to decide what a defeated mechanism means for a lost loved one. A participant does not have to become a symbol of support or failure. Private meaning remains private.

The applied lens that survives scientific narrowing should be used gently. It may help institutions ask where load is hidden or repair is blocked. It should not become a consolation prize that pressures people to extract lessons from suffering.

Care after scientific change includes care for staff. Researchers, coordinators, nurses, data stewards, and analysts who worked on a defeated component may feel that their labor has been wasted. The status system should help them see what remains useful and why honest loss was part of the work.

Care also includes care for public readers who misunderstood earlier language in good faith. A correction should not mock them for believing an overcompressed artifact. It should accept responsibility for the compression and replace it with a clearer path.

Useful applied tools can be retained on their demonstrated merits. A burden audit, staff-support protocol, or data-minimization rule earns continued use through its effects on the people it serves.

A precisely scoped claim can be easier to explain and use. Its reference conditions show readers where it applies and where further work can extend it.

27.8.1 — Care Does Not Rise or Fall With Status

Care follows present need, not scientific status. No supported, narrowed, retired, or defeated claim may delay relief or reduce the obligations already owed.

This rule prevents a subtle hierarchy. If support for terminal neutrality made caregivers less urgent, the science would have become dangerous. If defeat made people feel their pain was merely ordinary and therefore less worthy, the science would have become cruel.

Consider a family hearing that a terminal signature study has been defeated in their relative's diagnosis. The correct message is not that hope was foolish or care is different. The correct message is that scientific language changed while the duty to reduce suffering remains unchanged.

27.8.2 — No Victim-Blaming Under Any Verdict

Public statements assign scientific status to claims and describe participants with equal dignity, without blame, rank, or deserved-suffering interpretations. Care implications are stated separately and grounded in participants' needs.

27.8.3 — No Score or Rank Survives

PTVC research constructs may classify claims, uncertainty, missingness, transport limits, model performance, and declared site-method features. They may not rank people or groups, including diagnostic or cultural groups, or assign worth, eligibility, trust, holiness, loyalty, dignity, destiny, or care priority. Public displays must distinguish component or methodological status from any judgment of human or group standing.

27.8.4 — Applied Lens May Remain Useful

A surviving instrument, protocol, dataset, burden audit, or care tool may remain useful only under an independently justified use, its validated context, and a corrected label. Scientific defeat or narrowing must not travel with the tool as hidden authority, but practical care and institutional repair may continue where they have their own warrant.

27.8.5 — Public Communication of Loss

Public loss statements must be calm, dated, component-specific, and visible. Record the old and new labels, evidence path, reason, surviving claims, withdrawn language, correction schedule, corrected artifacts, and the responsible maintainer. Do not hide loss as nuance or delay correction to protect institutional image.

27.8.6 — A Smaller True Claim Is Success

A smaller true claim is a scientific success when stated plainly, tested within its scope, and not used to preserve a defeated universal claim. Summaries, graphics, and detachable sentences must carry the protocol-fixed verdict, reference class, and limits rather than a movement slogan. Answerable science is willing to become smaller than the hope that first motivated it.

Chapter 28 — Scientific Updating and Claim Revision

Science is not only a way of finding; it is a way of changing its own record when findings demand it. A claim that can be tested but cannot be corrected after testing is only partly exposed to reality. Chapter 28 governs what happens after a component is supported, narrowed, suspended, retired, or defeated: which wording changes, which versions remain visible, which public artifacts are corrected, and which authority never passes to a formula, institution, donor, software release, or artificial-intelligence system (Committee on Publication Ethics, 2025; Crossref, 2025).

A claim register preserves the current wording and status of a controlled scientific object. The object may be a definition, endpoint rule, instrument qualification, observation model, route statement, verdict, or public status sentence. Its authority comes from traceability, review, compatibility discipline, and the visible survival of prior versions, including versions that failed.

The pair boundary makes change control especially important. *The Law of Fairness* retains the formal root; *The Science of Fairness* receives that root, builds tests around it, and reports what evidence can responsibly say. A failed candidate realization may retire within this volume, but a root amendment cannot travel through a caption, appendix, or public summary as if the original claim had always meant something else.

Every update needs a destination. A result may alter notation, representation, an instrument, an endpoint model, a candidate route, a rival set, a reference class, a public artifact, or the root formal claim. Each destination has a different threshold, reviewer, migration cost, public consequence, and rollback route.

Versioning keeps failure from disappearing under improved language. A model that failed under one instrument remains failed in that version; reanalysis under another instrument is a new analysis. Failed instruments, rejected bridges, and withdrawn figures teach future researchers where the previous program broke and why a later version deserves separate evaluation.

Change control is an engine of learning rather than administrative drag. A theory learns honorably by narrowing after evidence or repairing a component in a way that creates new predictions and accepts new costs. It becomes evasive when failure is renamed refinement while the public conclusion remains untouched.

Dissent, external challenge, appeal, and reconsideration receive durable places in the system. Complex claims can be right in one component, wrong in another, unresolved in a third, and publicly risky even when technically coherent. A well-formed minority report can preserve an overlooked failure mode without turning disagreement into indefinite paralysis.

An ambitious project develops through careful testing and visible revision. Instruments can improve, diagrams can become clearer, and model comparisons can identify stronger explanations. A timely, traceable record of changes preserves those gains and helps later work build on them.

Chapter 28 gives evidence a governed afterlife. A result becomes a reviewable update packet; an approved packet changes a versioned register; the register controls downstream wording; and superseded objects remain accessible without continuing to authorize the old claim. The repair system is strong enough to

change the project and bounded enough to resist institutional capture.

What follows is a scientific change-control system with human authority at its center. It is formal enough to preserve exact objects, public enough to propagate correction, and limited enough to keep popularity from setting status. When the science changes, the active record changes with it, and no machine, institution, donor, movement, or applied domain owns the Law.

28.1 — Human-Governed Scientific Status Updates

A scientific status update begins with an evidence packet, not with a headline. The packet identifies the component, version, data, methods, quality, rivals, uncertainty, conflicts, dissent, public-risk review, and proposed status sentence. Named human reviewers then issue a reasoned, appealable decision whose scope cannot exceed the packet.

The first rule is that updates attach to named components. The update body should never vote on the Law as a whole when the evidence concerns an instrument, endpoint, population, mechanism, benchmark, or public artifact. This preserves the noncompensatory logic established in the previous chapter. A successful replication in one hospice context does not repair a failed measurement origin elsewhere. A public artifact corrected for overclaim does not change the empirical status of the underlying signature.

The second rule is that updates require human accountability. Statistical models can inform the decision. Red teams can force the decision. Repositories can preserve the decision. Artificial-intelligence tools can search for relevant contradictions or draft comparison tables. But the status change itself must be signed by accountable reviewers who declare their expertise, conflicts, dissent, uncertainty, and reasons. The bottleneck is deliberate, because claim status is a public meaning as well as a technical summary.

Table 28.1. Claim-status update decision fields.

Field	Required entry	Why it matters
Object	The exact claim, instrument, realization, endpoint rule, public artifact, or applied-domain bridge under review.	Prevents evidence about one component from changing the whole theory.
Trigger	New data, replication failure, rival victory, measurement defect, public-risk finding, code defect, or root inconsistency.	Makes correction responsive to cause rather than reputation.
Authority route	Technical update, public artifact correction, formal change request, or root handoff.	Keeps the science book from silently rewriting the formal root.
Reviewers	Named roles, expertise, conflicts, dissent, and abstentions.	Creates accountable human judgment rather than institutional fog.
Decision	Support, narrowing, suspension, retirement, defeat, correction, deprecation, or handoff.	Gives the record a usable status without making a global score.
Propagation	Books, websites, diagrams, captions, code, datasets, social excerpts, donor pages, and archive notices affected.	Prevents corrected claims from surviving in high-reach artifacts.

28.1.1 — Evidence Packet

The evidence packet is the first gate because a status decision cannot be fairer than the record it is allowed to see. The packet names the studies, replications, rival models, deviations, ethical findings, public-risk notes, and dissent that must travel together before any claim-status word is changed (Committee on Publication Ethics, 2025; Crossref, 2025).

The temptation to automate status arises from a good instinct: the project wants consistency. A dashboard can count replications, estimate heterogeneity, report calibration, and flag out-of-distribution failure. Those summaries are useful. They are not sovereign. The same numerical pattern can mean different things depending on endpoint validity, measurement invariance, rival strength, and public-risk context.

A model that gives a strong held-out score may still rely on an invalid endpoint. A benchmark that separates reserve coupling from a Brownian bridge in simulation may fail in field data where observation shuts down near death. A Bayesian synthesis may look favorable while a small subgroup carries a severe violation. Human review is needed not because humans are purer than models, but because the judgment has to join evidence, scope, language, and consequence.

The status register should therefore record inputs rather than hide them inside one number. It can display replication count, prediction intervals, model-recovery performance, calibration, rival comparison, quality of endpoint adjudication, public-artifact exposure, and dissent. The final status word remains a reasoned

human classification: preliminary support, partial support, replicated support, inconclusive, unusable, narrowed, rival-dominant, suspended, retired, defeated, or root-handoff required (Center for Open Science, 2025; Tabassi, 2023).

This protects the project from two opposite errors. It blocks promotional inflation, where a favorable metric is turned into discovery. It also blocks timid self-erasure, where any uncertainty prevents a bounded statement that the evidence actually supports. The right question is not whether a number is high. The right question is what claim, under what version, in what context, with what dependencies, the evidence permits.

A concrete example helps. Suppose a terminal-signature protocol shows equivalence-band neutrality under one candidate instrument version in two hospice networks, but leave-site-out prediction fails in a third network because sedation practices differ. An automated score might average across sites and call the result promising. A human update would separate the components: the signature receives partial support in contexts with the original sedation regime; transport to the third context is suspended; the observation model receives a revision request; public summaries lose any general wording.

The same burden discipline applies to science itself. The hidden load is the interpretive burden that a public reader, a family, a clinician, or a critic would carry if status moved too broadly. Human-governed updating keeps that load inside the scientific record instead of dropping it onto people who were never asked to adjudicate the nuance.

28.1.2 — Declared Review Criteria

Declared criteria keep update judgment from becoming hindsight. Before reviewers know which result will be emotionally easier, the record states what would justify preliminary support, partial support, suspension, narrowing, rival dominance, retirement, or defeat for the exact component under review (Crossref, 2025; Center for Open Science, 2025).

Proposer standing should be broad and decision authority should be narrow. A formal change request may be initiated by an internal analyst, an outside critic, a site investigator, a participant advocate, an applied-domain reviewer, a data steward, an accessibility reviewer, a cybersecurity reviewer, or a public-risk reviewer. The project should not require loyalty as the price of noticing a defect. Some of the best corrections will come from people who are trying to defeat the claim.

Decision authority, however, must be bounded by expertise and role. A notation clarification needs formal and mathematical review. A measurement revision needs psychometric, statistical, cultural, disability, and data-governance review. An endpoint revision needs consciousness, neurology, palliative, and ethics review. A public-artifact correction needs science, public-risk, accessibility, and communications review. A root-formal amendment requires formal-law handoff rather than science-book unilateral action.

The update body should be small enough to decide and diverse enough to see. It should include people who can understand the model, people who can understand the measurement, people who

can understand public harm, and people who are not invested in a preferred result. Its records should state the decision scope: what changed, what did not change, what remains under review, what public language is now forbidden, and what historical results must remain marked under prior versions (Tabassi, 2023; Committee on Publication Ethics, 2025).

Disclose conflicts alongside relevant expertise. Instrument developers may understand a method particularly well, while independent specialists may identify alternatives or overlooked defects. The review record lets readers assess both contributions and interests.

The process should include a decision clock. Some corrections must move quickly, especially public artifacts that create unsafe interpretation. Others require slow review, especially root handoff or endpoint changes. The clock should therefore name urgency categories: immediate public-risk correction, expedited technical correction, standard scientific review, and deferred reconsideration after new data. Delay itself becomes a recorded decision when the artifact remains public.

An update system with wide proposer standing and narrow decision authority is harder to manage, but easier to trust. It tells critics that their objections can enter the record. It tells readers that not every objection is accepted by noise or pressure. It tells the series that scientific correction is a public obligation without becoming public vote.

28.1.3 — Reviewing Authority Remains Open

Open authority means critics and outside specialists have a lawful scientific path into the process. It does not mean every comment becomes a vote; it means a methodologically serious objection can enter the packet without needing loyalty, institutional proximity, or permission from the favored interpretation (Center for Open Science, 2025; Tabassi, 2023).

The update packet must be written as if it may later be misunderstood. That does not mean it should be vague. It means the packet should distinguish the technical decision from the public consequence. If a candidate realization is retired, the packet should say whether the formal Law remains unchanged, whether a public diagram must be withdrawn, whether prior claims become historical only, and whether future studies may still test a narrowed version.

Each update should carry a claim-status sentence. The sentence should name the object and the scope. For example: the reserve-coupled reference realization remains a candidate consequence generator under the stated assumptions, but this particular measurement bridge is retired for terminal cohorts using the deprecated device version. A sentence like that prevents both exaggeration and concealment. It also gives public communicators language they can quote without inventing a safer gloss.

The packet should also contain an adverse-public-use scan. Could the correction be quoted as proof that the entire project failed when only a sensor failed? Could it be used to keep a dangerous

public artifact alive by saying the formal root was unchanged? Could it encourage self-testing, care delay, or pseudo-clinical inference? Could it be used by an institution to resist a needed correction because the headline is still attractive? The update must anticipate these misuses at the point of wording (Committee on Publication Ethics, 2025; Crossref, 2025).

A correction can itself create burden. A family who read an earlier public page may feel misled. A critic may discover that an objection was dismissed before the project had a route to hear it. A researcher may need to recontact collaborators or revise a protocol already in motion. The update system should not treat these costs as public-relations inconvenience. They are part of the ethical cost of scientific language at scale.

The public version of the update should be shorter than the technical packet but not cleaner than the truth. It should say what changed, why it changed, what remains, what is withdrawn, and where future work goes. It should avoid the reflex to write a triumphant correction. A good correction does not say, “the theory is stronger than ever,” unless the evidence supports that exact statement for a named component. Often the honest line is simpler: this component is now narrower, and the record has been corrected.

The update packet is therefore both a scientific document and a public-risk control. It keeps the cost of ambiguity inside the record. It prevents readers from carrying an interpretive load the project failed to carry for them.

28.1.4 — Conflict, Recusal, and Public Wording

Conflict and recusal rules identify interests that could affect a status decision, including authorship, funding, advocacy, instrument ownership, and exposure to the result. Apply the independent-role safeguards in Section 26.4.6: record the interest, the affected decision, any recusal, and the independent reviewer responsible. Technical clarification from an interested expert may remain useful without giving that expert sole control of the verdict or its public wording.

A status decision includes a concise public sentence naming the component, result, reference class, uncertainty, and strongest surviving alternative. Its wording should remain accurate when quoted on its own.

The sentence should avoid three temptations. It should not soften a defeat into refinement. It should not inflate a partial result into discovery. It should not reassure readers by praising the project's humility while hiding what changed. A phrase like “updated for clarity” may be appropriate for a notation fix, but dishonest for a realization failure. A phrase like “new evidence strengthens the project” should be used only when the component, scope, and rival comparison actually justify it.

Public wording should include the status cost. If an observation model is suspended, say what cannot currently be inferred. If a website page is corrected, say what earlier wording could have implied. If a figure is withdrawn, say whether the problem was visual overcompression, rival omission, measurement overreach, or old-language residue. The cost makes the correction useful

rather than merely defensive (Crossref, 2025; Center for Open Science, 2025).

The public sentence should also name care-independent consequences where relevant. A scientific correction never reduces present care, dignity, privacy, or nonparticipation rights. But that line should appear only where the correction could otherwise be misused. If an endpoint study is reclassified, the public sentence may need to say that care remains immediate and inference remains research-bound. If a code container is deprecated, that sentence is not necessary; the local risk is technical, not clinical.

A public status sentence should be tested against hostile quotation. Could it be clipped to imply unsupported proof or defeat, moral payment, promised rewards, or Artificial Intelligence authority? Could it be used by supporters to overstate and by critics to misstate? No sentence is immune to bad faith, but the wording should not hand bad faith an easy weapon. Precision is the project's first public defense.

The update board should maintain approved public-language templates for each status class, but templates cannot replace judgment. The point of a template is to prevent accidental inflation, not to make every correction sound the same. A correction about a failed endpoint rule should sound different from a correction about a website caption. One-author style is not sameness; it is disciplined recognizability across different local risks.

28.1.5 — Recorded Reasons

Recorded reasons turn a status transition into a scientific artifact rather than a mood. The decision states why stronger and weaker alternatives were rejected, which evidence carried weight, what remains unresolved, and what public wording must now change (Committee on Publication Ethics, 2025; Crossref, 2025).

Consider a late-stage result in which an independent replication finds no terminal concentration under the protocol-fixed endpoint rule, while an exploratory endpoint redefinition produces an appealing concentration pattern. The confirmatory result governs status; the exploratory analysis remains hypothesis-generating. Governance fails if the exploratory figure reaches public wording before root and endpoint review.

A second failure case occurs when a donor-facing summary keeps a stronger claim because the update board delayed public propagation. The technical register may be correct, but the public surface remains wrong. If a reader or funder sees the donor page first, the project has failed at the level of communication authority. The update system should treat this as an incident, not an inconvenience.

A third failure case occurs when a critic's model outperforms the candidate model and the project responds by changing the status label without naming rival dominance. The update may appear to preserve dignity, but it deprives the critic and future researchers of a clear scientific outcome. Rival victory should be visible because it is one way the program learns. Hidden rival victory is

just another form of proof drift (Center for Open Science, 2025; Tabassi, 2023).

A fourth failure case occurs when an artificial-intelligence assistant improves the tone of a correction notice but omits the exact consequence for claim status. Reviewers check the draft against the approved decision so that clearer language preserves scope, uncertainty, withdrawal, and every other material consequence. Readability and scientific accuracy must improve together.

A fifth failure case occurs when public reaction is treated as evidence against a correction. If supporters dislike narrowing, or critics celebrate defeat, neither reaction controls status. Public reaction can reveal misunderstanding and artifact risk. It cannot decide the scientific object. The update route should capture public reaction as a communication signal, not as a warrant signal.

These failure cases show why the update body needs records, authority limits, and public propagation. The risk is not only that the wrong scientific decision is made. The risk is that the right decision is made in one room and then loses its meaning on the way to the world.

28.1.6 — No Artificial Intelligence or Algorithmic Verdict

Computational tools may flag contradictions, summarize studies, and test consistency, while identifiable human reviewers issue reasoned and appealable status decisions. Governance frameworks support that work through oversight, evaluation, and accountability (Crossref, 2025; Center for Open Science, 2025;

Autio et al., 2024; World Health Organization, 2025; Feuerriegel et al., 2026).

Scientific vocabulary should identify the specific achievement: discovery of a pattern, validation of an instrument, confirmation of a prediction, or replication of a result. Direct, concrete language makes the finding clear.

Status language states the approved scientific outcome directly, including defeat, retirement, or rival dominance when applicable, and then identifies the knowledge and methods that remain useful (Tabassi, 2023; Committee on Publication Ethics, 2025).

Metaphor cannot bypass status. Phrases such as “coming into view,” “the world responding,” or “the model evolving” are acceptable only when they carry the same warrant as the technical register.

Maintain a versioned record of prohibited implications. Exclude moral desert, prescribed harm, human-worth ranking, machine sovereignty, archive-as-soul claims, and forced meaning. Review evidence-status claims against the findings they describe. Conditional net accounting and the Series Map’s “There is no free happiness” formulation are not prohibited merely for expressing a balance requirement; Section 3.7.1 defines their permitted meaning.

Every material update needs reasoned minutes: the object, evidence, rival pressure, options, rejected alternatives, decision, dissent, and public consequence. The record should explain why both weaker and stronger statuses were rejected.

Minutes must name the exact uncertainty that remains, whether measurement, endpoint, rival, transport, reproducibility, artifact safety, or root compatibility, because each implies a different next action.

Preserve rejected public wording and list every open propagation task with an owner and deadline. This prevents stale language from returning and keeps correction accountable until every dependent surface is closed.

These records let future readers judge whether a correction was careful, pressured, cosmetic, or complete while keeping the burden of explanation with the project.

28.2 — Versioned Claim, Model, and Evidence Registers

Versioned registers preserve the identity and lifecycle of claims, models, instruments, endpoint rules, evidence packets, verdicts, and public artifacts. Supersession changes current authority without erasing history. Each object carries a stable identifier, status, dependencies, effective date, owner, and reason for change.

The register versions scientific objects. For example, it can record that candidate instrument version 3.2 is suspended for a specified use until recalibration and requalification are complete, and identify which analyses the suspension affects.

A good register preserves the link from each version to its predecessor, lets public citations identify the exact scientific object, and connects circulating artifacts to their current status. These functions make change traceable across research and public communication.

28.2.1 — Claim Identifier and Version

A claim identifier prevents a repaired statement from pretending to be the same statement that failed. The version records the object class, the exact wording, the active scope, and the change level so readers know whether interpretation, measurement, endpoint, or public status has shifted (Crossref, 2025; Wilkinson et al., 2016).

Every object that can change public meaning deserves a version. This includes formal statements, notation choices, observation

models, candidate measurement-stack versions, endpoint adjudication rules, reserve proxies, candidate realizations, benchmark libraries, preregistration templates, public diagrams, website summaries, social excerpts, donor-facing descriptions, and dataset access packages. A change that affects interpretation must be visible enough to cite.

Object class belongs in the register. A notation clarification differs from a measurement revision, a figure correction differs from a realization replacement, and a root-formal amendment differs from a public wording update. An undifferentiated log can appear transparent while hiding the dependency structure. Versioning works because categories carry meaning.

The scheme can borrow the intuition of semantic versioning without becoming software theater. Major changes break interpretation or target identity; minor changes preserve identity while extending or narrowing controlled content; patch changes correct errors without altering meaning. The scientific register defines these categories rather than importing them mechanically.

A formal claim might therefore have a root version, an empirical bridge version, and a public-artifact version. A dataset can have a release identifier, a cleaning pipeline version, an access tier, and a provenance hash. A figure can have a caption version and a status label. The goal is not to create a maze. The goal is to let every future quotation know which object it quoted.

Versioning also protects old scholarship. A critic who defeated an earlier realization should not encounter a rewritten record in which that realization was supposedly never serious. Researchers

can cite deprecated instruments as historical objects, and later readers can see the movement of the field rather than only its cleaned final face.

Human readability comes first. Machine-actionable metadata improves search and audit, but the explanatory record remains the safeguard. A version identifier without a reason invites blind trust, while a reason without a stable identifier invites confusion. The two belong together.

Table 28.2. Minimum fields for versioned claim and evidence registers.

Register object	Minimum fields	Non-negotiable rule
Claim	Exact wording, status, scope, dependencies, date, reviewers, dissent, public language.	No global headline may move without object-specific scope.
Instrument	Version, calibration population, context of use, known failures, replacement status, data-retention limits.	Measurement failure cannot be overwritten by new wording.
Protocol	Study-registration, protocol, and analysis-plan versions; endpoint rule; observation model; consent scope; analysis container; deviations.	Reanalysis under a new protocol is a new analysis.

Register object	Minimum fields	Non-negotiable rule
Dataset	Release identifier, access tier, provenance, transformations, consent boundary, withdrawal notices.	A dataset is not public model-training permission.
Public artifact	Approved wording, source claim, status label, image/caption version, correction history, withdrawal state.	A public graphic cannot carry a stronger claim than its source.
Failure memory	Failed object, criterion, affected results, public consequence, reconsideration trigger.	A rejected bridge remains visible as a hazard marker.

28.2.2 — Evidence Links

Evidence links connect each status to the studies, code, datasets, protocols, replications, red-team reports, negative findings, and public-risk records that justify it. The links are not raw public exposure; they are traceability rules that let qualified review follow the chain from claim to warrant (Wilkinson et al., 2016; Barker et al., 2022).

Historical results remain attached to the versions that produced them. Reanalysis under a new observation model creates a new result, with an explicit link showing how it reinterprets, narrows, or supersedes the earlier finding.

Imagine an early terminal study that used a physiological channel later found to be strongly medication-sensitive. The old result

should not be deleted, nor should it continue to support public claims. It should remain in the evidence register as a version-bound result: preserved under the old protocol for historical audit, downgraded for current inference, and marked as requiring reanalysis if raw data and consent scope permit.

This is especially important for public artifacts. A diagram may have been accurate under an earlier candidate realization but misleading after a rival model wins. The archive should show both the withdrawn diagram and the correction notice. It should not keep the diagram active as if nothing changed. It should not delete the diagram so thoroughly that critics cannot see what was once claimed (National Institutes of Health, 2026a; National Institutes of Health, 2026b; Crossref, 2025).

The same rule applies to code. A benchmark container that used a biased preprocessing step remains the container that generated its results. A corrected container receives a new release identifier. The record should link them. It should state what changed, which results are affected, which are unaffected, and whether prior conclusions are withdrawn, narrowed, or merely marked with a sensitivity warning.

An archived result remains accessible under its historical version and access conditions. Active summaries use the current approved status, with links to earlier versions and the reasons for change.

Historical versioning is a form of respect. It respects critics who identified defects, participants whose data should not be reused under hidden assumptions, readers who need honest correction,

and researchers who must know which path was tried and why it no longer controls.

28.2.3 — Scope, Provenance, and Failure Memory

Scope and reference class keep a true local result from becoming a false universal statement. The register records population, setting, language, instrument, endpoint rule, care regime, device version, cultural context, and intended inference before public language is allowed to travel (Barker et al., 2022; National Institutes of Health, 2026a; National Institutes of Health, 2026b).

Provenance records the lineage of a scientific object: who created it, what data or code contributed to it, what activity transformed it, which version produced it, and which later decision changed its status. In this program, provenance is not decorative metadata. It is the backbone of correction because it lets a future reviewer trace a public statement back through claim, instrument, protocol, dataset, code, and review.

Every public-facing scientific artifact should carry an internal identifier even when that identifier is not printed prominently on the page. The identifier should connect the artifact to its source claim, evidence version, public-status label, approved wording, correction history, and withdrawal state. A social excerpt is not too small for this discipline. Small artifacts travel farther than chapters.

Failure memory belongs in the same architecture. A rejected instrument, retired realization, misleading diagram, invalid bridge, or defeated benchmark should have a stable record. The record should not be framed as shame. It should be framed as a

hazard marker. Future researchers can then avoid rebuilding the same failed bridge under a new name (Crossref, 2025; Wilkinson et al., 2016).

A failure memory should record what failed, under which version, by which criterion, which alternatives were considered, what public language was withdrawn, and what would be required for reconsideration. This is more informative than a flat retired label. It distinguishes permanent defeat, bounded failure, and a No adequate estimate region without allowing any of them to dissolve into generic uncertainty.

Provenance also keeps donors and institutions from owning the story. If a major site funded a study, the provenance record says so. If an outside critic forced a correction, the record says so. If artificial-intelligence tools generated draft code or extracted candidate contradictions, the record says so. Visibility does not solve every incentive problem, but invisibility makes every incentive problem worse.

The result is a scientific memory that can be audited. The register becomes a map of burden carried by the program itself: interpretive burden, correction burden, historical burden, and public burden. A project that asks readers to trust its humility must show them the trail of that humility.

28.2.4 — Outstanding Uncertainty and Release States

Outstanding rivals and uncertainties remain visible beside the status instead of being footnoted away. A claim may be partially supported while a Brownian bridge, observation-shutdown model, cultural script, medication confound, or endpoint-

selection rival still limits what can honestly be said (National Institutes of Health, 2026a; National Institutes of Health, 2026b; Crossref, 2025).

Every versioned object needs a release state. Draft means internal and not citable. Candidate means under review and usable only within declared limits. Active means current authority. Superseded, deprecated, withdrawn, and defeated each preserve history while removing some or all current authority.

The difference between superseded and deprecated is important. A superseded formatting template may simply have a cleaner successor. A deprecated observation model may have known bias or failed calibration. A withdrawn public graphic may have been too easy to crop into false certainty. A retired candidate realization may have lost to stronger rivals. Each state tells users what they may do next.

Deprecation language should be explicit about permitted use. A deprecated instrument may remain available for historical replication or sensitivity analysis, but not for new confirmatory claims. A deprecated figure may remain in the archive with a warning, but not in active public materials. A deprecated dataset release may remain citable, but any current inference should use the corrected pipeline if consent and provenance permit (Wilkinson et al., 2016; Barker et al., 2022).

Safety withdrawal and scientific defeat require separate register fields. A public artifact may be withdrawn because it is unsafe even while the underlying science remains active, or because the science itself changed. Combining those reasons creates

confusion: communication can fail while a model remains alive, and a model can fail while an artifact explaining that failure remains useful.

Release states should travel with metadata. A file name alone is too fragile. The release state should appear in the register, artifact metadata, readme, caption source, website revision note, and model card where relevant. If a public page displays only the newest material while the archive lacks state labels, future readers will not know whether older material was superseded, deprecated, withdrawn, or defeated.

A clear release-state vocabulary makes corrections understandable and traceable. The reader sees not merely that something changed, but how it changed and what that change permits.

28.2.5 — Stewardship of Superseded and Retired Claims

Superseded and retired claims are preserved as history and removed as active language. The record should allow a critic to see what failed, what replaced it, why the replacement was allowed, and which public surfaces are no longer permitted to quote the retired version (Crossref, 2025; Wilkinson et al., 2016).

A register needs stewards. The steward is not the owner of truth. The steward is responsible for completeness, access control, update hygiene, version identifiers, and correction visibility. Different registers may need different stewards: scientific claims, public artifacts, code releases, datasets, and root handoff packets do not have the same expertise or access requirements.

Access should be tiered by sensitivity and public purpose. Public registers can show claim status, correction notices, artifact versions, deprecation states, and failure summaries. Reviewer registers can show detailed dissent, code logs, model-recovery failures, and benchmark results. Restricted registers can hold sensitive participant information, raw vulnerable-context data, and security-sensitive details. The register should not make transparency a pretext for exposure.

Tiered access should not become secrecy by convenience. If a detail is withheld, the public record should say the class of reason: participant privacy, consent boundary, clinical sensitivity, security risk, legal restriction, or ongoing review. A blank space without reason invites distrust. A reasoned restriction preserves dignity while keeping the record answerable (Barker et al., 2022; National Institutes of Health, 2026a; National Institutes of Health, 2026b).

Stewardship also includes correction latency. Each register should track when a change was approved, when public surfaces were updated, and which dependencies remain pending. A correction that sits unpropagated for months should become visible as an open propagation item. Delay is sometimes unavoidable, but it should not disappear.

Independent audit belongs in the register. Someone outside the originating team periodically checks whether version labels, public artifacts, dataset releases, and code identifiers agree. This is not merely clerical work; many public-risk failures occur because one surface continues to quote a claim after another surface corrected it. Audit makes the series one voice in practice.

Good stewardship keeps the register from becoming a graveyard of files. It makes the register a living map of claim status, public consequence, and scientific memory.

28.2.6 — Public and Internal Views

Public and internal views separate dignity from opacity. The public summary must reveal status, scope, and correction cost, while protected review layers may contain sensitive participant information, clinical detail, security incidents, or confidential dissent that cannot be exposed without creating new harm (Wilkinson et al., 2016; Barker et al., 2022).

A release note should be written for supporters and critics at the same time. Supporters need to know what they may still say. Critics need to know what changed, what remains vulnerable, and where the project may still be wrong. A release note that only reassures supporters becomes publicity. A release note that only lists technical details becomes unusable. The right note is exact enough for a critic to reproduce the status consequence.

A useful release note names the previous version, the new version, the reason for change, the affected claims, the unaffected claims, the data or artifacts requiring reanalysis, and the public surfaces requiring correction. It should identify whether the change is major, minor, or patch-like in its interpretive consequence. It should not rely on the reader to compare two long documents to find the difference.

Release notes should include a “what not to infer” field. After a measurement revision, do not infer that old participants were mismeasured as persons. After a realization replacement, do not

infer that the root was validated. After a public-artifact withdrawal, do not infer that every component failed. This field prevents the correction from creating a new public error while repairing the old one (National Institutes of Health, 2026a; National Institutes of Health, 2026b; Crossref, 2025).

Where relevant, release notes include a “critic standing” field. When a specific rival, red-team report, replication failure, or public-risk objection motivates the change, the note names it. This is not praise management; it is provenance of pressure, including an honest record that criticism forced a better version.

A useful note is concise but not evasive. It answers four questions: whether the claim remains usable, in which context, at what status, and what changed from the prior version. A note that leaves those questions unresolved has not done its work.

Release notes make the register usable. They turn a static version list into a scientific conversation across time.

28.3 — Dissent, External Challenge, and Reconsideration

Dissent becomes scientifically useful when it identifies a specific object, assumption, omitted rival, public risk, or procedural defect. The challenge record preserves the submission, evidence, response, decision, minority view, and reconsideration trigger without turning every disagreement into an indefinite veto.

Dissent is different from noise. Noise repeats a preference without engaging the object. Dissent names the claim, the version, the evidence, the rival, the public risk, or the missing expertise. It explains what decision should change and what evidence would change the dissent. A useful dissent is falsifiable in its own way: it can be answered, narrowed, accepted, or superseded.

Appeal and reconsideration protect the same principle at different time scales. Appeal challenges a decision soon after it is made. Reconsideration reopens a settled or suspended question because new evidence, new methods, new failures, or new public artifacts changed the landscape. Both routes must be available. Neither can become endless status litigation that prevents the project from saying anything at all.

28.3.1 — Minority Report

A minority report preserves serious disagreement without forcing false consensus. It names the methodological, evidentiary, ethical, or public-language objection that reviewers could not resolve, and it stays attached to the status so later readers know where the decision remained vulnerable (Mellers et al., 2001; Silberzahn et al., 2018).

Dissent sits beside the decision rather than behind it. The scientific register preserves the majority decision, minority objections, unresolved dependencies, and conditions for revisiting status. Public artifacts need not reproduce the full dispute, but a clean label may not pretend that serious disagreement never existed.

Dissent may concern method, scope, status, language, ethics, or public artifact risk. A statistician may accept the data but reject the heterogeneity interpretation. A palliative clinician may accept the model but reject the terminal observation window. A disability expert may accept the instrument in one group but reject its transfer to another. A public-risk reviewer may accept the science but flag a diagram as hostile-crop vulnerable.

The form of dissent should require specificity. “The claim is overstated” is useful only if the object and remedy are named. Better is: the evidence supports preterminal variance compression under candidate instrument version 4 in one care regime, but the proposed public wording implies terminal neutrality across diagnoses. That dissent can be adjudicated. It also helps future writers avoid the same drift (Nosek et al., 2018; Mayo, 2018).

Dissent should not be framed as disloyalty to the project. A theory that needs silence from experts is not ready for public ambition. Nor should dissent automatically become a veto. One reviewer’s objection may reveal a real problem, or it may be answered by evidence the reviewer missed. The record must preserve the objection and the response without converting either into theater.

Recorded dissent can later become decisive. A minority warning about endpoint leakage may look cautious before a benchmark reveals a Brownian bridge rival. A public-artifact warning may look excessive before a cropped graphic circulates with false certainty. Dissent is therefore part of failure memory even when the majority decision stands.

Every material update decision should contain a dissent field, even when no formal dissent was entered. The field should identify the review route, the eligible reviewers, and whether silence followed genuine opportunity to object; otherwise an empty box can imitate consensus without showing that disagreement was possible.

28.3.2 — Appeal Route

An appeal route lets a procedural error, excluded rival, overlooked confound, improper conflict ruling, or misleading public sentence be challenged without turning correction into personal battle. Appeal has standing rules and deadlines, but it is real enough to change the record (Silberzahn et al., 2018; Nosek et al., 2018).

Appeal exists for decisions that appear procedurally flawed, inadequately reviewed, inconsistent with the source hierarchy, or disproportionate to the evidence. An appeal should not be a second attempt to win the same argument by exhausting the reviewers. It should name what failed in the decision route: missing expertise, unreviewed data, incompatible wording, conflict of interest, improper scope, public-risk omission, or incorrect root handoff.

Meaningful appeal standing extends to a critic who specified a rival in advance, a site investigator whose data were reclassified, an external expert whose domain was used, a participant advocate whose concern was ignored, and an applied-domain steward whose artifact is affected. Correction machinery loses credibility when only insiders may challenge it.

The appeal clock should be finite but not cruel. Some appeals concern slow scientific interpretation and can wait for scheduled review. Others involve public artifacts that may mislead vulnerable readers and require immediate provisional action. A banner, hold notice, or temporary withdrawal can protect public meaning while appeal proceeds. The appeal system should therefore distinguish public-risk urgency from technical review pace (Mayo, 2018; Mellers et al., 2001).

The appeal outcome should be specific. It may affirm the decision, revise the wording, add dissent, reopen the technical review, change the propagation plan, issue an interim public notice, or send the matter to formal root handoff. A vague statement that “concerns were considered” is not enough. It leaves the interpretive burden on the person who raised the concern.

Infinite reopening is prevented by threshold rules. A closed appeal can be reopened only by new evidence, new method, new public artifact, undisclosed conflict, material error, or a downstream incompatibility not visible at the time. Repetition of the same preference does not reopen the record. This protects the project from paralysis without silencing real correction.

The appeal route also protects critics. A critic should not have to fight the whole public identity of the project to challenge one component. The route says: there is a door for this claim, this version, this evidence, this wording. The existence of the door reduces the incentive for hostile escalation because the project has given challenge a legitimate path.

Table 28.3. Dissent, appeal, and reconsideration routes.

Route	Trigger	Permitted outcome
Dissent	Reviewer or critic disagrees with scope, method, status, language, public-risk interpretation, or dependency logic.	Recorded minority position, requested wording change, future test condition, or escalation to appeal.
Appeal	Procedural flaw, missing expertise, improper scope, conflict, ignored evidence, or public-risk omission.	Affirmation, revised decision, reopened review, interim hold, or formal root handoff.
Reconsideration	New evidence, method, rival, artifact misuse, device drift, context change, or sunset review.	New version, deprecation, correction, reinstatement, narrowed status, or retirement.
Closure	No new evidence, no procedural defect, and repeated objection already answered.	Closed record with rationale and threshold for reopening.

28.3.3 — New Evidence Reopening

New evidence reopening distinguishes learning from endless relitigation. A status may reopen when a new replication, benchmark, method, adverse event, public-risk failure, or formal audit materially changes the evidence position, not merely because the prior decision was inconvenient (Nosek et al., 2018; Mayo, 2018).

Reconsideration is not an admission that the first decision was careless. Science changes because instruments improve, rival models sharpen, public artifacts travel differently than expected, and applied contexts reveal confounds. A decision that was responsible under one information state may become inadequate later. The record should allow this without pretending that the past was either perfect or fraudulent.

A reconsideration trigger can be technical: new model-recovery results, new endpoint adjudication methods, new measurement-invariance failures, new device-version drift, or new transport evidence. It can be ethical: an observation practice becomes burdensome, a public graphic is misused, or a participant-return policy proves confusing. It can be institutional: a website, archive, classroom excerpt, donor page, or applied-domain protocol carries old language into a new audience.

Reconsideration should distinguish revision from rescue. A progressive reconsideration adds empirical content, improves prediction, accepts costs elsewhere, or narrows scope in advance of further tests. A degenerating reconsideration keeps the public headline while moving the bridge every time data fail. The

register should force the question: what would this revision newly risk losing? If the answer is nothing, the revision is probably a shelter, not science (Mellers et al., 2001; Silberzahn et al., 2018).

The system also includes scheduled sunset review for objects that can drift without a crisis: candidate instrument versions, public figures, benchmark libraries, endpoint rules, website summaries, artificial-intelligence-assisted workflows, and applied-domain evidence-firewall language. Scheduled review prevents important objects from remaining active merely because no incident has yet forced attention.

Reconsideration decisions should preserve old dissent. If a minority warning is vindicated, the record should say so. If it remains unpersuasive, the record should explain why. This is not a scoreboard. It is a way of making scientific judgment accountable across time. A theory that learns should remember who taught it.

The result is a living claim register without soft boundaries. It can move, but it cannot move secretly. It can revise, but revision has cost. It can reopen, but reopening has threshold. It can disagree, but disagreement leaves a trace.

28.3.4 — Nonretaliation and Applied-Domain Appeals

No retaliation for critique protects the people who make correction possible. Analysts, participants, site staff, outside critics, applied-domain observers, and minority reviewers must be able to report a defect without losing access, safety, credit, employment standing, or public dignity (Mayo, 2018; Mellers et al., 2001).

Applied-domain stewards need a route to challenge scientific wording that affects their domain. A City designer may see that a scientific correction changes the safe framing of transparency. A government reviewer may see that an evidence summary could be mistaken for administrative scoring. A reviewer from a religious community may see that a scientific phrase is being heard as doctrine. A transition steward may see that readiness language now depends on a narrowed component. These are legitimate appeals when they name the affected scientific wording and its domain consequence.

Appeals let applied domains identify misinterpretation and practical consequences. Scientific reviewers evaluate the evidence and decide its status through the same independent process used for the original decision.

Applied appeals are especially important for public artifacts. An artifact safe in a technical context can become unsafe in a civic, pastoral, or transition context. A figure that specialists read as a candidate model may be read by ordinary readers as a diagram of destiny. An applied steward can identify this transfer risk and request correction even when the technical claim remains unchanged (Silberzahn et al., 2018; Nosek et al., 2018).

The appeal record should state the receiving domain. The correction may be a domain-specific public wording note rather than a global scientific change. For example, a claim can remain technically active while a religious-community artifact is withdrawn because it could be heard as forced meaning. That is not scientific defeat. It is domain-sensitive public-risk correction.

Applied appeals also prevent the science book from becoming socially tone-deaf. A technically exact sentence can still carry burden when it reaches families, patients, public workers, spiritual seekers, or pilot participants. Applied-domain reviewers help locate that burden before it travels. Their role is advisory but serious.

The appeal route therefore expresses mutual humility. Science owns evidence status. Applied domains own lived deployment context. Neither should silence the other, and neither should borrow the other's warrant.

28.3.5 — Independent Reanalysis and Sunset Review

Independent reanalysis uses the robustness tools described in §27.2, but Chapter 28 adds a governance requirement: the challenge must produce a traceable decision. Record the alternative specification, access conditions, result, affected claim version, responsible reviewer, and whether the outcome triggers correction, sunset review, or no change.

Independent reanalysis tests whether existing evidence survives another competent implementation. Sunset review asks whether an instrument, benchmark, endpoint rule, or public summary remains current after time, drift, and new evidence. The following review clock complements reanalysis; it does not replace it.

A sunset clock does not presume the object wrong; it recognizes that the object is too important to leave unattended. The register displays the next review date and the reason for the interval. High-reach artifacts, artificial-intelligence-assisted workflows, endpoint rules, public diagrams, and future-testbed language may

need shorter clocks than technical appendices or historical records.

Reconsideration thresholds should be higher than ordinary comment thresholds but lower than crisis thresholds. New evidence, new rivals, public misuse, repeated confusion, device drift, translation failure, or accessibility barriers can trigger review. Aesthetic preference alone should not. The project should be open to correction without becoming unstable because every reader would phrase the sentence differently (Nosek et al., 2018; Mayo, 2018).

A sunset review can end in reaffirmation. The record should say that the object was reviewed and remains active. That matters because absence of correction is not evidence that review occurred. A visible reaffirmation tells later readers that the object survived a check under the current context. It also gives critics a date and route for future challenge.

If sunset review produces no decision because evidence is missing, the object should be marked under watch rather than silently renewed. “Under watch” is a useful state for artifacts whose current wording remains usable but whose dependencies are unstable. It protects public language while avoiding premature withdrawal.

Sunset clocks are a quiet discipline. They prevent the project from treating correction as something that happens only when critics force it. A serious scientific program reviews its own surfaces because memory is never self-maintaining.

28.3.6 — Finality Is Provisional

Finality is provisional because public language needs current stability while science needs future correction. A decision can be binding for active artifacts and still remain reopenable under better evidence, better methods, or a newly visible public-risk failure (Silberzahn et al., 2018; Nosek et al., 2018).

Dissent does not disappear after a correction is published. A public correction may itself be disputed: too narrow, too broad, too slow, too soft, too technical, too public, or too quiet. The dissent route should remain open for the correction action, not only for the original claim. A project can correct the science and still mishandle the correction.

Public-correction dissent may concern wording. A reviewer may argue that a notice says “clarification” when the artifact required withdrawal. Another may argue that a withdrawal notice implies scientific defeat when the problem was only graphic overcompression. These are not cosmetic disputes. Public status language can redistribute interpretive burden across readers, critics, participants, and applied domains.

Dissent may also concern propagation. A reviewer may accept the technical correction but object that the donor page, social excerpt, or archived figure remains active. This is a propagation dissent. It should create a checklist item rather than reopen the entire scientific decision. The route should distinguish object-level disagreement from propagation failure (Mayo, 2018; Mellers et al., 2001).

The correction record should show whether dissent was resolved, maintained, or escalated. If the project keeps a contested public wording, it should explain why. If it accepts the dissent, the correction itself receives a new version. The old correction notice may remain in the archive with its own correction history. This may feel intricate, but public scientific language at scale is intricate.

Dissent after correction should not become a reputational battle over who was most careful. The goal is to reduce public error. The record should focus on the object, not personalities. A critic may be right about wording and wrong about theory. A supporter may be right about scope and wrong about artifact risk. The route should separate these judgments.

28.4 — Formal Change Requests and Root Concordance

A formal change request distinguishes clarification, correction, component revision, branch narrowing, non-equivalent successor creation, and root amendment. The packet shows the old and proposed text, evidence, dependencies, compatibility, migration, dissent, public corrections, and rollback route so reviewers can determine whether the change predicts, narrows, or rescues.

The request must begin with exact old wording. A project cannot responsibly change what it has not quoted. It must then state proposed new wording, the reason for change, the evidence or argument, affected dependencies, compatibility cost, public consequence, dissent, migration plan, and rollback plan. This is not a formality. It is the way the project prevents a new mechanism from silently preserving an old public headline after the old bridge fails.

The most important boundary is root handoff. The science volume may revise candidate realizations, instruments, protocols, observation models, evidence registers, public scientific status, and correction routes. It may not redefine the formal Law that *The Law of Fairness* owns. If a correction changes the latent claim, endpoint definition, formal currency, or root boundary condition, the request must become a formal root-handoff packet rather than a science-book patch.

28.4.1 — Trigger for Formal Review

A trigger for formal review appears when scientific work pressures the received formal root rather than only an instrument

or interpretation. Unit failure, endpoint leakage, process-class conflict, notation ambiguity, impossible identification, or a better construct can justify opening the formal route.

The first type is notation clarification. It fixes ambiguity without changing the object. A symbol may be overloaded, a subscript may need explanation, or a display may require status labeling. This is the lowest-risk route, but it still requires a record when public interpretation could change. A change that introduces a new construct is recorded as a substantive amendment.

The second type is representation change. This alters how a component is expressed: scalar to vector reserve, latent-state representation to belief-state representation, or single-channel estimator to multi-channel observation model. Representation changes require compatibility analysis because old results may not map cleanly into the new object. The request must state which prior findings remain comparable and which become historical.

The third type is measurement revision. It changes instruments, calibration, anchors, channel weights, abstention rules, missingness handling, or context-of-use limits. Measurement revisions often look technical but carry large public consequences. A revised candidate momentary-valence estimator cannot be allowed to rewrite old data by default. Raw data may be reanalyzed only if consent, provenance, and compatibility permit it (Crossref, 2025; Committee on Publication Ethics, 2025).

The fourth type is endpoint revision. This is high-risk because the endpoint firewall protects the theory from tautology and misuse.

Any revision to endpoint adjudication must state how the endpoint remains independent of the ledger estimator, how prior endpoint-window studies are affected, and what public language must be held during review. A weaker endpoint can make apparent closure meaningless.

The fifth type is candidate-realization replacement. A bridge from formal claim to observable consequence may be retired and replaced. The request must preserve the difference between replacing a bridge and redefining the formal Law. If reserve-coupled realization A fails and realization B is proposed, the packet must say what B predicts that A did not, what A's failure now means, and which public artifacts built on A are deprecated.

The sixth type is claim-strength change or theory reclassification. This changes public status: preliminary to replicated, partial to narrowed, active to suspended, mechanism to retired, or candidate Law-language to weaker lawhood language. It may be triggered by evidence, rival dominance, repeated bridge failure, public-risk review, or formal root handoff. It is the route with the greatest public consequence and therefore requires the clearest wording.

Table 28.4. Formal change-request packet.

Packet field	Required content	Failure if missing
Old object	Exact prior wording, version identifier, affected figure/table/code/protocol, and status label.	The change cannot be audited because no one knows what changed.

Packet field	Required content	Failure if missing
Proposed object	Exact new wording or object, proposed status, and version class.	The request becomes aspiration rather than reviewable text.
Reason	Evidence, error, rival victory, public-risk finding, dependency conflict, or root inconsistency.	The change looks reputational or cosmetic.
Dependency list	Formal definitions, instruments, protocols, datasets, code, public artifacts, applied references.	Downstream contradictions survive the correction.
Compatibility analysis	Unchanged, patch, deprecate, withdraw, reanalyze, or root handoff for each dependency.	Old results are silently overwritten or improperly reused.
Review and dissent	Reviewers, expertise, conflicts, votes, dissents, appeal conditions.	Authority becomes opaque.
Migration and rollback	Implementation steps, public notice, archive rule, rollback trigger, failure memory entry.	The correction cannot be completed or reversed safely.

28.4.2 — Proposed Amendment

A proposed amendment must say exactly what changes and what does not. It gives old wording, proposed wording, status, assumptions, affected variables, scope, and public consequences

so the change can be accepted, narrowed, rejected, or returned for stronger evidence (Crossref, 2025).

Compatibility analysis asks what breaks when the change is accepted. It should cover formal definitions, measurements, datasets, protocols, benchmarks, figures, captions, public summaries, applied-book references, social excerpts, donor pages, classroom materials, and archived pages. A change that looks small in a methods table may break a public diagram or a cross-series sentence.

The analysis should classify each dependency. Some objects are compatible without change. Some require a patch. Some require deprecation. Some require withdrawal. Some require reanalysis. Some require root handoff. A migration plan then states who changes what, by when, with which reviewer sign-off, and how the public will see the new version.

Migration should avoid retroactive erasure. If a dataset was analyzed under observation model 2.1, it remains associated with 2.1 even after 2.2 is released. Reanalysis under 2.2 becomes a new analysis with a new record. If a figure was created under a retired realization, the figure can be archived with a warning, replaced with a new figure, or withdrawn from public circulation. It cannot remain silently current (Committee on Publication Ethics, 2025).

Backward compatibility has ethical meaning here. If a correction changes public claims about terminal studies, families, clinicians, or vulnerable participants may have encountered older language. The migration plan should decide whether a public correction notice is needed, whether high-reach artifacts require direct

replacement, and whether participant-facing materials must be reissued. Technical correction without public migration leaves the burden outside the record.

The migration plan also needs a rollback route. Some revisions will fail. A new instrument may introduce bias. A new website summary may be safer scientifically but confusing publicly. A new benchmark may prove impossible to reproduce across sites. Rollback is not humiliation. It is version control. The record should say which version is restored, which artifacts are affected, and what new evidence is required for another attempt.

Compatibility analysis turns correction from aspiration into work. It tells the project that every word has dependencies. It also tells critics exactly where to look if a change has been accepted in name but not propagated in practice.

28.4.3 — Scientific Evidence and Open Questions

Scientific evidence and open questions remain separate fields. A change request may have strong simulation support, weak human transport, unresolved measurement invariance, or live rival pressure; the packet must show both the reason for the proposal and the uncertainty that still constrains it (Crossref, 2025; Committee on Publication Ethics, 2025).

The hardest ordinary change is candidate-realization replacement. A candidate realization connects the formal latent boundary condition to observable dynamics. It can fail without proving the root false, and it can be replaced without proving the root true. The danger is public drift: a failed bridge is retired, a new bridge

is introduced, and the public headline remains exactly as strong as before. That is rescue unless the cost is recorded.

Suppose an early reserve-coupled realization assumes finite-variation reserve and a signed arithmetic reference process. Later mathematical work shows that the product realization does not entail the received route claim over the intended process class. The correction does not quietly widen the process class or replace the target. It retires or narrows the realization and opens a formal change route if the received root itself requires amendment.

The packet must state what remains unchanged: the formal root, if it truly remains unchanged; the endpoint firewall; the latent/measured distinction; the public empirical burden; and the ethical firewall. It must also state what changes: process assumptions, observable signatures, model-recovery benchmarks, prior results, figures, public summaries, and future protocols. If the new realization weakens a previous prediction, that weakening is a status consequence, not a footnote.

A replacement becomes progressive when it predicts new losses. It should state where it can be defeated: a rival bridge that matches the same signatures more simply, a failure of parameter recovery, a failed transport test, an inability to separate stochastic reserve from observation shutdown, or a public-risk cost that makes the model unusable. A replacement that never risks defeat merely changes the surface of the same protected claim.

This distinction matters for *The Law of Fairness* because the formal root should not be rewritten inside a technical chapter. If the replacement changes the latent ledger, terminal target,

endpoint architecture, stream definition, or phenomenal representation, it is not merely a realization replacement. It is a root-formal amendment, and the science volume must send it back through the formal root route.

A reliable change-control system lets the project improve while showing exactly what changed. The record connects each new instrument, model, and interpretation to the evidence that motivated it.

28.4.4 — Root-Book Authority

Root-book authority keeps *The Science of Fairness* from rewriting the Law it tests. The science volume may recommend, pressure, and document, but formal adoption belongs to the formal-law route and leadership-approved change control, not to repeated scientific convenience (Committee on Publication Ethics, 2025).

A root handoff packet is required when a proposed change touches the formal claim rather than a scientific bridge. The packet should state the exact root element implicated: unified conscious stream, felt-experience currency, latent ledger, terminal neutrality, endpoint discipline, boundary condition, or ethical firewall. It should explain why a science-level correction cannot resolve the issue without altering that root element.

The handoff packet should not be written as a demand. The science volume does not command the formal-law book. It reports the conflict: evidence, model failure, measurement impossibility, endpoint contradiction, rival dominance, or public-risk pressure. The formal root then decides whether to clarify, amend, narrow,

or preserve the root claim. That decision belongs to the formal route because it changes the object all other books receive.

A root handoff should include compatibility costs across the whole series. If the latent claim narrows, synthesis scenes, ordinary-life language, City architecture, government claims, constitutional models, material-burden framing, religious doctrine, and transition gates may all need adjustment. The science volume can identify these dependencies, but it should not rewrite them unilaterally (Crossref, 2025).

The packet should include public-status advice. During root review, public artifacts relying on the challenged wording may need holds, provisional labels, or withdrawal. It may be irresponsible to keep old language active while the root question is under formal review. The handoff therefore includes temporary public-risk controls even before the root route decides.

If the root route declines to amend, the science register should preserve the conflict record. It may say that the formal root remains unchanged while a scientific bridge, observation model, or empirical target has narrowed. It may also record dissent. Silence would make future readers think the conflict disappeared rather than being judged.

Root handoff is the clearest example of no-domain-theft discipline. It lets science pressure the root without becoming the root. It lets the root learn from science without pretending every technical adjustment is a formal amendment.

28.4.5 — Version and Dependency Audit

A version and dependency audit names every downstream surface touched by the change: chapters, formulas, diagrams, datasets, protocols, code, captions, summaries, websites, donor pages, social excerpts, and archived editions. A change that cannot find its dependencies is not ready.

Every formal change request should include an ad hoc rescue audit. The audit asks whether the proposed revision was motivated independently, whether it improves prediction, whether it accepts costs elsewhere, whether it exposes new failure, and whether it preserves a public failure memory. A revision that answers yes to these questions may be progressive. A revision that answers no may be a rescue maneuver.

Independently motivated means the revision arises from theory, prior data, measurement limits, rival comparison, or public-risk analysis that can be stated before seeing the outcome it protects. It does not mean the revision cannot respond to failure. It means the revision is not only a way to keep the headline intact after failure. The timing and reasoning should be visible.

Improves prediction means the revised object should do more than fit past trouble. It should produce new observable constraints, better model recovery, sharper rival separation, improved transport logic, or clearer failure conditions. If a revision makes the claim harder to test and easier to defend, the audit should flag empirical-content loss (Crossref, 2025; Committee on Publication Ethics, 2025).

A revision records every actual change in scope, interpretation, prior-result use, or public wording. Some corrections require narrowing or withdrawal; others repair notation or code while preserving the claim and its predictions. The audit asks whether the consequences are disclosed, not whether the revision necessarily sacrifices a claim.

Exposes new failure means the revised object says what would defeat it. This is the difference between a repair and a shield. A revised endpoint rule, measurement model, or realization should create new ways to lose. If it does not, the project has probably reduced vulnerability while claiming to increase rigor.

The rescue audit should be published at least in the scientific register. Public summaries can compress it, but the reasoning should exist. The audit makes claim register vulnerability credible because it shows that repair itself can fail.

28.4.6 — No Quiet Claim Change and Rollback Planning

A candidate repair does not become settled through repeated use. Until formal adoption, it remains labeled candidate, provisional, superseded, retired, or under review as appropriate (Crossref, 2025).

Compatibility cost should be recorded because the depth of affected dependencies is scientifically informative: a wording correction differs from a change to the endpoint, observation model, or target. High cost does not defeat a true improvement, and low cost does not excuse a rescue that removes vulnerability. The matrix should distinguish scientific breakage from editorial

propagation so reviewers can see whether the evidence object changed or only its downstream expression.

Every approved change should include a rollback state and a reviewable trigger, such as failed replication, reproducibility failure, accessibility or public-risk defect, rival-model result, or discovery that the change reached a deeper formal object. The previous safe state may be suspension or withdrawal rather than the old claim.

A rolled-back revision remains in the version history with the evidence that triggered reversal. Public correction should identify the withdrawn revision and the current state so reversibility itself remains auditable. That history also prevents a failed repair from returning later under a new label without confronting the evidence that caused its withdrawal.

28.5 — Correction Propagation Across the Series

Correction follows dependencies, not publicity. An approved scientific update changes the exact interfaces that inherit its meaning, while other domains retain their own authority. The propagation map names every affected title, artifact, source, formula, caption, summary, protocol, website, dataset, and public reply together with the required action and owner.

Correction propagation is the discipline that prevents that drift. It begins with a dependency map: which titles, sections, diagrams, summaries, public artifacts, code packages, datasets, classroom materials, and public pages rely on the changed object. It then assigns a correction action: revise, deprecate, withdraw, replace, add notice, freeze as historical, or open a further change request. Without this map, the project can become correct in private and misleading in public.

Applied titles do not absorb the full scientific protocol. They receive only the corrected status needed by their own conditional claims, while the formal root receives any root-level issue through its own change route. This preserves standalone accuracy without turning every book into a duplicate of *The Science of Fairness*.

28.5.1 — Status-Labeled Cross-Book Notice

A status-labeled cross-book notice tells each owner title what changed scientifically, what stayed untouched, what language is now unsafe, and what review is required. It carries the status cost without turning the science book into a master authority over the series (Crossref, 2025; Committee on Publication Ethics, 2025).

A dependency map begins with a changed object and asks where it appears directly or indirectly. Direct dependencies include quotations, definitions, equations, tables, figures, and named protocols. Indirect dependencies include public metaphors, introduction summaries, public-diagram panels, public talks, donor pages, social posts, and applied-book scenarios that rely on the same status even if they do not name the object.

The map should distinguish technical dependencies from public dependencies. A code container may need a new hash, a benchmark table may need a new row, and a dataset release may need a new metadata record. A public page may need a shorter correction notice, a caption may need a status label, and a high-reach image may need withdrawal. Treating these as the same task creates either excessive technical detail in public surfaces or inadequate traceability in scientific ones.

The dependency map includes *The Law of Fairness* whenever a correction touches the formal root or its public definition. Science can identify pressure, evidence, and consequences, but the root owner decides whether the change is clarification, correction, amendment, or a non-equivalent successor. The map preserves both authority and traceability.

A correction should also map non-book artifacts. Website pages, visual explainers, public graphics, cover copy, interviews, donor summaries, excerpt cards, classroom handouts, code repositories, dataset readme files, model cards, and archive pages are all surfaces where old language can survive. The map should be ruthless because public trust is often lost at the smallest surface.

The map must be stored with the change request. If someone later asks why a chapter changed, or why a public diagram disappeared, the answer should not depend on institutional memory. The correction should show its route. It should say which surfaces were changed, which were frozen as historical, which were not affected, and which require future review.

The dependency map makes correction finite. It turns an overwhelming series-wide worry into a list of affected surfaces. It also prevents overcorrection by showing what does not need to move. A precise correction should be wide enough to reach every dependency and narrow enough to avoid rewriting unrelated material for aesthetic uniformity.

Table 28.5. Compatibility and migration matrix.

Affected object	Compatibility status	Required migration action
Formal root wording	Root-dependent	Prepare root-handoff packet; do not change inside the science book alone.
Science chapter prose	Directly affected	Revise wording, status label, figure captions, and dependency references.
Applied-book scenes	Conditionally affected	Update conditional language or mark as imaginative architecture, not evidence.

Affected object	Compatibility status	Required migration action
Public diagram	High-risk if overcompressed	Replace, deprecate with notice, or withdraw from active public use.
Website summary	Public-facing dependency	Update headline, status sentence, correction date, and archive link.
Dataset and code release	Reanalysis-dependent	Create new release identifier; preserve old result under old version.
Social excerpt	High-reach fragment	Issue corrected excerpt or remove from active rotation with historical notice.

28.5.2 — Routing Corrections to Each Title

Applied domains can investigate their own outcomes. A City practice, government service, religious ritual, Workgame pilot, or ordinary-life habit can be evaluated through its effects on burden, participation, access, or wellbeing.

Formal-root corrections follow the handoff procedure in §28.4. The science volume supplies the evidence, proposed wording, compatibility costs, and public consequences; The Law of Fairness retains authority over changes to the formal statement and root vocabulary.

The Science of Fairness maintains corrections to measurement, protocols, observation models, signatures, model recovery,

replication, evidence synthesis, verdict language, and change-control procedures. It sends implications for other titles through the relevant handoff route.

The Utopia of Fairness and the applied titles distinguish conditional exploration from claims that a finding is established. When a scientific result changes, update any passage that relies on its former evidential status. A clearly stated exploration of what would follow if PTVC were true may retain that conditional premise and its valid consequences without claiming confirmation. The humane aims of the series remain ethical and practical commitments rather than a theorem of terminal balance.

Religious interpretation can continue within its own domain, while scientific descriptions in religious material track the active evidence register. The handoff identifies which empirical wording requires updating and which interpretive questions remain local.

Readiness language in The Transition of Fairness updates when its scientific dependencies change. Observations from a transition pilot can generate research questions for separate qualification and testing.

Role-based correction keeps the books coordinated without making them subordinate to a single institutional body. The series sounds like one author because it shares corrected status. It remains safe because each book receives correction in the language of its own domain.

28.5.3 — Independent Duties and Correction Examples

Ethical and legal independence means duties of care, privacy, consent, nonparticipation dignity, and lawful remedy do not wait

for scientific status. A narrowed mechanism or defeated instrument may change claims, but it does not reduce human protection.

A public correction should be concrete. Suppose a diagram once showed a smooth path from reserve coupling to terminal concentration. Later model recovery shows that endpoint-conditioned bridge rivals can mimic the same pattern under the observation model. The correction action is not merely to add a footnote. The diagram should be replaced with a comparison diagram or withdrawn from high-reach surfaces. Captions should state that the old diagram represented a candidate realization, not evidence.

A website summary should match the result's current registered status. For example, a study recorded as partial support for one measured signature is described at that component and context, with a link to the supporting report and remaining research questions.

Suppose a donor page describes a future city as a natural testbed for the Law. The correction route should replace that phrase with a research-question sentence: applied observations may identify hypotheses and confounds, but evidence requires an ethical, prospectively specified design and, when a public registry claim is made, a persistent preregistration record. This protects supporters from confusing institutional coherence with scientific confirmation (Elliott et al., 2017; Crossref, 2025).

Suppose an archived social excerpt presents suffering as morally owed payment, prescribes harm, or promises a chosen reward.

Mark that misleading excerpt as withdrawn, explain the problem, and point to the corrected wording while preserving appropriate historical records. A statement of conditional net accounting is not withdrawn merely because it uses an explicitly limited accounting metaphor. Silent deletion hides the correction; unmarked preservation can repeat the actual overclaim.

The same logic applies to code. If a released analysis pipeline changes a preprocessing step that affected claims, the old container should remain citable as historical and the new container should receive a new identifier. The correction notice should state which results are affected. Reproducibility is not only the ability to rerun current code; it is the ability to understand the path from old code to corrected interpretation.

Correction examples should not be written as apology theater. They should be exact, restrained, and useful. The aim is to reduce public error and preserve scientific memory, not to perform purity after the fact.

28.5.4 — Removal of Outdated Proof Language

Removing outdated proof language is a search-and-adjudication task. Introductions, summaries, captions, figures, visual explainers, donor materials, media passages, glossary entries, and websites are scanned for proof, validation, demonstrated, settled, inevitable, or confirmed whenever the active claim register no longer permits them. Living-review methods help maintain this process over time rather than treating correction as a one-time editorial event (Akl et al., 2024; Elliott et al., 2017).

Propagation uses a checklist rather than memory. The checklist starts with the changed object, then asks which surfaces quote it, visualize it, summarize it, depend on it, teach it, fundraise from it, archive it, train on it, or hand it to an applied domain. Each affected surface receives an owner, action, due date, and completion state.

Owner sign-off is domain-specific. The science editor signs scientific accuracy; the formal-root owner signs root wording; applied-domain owners sign local translation; public-risk reviewers sign high-reach artifacts; accessibility reviewers sign figures, alternative text, and readable tables; data stewards sign repositories. No single approval pretends to cover all surfaces.

The checklist should include negative surfaces: materials not affected. This prevents future confusion when someone asks why a chapter did not change. A record saying “not affected because the claim is purely applied and does not rely on the corrected instrument” is useful. It shows that the surface was reviewed rather than forgotten (Crossref, 2025; Committee on Publication Ethics, 2025).

Propagation includes a search phase across public pages, manuscript files, draft excerpts, figure folders, captions, slides, social posts, readme files, model cards, donor language, and training materials. Automation can locate candidates, but human review decides whether each hit is current authority, historical record, quotation, or harmless coincidence. Automated absence is evidence for review, not proof that obsolete language has vanished.

Owner sign-off should not become a bureaucratic theater where everyone clicks approved. Each sign-off should state the action taken: revised, no change, deprecated, withdrawn, archived with notice, or escalated. When a surface cannot be updated immediately, it should receive a temporary status banner or access hold if the risk justifies it.

The checklist makes correction public in a practical sense. It does not ask readers to trust that the project is careful. It shows where care moved.

28.5.5 — Owner-Book Review and Correction Lag

Owner-book review protects domain boundaries during correction. The legal architecture, religious interpretation, City formation, government administration, ordinary-life guidance, material-burden analysis, synthesis, and transition sequence each adapt scientific notices inside their own mandate.

Correction lag is the time between approval and full propagation. Some lag is unavoidable in a ten-book series with public artifacts and code. Unnamed lag is dangerous. The register should track open propagation items and display interim notices where outdated material remains reachable. If a figure is awaiting replacement, the page should say so.

Interim notices should be proportional. A low-risk formatting inconsistency does not need a public banner. A high-risk artifact that could imply unearned proof, moral payment or prescribed harm, direct inner-life access, or AI authority may require immediate withdrawal before full replacement exists. The notice

should say the artifact is under correction and should not be used for claim-status inference.

Correction lag can itself reveal infrastructure weakness. If public pages take months to update because no one knows the owner, the propagation system needs repair. If social excerpts keep circulating because files were copied into multiple folders, the release system needs better artifact identifiers. If applied domains resist update because the old language was useful, the boundary system needs reinforcement (Committee on Publication Ethics, 2025).

The record should distinguish pending, delayed, blocked, and resolved. Pending means work is underway. Delayed means a time issue. Blocked means a dependency or dispute prevents action. Resolved means the surface has been updated or marked. This prevents vague project-management language from hiding public-risk exposure.

Interim notices should be written with the same severe compassion as the chapters. They should not shame readers who saw earlier material. They should not scold critics who noticed the issue. They should simply say what changed, what not to infer, and where the corrected status will appear. A clear interim notice can build trust even before the final replacement is ready.

A correction is not an event. It is a propagation process. Naming lag makes the process honest.

28.5.6 — Correction Completion Audit

A completion audit confirms revised status across active text, archives, code, data, summaries, and high-reach surfaces (Crossref, 2025; Committee on Publication Ethics, 2025).

Before crisis, synthetic drills retire a fake instrument, deprecate a figure, narrow a public claim, or stage a mock root handoff. They test surface detection, owner action, and time to closure.

Drills must include public artifacts and applied domains, where captions, websites, donor summaries, social cards, model readmes, and neighboring books may preserve stale implications. Each domain receives correction without taking scientific authority or losing its voice. Correction drills should verify that each domain receives the new scientific ceiling while retaining its own independent legal, ethical, or practical reasoning.

Drills record missed surfaces, unclear roles, disagreement, and latency, then repeat after structural changes, new websites, release pipelines, or pilots. Their value lies in exposing brittle infrastructure before public pressure does. Latency metrics can show whether the correction system improves over time and which surfaces repeatedly resist propagation.

Search manuscripts by meaning as well as phrase. Introductions, summaries, captions, illustrations, and neighboring chapters may retain an old inference; verify upstream and downstream dependencies. Dependency search should include paraphrases and translated materials, because stale meaning can survive even after the original wording disappears.

House-phrase searches target discovery language, body-reading or score implications, retired bridges, and stale figures; the Table of Contents and retained introductions receive special scrutiny as reader maps. Automated discovery can assist, but every hit still requires human judgment about whether the underlying claim actually depends on the changed component.

Final prose remains natural: reader-facing sentences carry corrected meaning, while the register holds machinery and provenance. One coherent book replaces visibly patched files. This separation keeps provenance exhaustive internally while preventing editorial scars from becoming part of the public argument.

28.6 — Public Artifacts, Websites, and Withdrawal

Public artifacts are scientific surfaces when they compress or display scientific meaning. A caption, diagram, website, donor page, social image, video, or interview can remain active long after the technical context changes. Each artifact therefore carries a version, status, owner, correction route, and hostile-crop review (Committee on Publication Ethics, 2025; Crossref, 2025).

An overstated caption is not merely a design defect, and an obsolete website status is not a harmless delay. Public surfaces can change what readers believe the science has authorized, so they enter the correction system with the same seriousness as other dependent objects.

A public graphic can be beautiful, memorable, and emotionally compelling while conveying the finding clearly. A well-designed artifact identifies the observed result and its scope, carries its current scientific status, and gives readers a route to the supporting detail.

28.6.1 — Cover and Visual Explainers

Cover and visual-explainer materials receive correction because images carry status before readers reach prose. A visual that implies confirmation, universal scope, archive-as-soul, Artificial Intelligence authority, or automatic uplift must be revised even if the surrounding text is technically correct (Committee on Publication Ethics, 2025; Crossref, 2025).

The first class is interpretive artifacts: visual-explainer panels, diagrams, captions, summary pages, public slides, social cards,

and short excerpts. These artifacts translate scientific objects into public understanding. Their risk is overcompression. They should carry object labels, status labels, and source-version references where feasible. If a diagram cannot remain safe after cropping, it should not be released in that form.

The second class is institutional artifacts: donor pages, partnership summaries, research invitations, recruitment materials, classroom handouts, media kits, and public FAQs. Their risk is authority transfer. They can make funding, participation, or institutional association look like scientific validation. They should separate invitation, funding, research question, ethical boundary, and evidentiary status.

The third class is archival artifacts: prior versions, withdrawn graphics, old public statements, deprecated code, historical datasets, and correction logs. Their risk is either erasure or resurrection. They should remain available under appropriate access and with clear notices, but they should not circulate as current. An archive should preserve history without giving old language present authority (Tabassi, 2023; UNESCO, 2021a).

The fourth class is computational artifacts: code containers, benchmark libraries, model cards, dataset cards, analysis notebooks, synthetic fixtures, and automated reports. Their risk is hidden status transfer through technical confidence. A container that runs cleanly can still implement a flawed assumption. A model card should therefore carry claim-status boundaries, training or simulation scope, known failures, and prohibited uses.

The fifth class is conversational artifacts: public replies, interviews, moderated discussions, and short responses to critique. Their risk is tone drift. A careful reply can build trust; a defensive reply can make the theory look like a movement protecting itself. Conversational artifacts should be correction-ready and should avoid making claims stronger than the current declared status because the audience is skeptical or hostile.

Risk level should determine review. High-reach, high-compression, vulnerable-reader-facing, or quote-crop-prone artifacts require stronger pre-release review and faster withdrawal authority. A table inside a technical chapter and a shareable image on a website are not the same public object.

Table 28.6. Public artifact correction example.

Artifact	Detected problem	Correction action
Visual-explainer panel	Shows candidate realization as a smooth path without rival comparison.	Replace with a candidate-versus-rival panel and add status label.
Website headline	Says early evidence for terminal neutrality when status is partial support for one measured signature.	Rewrite headline, add correction date, archive prior text with notice.
Donor page	Implies applied pilots are testbeds proving the Law.	Replace with research-question language and evidence firewall statement.

Artifact	Detected problem	Correction action
Social card	Uses wording that turns a conditional balance requirement into moral payment or prescribed harm.	Withdraw active card, preserve historical copy only with warning.
Code release	Implements deprecated observation model without status warning.	Create new release, mark old container deprecated, link affected results.

28.6.2 — Summary, Glossary, and Archive Status

Summary and glossary language helps readers retain the book’s central distinctions. Each short definition should preserve the corrected term’s status, scope, and uncertainty, so concise wording remains faithful to the full scientific account (Crossref, 2025; Tabassi, 2023).

The archive preserves versions, corrections, artifacts, and results so the project can be audited. Clear purpose and access limits govern the records it contains.

Archived artifacts should be marked by status: current, superseded, deprecated, withdrawn, historical, restricted, or removed for safety/legal reasons with a public notice where appropriate. A withdrawn artifact may still be retained internally for audit. A restricted dataset may be findable through metadata without being accessible to the public. A public correction can state that an artifact existed and why it was changed without exposing participants or reviving unsafe language.

The archive must also preserve negative results. Failed instruments, abandoned mechanisms, defeated bridges, public artifact corrections, and red-team objections belong in the memory of the program. If only positive artifacts remain visible, the archive becomes a publicity surface. If negative artifacts are sensationalized, it becomes a spectacle. The right posture is factual memory (UNESCO, 2021a; Committee on Publication Ethics, 2025).

Apply the access tiers defined in §§26.5.2 and 28.2.5 while preserving each artifact’s status and version history. Historical availability does not restore a superseded claim’s authority or enlarge permission to release sensitive material.

The archive should support citation without raw links in manuscript prose. Public materials can cite stable identifiers, release names, or version labels in controlled references. Manuscript copy should not depend on live links for meaning. The text should remain intelligible if a website changes. If an artifact is withdrawn, the record should tell future readers what changed.

A good archive shows earlier claims, the evidence that changed them, the current findings, and the access conditions for supporting records. These links make the project’s scientific development traceable.

28.6.3 — Websites and Social Excerpts

Websites and social excerpts require version dates, correction notices, share-card updates, and cache-aware replacement where possible. A public sentence clipped from an old page should not

keep speaking as current science after the register has changed (Tabassi, 2023; UNESCO, 2021a).

A correction notice should answer five questions: what changed, why it changed, what prior wording should no longer be used, what current wording replaces it, and which materials are affected. It should be written plainly enough for a serious public reader and precisely enough for a critic. It should not bury the correction beneath gratitude, mission language, or reassurance.

The notice should distinguish correction, clarification, deprecation, withdrawal, suspension, and reclassification. A clarification says the object was ambiguous. A correction says the object was wrong or misleading. Deprecation says an object remains historically available but should not be used going forward. Withdrawal says active circulation stops. Suspension says no current status should be asserted. Reclassification says the evidentiary status has changed.

Public wording should state the gain and its consequence together. A model may improve while an earlier claim weakens, narrows, or fails; readers need both facts. A clear correction preserves confidence in the research process by giving readers the current evidential status and identifying which earlier statement no longer applies (Committee on Publication Ethics, 2025; Crossref, 2025).

Correction notices should be connected to artifacts. If a figure changes, the figure caption should carry a version notice or link internally to the correction register. If a website page changes, the page should show the correction date and prior status. If a social excerpt is withdrawn, active channels should stop using it. The

correction should travel through the route defined in the previous section.

Some public artifacts should be predesigned for correction. A figure template can include a status field. A website card can include a version line. A donor summary can include a claim-status paragraph. A model card can include prohibited uses. Designing for correction prevents the project from treating updates as emergencies every time science does what science should do.

The public artifact rule is simple: a surface that can carry scientific authority must be able to lose that authority visibly. If it cannot be corrected, deprecated, or withdrawn, it should not be released in a form that invites trust.

28.6.4 — Persuasive Copy, Graphics, and Captions

Donor, media, and recruitment copy must not borrow authority from outdated science. Persuasive materials receive stricter review because they can convert public attention, money, participation, or institutional prestige into pressure to preserve a claim beyond its warrant (UNESCO, 2021a; Committee on Publication Ethics, 2025).

Every public graphic receives a caption review before release. The caption names whether the figure is a candidate model, diagnostic workflow, evidence map, rival comparison, protocol route, failure memory, or public-artifact example. Visual elegance never substitutes for status, and a clean arrow never creates inevitability.

Graphic review should test cropping. If the title and caption are removed, does the remaining image imply proof, ranking, person measurement, AI authority, archive-as-soul, or transition destiny? If so, the figure needs embedded status language, design revision, or restricted release. A graphic that survives only when surrounded by paragraphs may be safe for a chapter but unsafe for social media.

Caption review should also test visual hierarchy. If the Law-candidate path is bold and rivals are faint, the figure teaches overclaim even if the caption is cautious. If correction paths are hidden in small type, the artifact may imply that update is secondary. Visual style is part of claim-status discipline. Grayscale elegance is not enough; hierarchy must match warrant (Crossref, 2025; Tabassi, 2023).

Figures about Artificial Intelligence require extra care. A diagram showing an AI tool assisting correction should visually subordinate the tool to human review. If the tool sits at the center and human reviewers sit at the margins, the artifact says the opposite of the prose. Readers learn from layout before they read sentences.

A figure should also have alt text that preserves claim status. Accessibility is not merely a technical requirement. An alt description that says “the model proves correction route” would be false even if the visible figure is careful. The alt text should describe the diagram as a workflow, candidate route, or boundary, not as validation.

Graphic review belongs in the same correction process because public artifacts are where a claim register often escapes its own limits. The figure is part of the argument. If it cannot carry its status safely, it should not carry the public.

28.6.5 — Artificial Intelligence Summaries and Withdrawal

Artificial-intelligence summaries become public artifacts when they repeat the project. Search snippets, assistant answers, autogenerated abstracts, and indexed summaries are corrected where possible through updated source pages, metadata, public notices, and visible superseded labels. Rapid model change makes source identity, retrieval date, prompt or instruction context, and human verification especially important (Committee on Publication Ethics, 2025; Crossref, 2025; Feuerriegel et al., 2026).

Withdrawal is sometimes necessary. A public graphic, excerpt, or page may be unsafe enough that correction is not sufficient. Withdrawal should be prompt, visible, and restrained. It should explain that the artifact has been removed from active use because it could mislead, overstate status, revive unsafe language, or conflict with an updated register. It should not dramatize the removal as catastrophe or victory.

Withdrawal should preserve audit memory. The artifact may remain internally archived with access controls and a notice. In some cases a public historical notice is appropriate. In others, the artifact may be too unsafe or legally sensitive to display. The key is that the withdrawal decision itself remains traceable. Future

readers should know that a correction occurred, even if the artifact is not reproduced.

Withdrawal should trigger search. If a figure was posted on a website, it may also appear in slides, donor decks, draft chapters, social excerpts, image folders, and archived pages. The propagation checklist should handle this. Otherwise the most dangerous version may survive in the least governed location (Tabassi, 2023; UNESCO, 2021a).

Withdrawal should not be confused with defeat. A graphic can be withdrawn because it compresses uncertainty poorly while the underlying component remains under study. Conversely, a scientifically defeated component may remain in a public failure-memory artifact because its defeat teaches the field. The withdrawal notice should state the reason so readers do not invent one.

Withdrawal should also include replacement planning when needed. If the removed artifact served an important educational role, the project should create a safer replacement rather than leaving a hole. The replacement should teach the corrected distinction, not merely repeat the old point with softer words.

This is the public form of claim register vulnerability. The project can say: we removed this because the way it traveled was not safe or accurate. That sentence is stronger than pretending the artifact never existed.

28.6.6 — Archive Memory and Public Correction Intake

An archive should distinguish current, corrected, superseded, and withdrawn artifacts and maintain stable correction pages with

date, version, affected objects, current wording, and access state. Prior language may remain visible as history but should not be confusable with current authority.

Metadata, redirects, preview cards, filenames, cached images, and other high-reach discovery surfaces are part of correction because they can continue to surface obsolete claims after a page changes (Committee on Publication Ethics, 2025; Crossref, 2025). Restricted artifacts may be listed without unrestricted download when participant, privacy, or misuse risks require it.

Public error intake should identify the artifact and problem type, protect privacy, acknowledge receipt without pre-judging correctness, and route science-status, safety, accessibility, hostile-crop, and version concerns to accountable review. A resolved report should point to the current artifact and explain the decision.

The archive provides a door for correction, not a mechanism for public vote on scientific status; review decisions and their reasons remain visible.

28.7 — Applied Evidence Intake and Future Testbeds

Applied settings can generate research questions about burden, feasibility, context, confounding, and measurement, but they do not become evidence testbeds merely because a City, public office, religious community, Workgame pilot, or ordinary-life practice already exists. Evidence begins only when a separate, ethical, prospectively specified design defines the object, consent route, context of use, estimand, measurement and observation processes, rivals, burden limits, and stop conditions. A living institution is not a laboratory by mere existence.

This distinction protects both science and applied domains. Science is protected from proof by institutional success. Applied domains are protected from becoming measurement traps, recruitment funnels, or public demonstrations staged for theory. The ordinary dignity of a person in a city, church, office, family, or transition pilot does not become evidence unless a legitimate research protocol exists and participation is voluntary, informed, minimized, and reviewable.

28.7.1 — Testbed Status

Testbed status means possible research context, not validation. Cities, government offices, religious settings, Workgame pilots, clinical systems, digital tools, and ordinary-life practices may produce questions, but evidence begins only when a separate study design is opened (National Institutes of Health, 2026a; National Institutes of Health, 2026b; Rieke et al., 2020).

Applied domains can notice patterns that matter. A city transparency process may reveal that people experience relief

when burden-routing becomes visible. A government office may discover that administrative delay carries a measurable stress load. A religious community may hear recurring pastoral language around repair and grief. A Workgame pilot may show that participants respond differently when failure memory is preserved rather than hidden. These observations can inspire research questions.

The question route should be explicit. An applied observation is written as a question, not a finding: does transparent administrative routing reduce reportable vigilance in this population; does correction visibility change trust under public uncertainty; does voluntary ritual language alter grief reports without changing scientific status beliefs; does preserved failure memory improve decision learning without increasing shame? The wording matters because it prevents the applied domain from speaking as if it already knows.

The observation should also name its confounds. In applied settings, relief may come from being heard, from faster service, from social belonging, from reduced cost, from expectation, from status, from novelty, from selection into participation, or from institutional attention. These are not nuisances to be brushed aside. They are rival explanations and design warnings (Tabassi, 2023).

Applied observations should not be harvested through ordinary participation without prior boundaries. A person entering an ordinary-life practice, City process, religious setting, or transition pilot should not later discover that their experience was treated as scientific evidence. Research begins when consent, purpose,

measurement, minimization, and withdrawal are declared. Before that, applied observations remain program learning, pastoral learning, design learning, or public-risk learning.

The research-question intake process should include negative observations. If a public artifact confuses readers, if a pilot creates measurement pressure, if a ritual phrase is heard as forced meaning, if an administrative tool begins to feel like a score, those failures are testbed signals. They may not test the Law directly, but they test whether public and applied surfaces are safe enough to host questions.

The value of applied observation is therefore real but bounded. It helps the science program ask better questions. It does not spare the science program from doing the work.

Table 28.7. Future-testbed evidence firewall.

Applied source	What it may generate	What it cannot become by default
Transparent City	Research questions about public burden routing, consent, and civic trust.	Evidence for terminal neutrality or proof of the formal Law.
Government office	Questions about administrative load, delay, error correction, and public records.	Scientific validation through service improvement.
Religious setting	Questions about meaning, grief language, ritual effects, and pastoral safety.	Scientific support through spiritual resonance.

Applied source	What it may generate	What it cannot become by default
Workgame or transition pilot	Questions about sequencing, failure memory, readiness, and rollback behavior.	Transition authorization or destiny.
Ordinary-life practice	N-of-1 questions, private reflection, and design insights.	Research evidence without consent and protocol.
Public artifact response	Public-risk signals and communication hypotheses.	A popularity or controversy metric for truth.

28.7.2 — Separate Consent and Data Doors

Separate consent and data doors keep service participation, spiritual practice, civic interaction, public administration, private reflection, research participation, archive storage, and model training from collapsing into one permission. Each door has its own purpose, risks, refusal rights, and governance (Rieke et al., 2020; Tabassi, 2023).

The future-testbed firewall has four gates: translate the applied observation into a research question; pass ethics, consent, and burden review; specify measurement, endpoint, context of use, rivals, and failure conditions; and enter results into the component evidence register under the same status rules as any other study. Skipping a gate turns operational coherence into overclaim.

Each applied domain contributes a distinct practical question. A Transparent City can reveal where public power shifts burdens; a government office can measure administrative load; a constitutional model can define lawful visibility; a religious

practice can support meaning; and a transition pilot can test sequencing.

Meaningful private practices can generate useful research questions about attention, ritual, apology, rest, service, and relationships. Participation in such research remains a voluntary choice, with consent and independent safeguards appropriate to the study (National Institutes of Health, 2026a; National Institutes of Health, 2026b).

Future testbeds should be context-of-use specific. A pattern in one city language community may not transport to another. A finding in one care regime may not travel to a workplace. A public artifact safe for academic readers may be unsafe for grieving families. The testbed question must name population, setting, language, authority relation, data source, intended inference, and prohibited inference.

The firewall includes a no-default-training rule. Applied-domain records, pastoral notes, ordinary-life reflections, government service records, and transition artifacts are not artificial-intelligence training corpora by default. Research access and model-training access require separate purpose, consent, governance, minimization, and review; the desire to learn does not create permission to absorb a life into a dataset.

The firewall makes future testbeds honorable. It lets applied worlds become sources of questions and confounds without becoming theaters of proof. It allows the series to learn from reality while refusing to convert participation into validation.

28.7.3 — Operational Success Is Not Validation

Operational success is not validation because a practice can help for ordinary reasons. Reduced complaint burden, better service timing, stronger ritual comfort, or improved user retention may matter deeply while remaining outside the scientific status of the formal Law (Tabassi, 2023).

A science correction may travel to applied domains, but it does not give the science body ownership over them. The City book owns voluntary bounded civic-public-power formation. The government book owns public administration. The constitutional book owns legal architecture. The religion volume owns optional doctrine and pastoral limits. The transition book owns sequencing and gates. The science book owns evidence status, not the total meaning of these domains.

Applied domains contribute questions and relevant observations through the research process. Independent scientific review determines evidence status, while each domain retains responsibility for its practical and interpretive decisions.

Handoffs identify the question or finding being transferred. An applied domain can describe an observation that suggests a scientific research question. A science update can identify which empirical statement should change in applied materials. Each handoff names the affected claim and leaves the receiving domain's other purposes and judgments clear.

Testbed review should identify when observation burden or consent conditions make a proposed question unsuitable for the

setting. It can then recommend a less burdensome design, another setting, or a documented decision to leave the question open.

Other observations may become design constraints rather than scientific claims. If a public artifact repeatedly misleads, the correction may be to redesign artifacts, not to update the Law. If a City protocol reduces administrative burden, the lesson may belong to government design, not terminal neutrality. If a religious phrase protects someone from forced meaning, the lesson may belong to pastoral language, not empirical validation.

Handoff without ownership transfer is the series operating at its best. Domains speak to one another without borrowing warrant. Science corrects what science owns. Applied life remains meaningful without becoming evidence by proximity.

28.7.4 — Negative Operational Findings

Negative operational findings deserve a route before they become scandal or silence. Increased stress, exclusion, dropout, privacy fear, staff burden, family pressure, or cultural mistrust can generate safety and research questions without being minimized to protect the theory (National Institutes of Health, 2026a; National Institutes of Health, 2026b).

Future testbeds must treat measurement as an intervention. Asking people to report, wear devices, consent to records, or become visible to researchers changes the setting. In a city office, a church, a game, a household, or a transition pilot, measurement can create compliance pressure even when participation is formally voluntary. The testbed route must therefore minimize cadence, data scope, identifiability, and downstream reuse.

Consent must be separated from access. A person may choose to use a service, attend a religious gathering, participate in a Workgame activity, or interact with a civic institution without consenting to research. Research consent requires separate explanation, refusal without penalty, withdrawal, data minimization, and purpose limits. A future testbed that blurs service and research converts ordinary life into a recruitment pool.

Burden monitoring should include staff and bystanders. A public office can become overloaded by study procedures. A family member can become a proxy reporter without clear consent. A facilitator can feel responsible for producing positive results. These loads are not merely operational. They can bias evidence and harm people. Testbed governance should track them as part of validity (Rieke et al., 2020; Tabassi, 2023).

Data minimization should begin before measurement design. The question should ask what data are truly needed to distinguish the hypothesis from rivals, and what data would merely be interesting. Interesting data are not justified by ambition. If an applied observation can be studied with less intrusive reports, synthetic fixtures, aggregate timing, or qualitative design, high-intensity telemetry may be unnecessary.

Participant return should be carefully bounded. Testbed participants may deserve to know what happened to the study without receiving personal scores or inner-life interpretations. Return materials should describe study status, aggregate findings, limitations, and corrections. They should not tell participants

what their ledger was, whether they balanced, or what their life meant.

Future testbeds can study practical *improvements* while protecting the people whose experience makes that research possible.

28.7.5 — Science Constrains Claims, Not Governance

Science constrains claims, not governance. A scientific result can limit what the series may say about evidence, but legal rights, civic design, religious practice, material policy, and transition gates remain governed by their proper books and institutions.

An applied-domain failure can be scientifically valuable without being evidence for the Law. If a public artifact creates confusion, the failure informs communication design. If a City process produces distrust because records feel like surveillance, the failure informs consent and record boundaries. If a religious phrase is heard as forced meaning, the failure informs pastoral language. If a Workgame pilot makes readiness feel like ranking, the failure informs transition gating.

These failures should be logged in a testbed incident register. The register should state the domain, artifact or practice, observed failure, affected population, immediate mitigation, research question generated, and whether scientific evidence status is affected. Most applied failures will not directly change the Law's empirical status. They will change public-risk controls and research design.

Applied failure can also reveal confounds. A study planned in a civic setting may discover that changes in reported burden are

driven by caseworker kindness, speed of service, or relief from paperwork rather than by any Law-specific mechanism. That is useful. It helps build better rivals and prevents the project from claiming credit for ordinary humane administration (Tabassi, 2023).

Failure in applied domains should not be hidden to protect the image of the series. A public theory about fairness becomes untrustworthy if it cannot admit when its own surfaces shifted burden. The applied incident register is not a scandal list; it is a learning system. It keeps the burden of public experimentation inside the record.

Some applied failures may require scientific status holds. If a public artifact strongly misleads readers about a scientific claim, the artifact's status must change even if the underlying science remains open. If an applied pilot generates coercive measurement pressure, research using that context should pause. Applied failure can therefore affect the conditions under which science may proceed.

The positive rule is this: failure travels to the route it belongs to. Communication failure travels to artifacts. Governance failure travels to applied design. Measurement failure travels to science. Root conflict travels to the formal root. The project becomes safer when failures are not forced into the wrong category.

28.7.6 — Transition Timing Remains Separate

Transition timing stays separate because readiness is not a laboratory output. Even strong evidence cannot authorize rollout, artifact release, Workgame scaling, political movement, or public

transition without independent gates, rollback, refusal rights, and timing control.

The route from observed practice to research protocol should protect people while preserving learning. First record the observation without evidentiary status; list confounds and ethical risks; turn the question into an estimand or qualitative aim; and specify consent, measurement, rivals, burden, and stop conditions. Only then may the study become protocol-fixed or publicly preregistered through an external registry with a persistent identifier.

Protocols should declare what each context adds and prevents. City settings may add ecological validity and public-power relevance but complicate consent and authority; religious settings may enrich language but introduce belief and belonging effects; Workgame settings may structure choices but create performance pressure. These are design features, not afterthoughts.

The protocol should avoid demonstration design. Demonstration design begins with institutional hope and gathers favorable impressions; science begins with a question that can lose. The protocol names rivals, negative controls, nonresponse, public-risk boundaries, and results requiring route suspension. A testbed unable to produce an adverse result is a demonstration, not a discriminating evaluation. Program evaluation can itself test specified outcomes and report failure; a PTVC test additionally needs the target, measurement, and comparison requirements stated here (National Institutes of Health, 2026a; National Institutes of Health, 2026b).

Prospective public-communication rules belong in the study record. Before results, the applied domain may say only that the setting generates questions, the design is prospective, participation is voluntary, results may be negative, and public status awaits review. Public preregistration may be claimed only with an external registry record and persistent identifier.

A good future-testbed protocol lets applied life inform science without using lives as proof; it is neither shy nor extractive.

28.8 — No Formula, Score, or AI Sovereignty

Scientific governance uses formulas, code, dashboards, registries, archives, and artificial-intelligence systems as accountable tools. They can calculate, search, reproduce, compare, flag, and summarize within declared limits. They cannot decide truth, personhood, worth, care, eligibility, spiritual meaning, claim status, or acceptable risk; those judgments remain with identifiable human authorities.

Formula sovereignty is the error of letting mathematical elegance decide what evidence has not established. Artificial-intelligence sovereignty is the error of letting system output decide what accountable humans must judge. Both errors can appear modern, efficient, and impartial; both are dangerous when the project concerns conscious life, public meaning, scientific status, spiritual interpretation, legal imagination, and transition risk.

This is not an anti-technology rule. The science volume should use computation seriously. It should use model recovery, simulations, version control, provenance, automated tests, accessibility audits, plagiarism checks, contradiction search, and reproducible containers. The point is to keep every tool inside its lane. A useful tool produces evidence support, warnings, drafts, comparisons, or diagnostics. It does not own the decision.

28.8.1 — No Claim-Status Equation

No claim-status equation means a formula may summarize fields but may not decide truth. Replication count, heterogeneity, prediction score, safety incidents, dissent, and public risk are not

compensatory inputs that can be collapsed into one authority number (Tabassi, 2023; UNESCO, 2021b).

Search is one bounded use of Artificial Intelligence. A tool may locate contradictions, summarize candidate literature, compare chapters with claim-status registers, or flag old-language residue, but its output remains a lead requiring source verification and human judgment.

Code generation and static analysis are another bounded use. Tools may draft tests, generate fixtures, inspect containers, or propose metadata checks, yet human code review, independent execution, provenance, and benchmark comparison remain necessary before any result enters the evidence record.

Drafting and language review are a third bounded use. Tools may propose phrasing, detect repetition, or flag apparent overclaim, but final manuscript copy, artifact language, and correction notices require accountable human editorial and scientific responsibility (Council for International Organizations of Medical Sciences, 2016).

Automated systems may assist monitoring. They can flag outdated version references, broken artifact links, inconsistent status labels, missing alt text, uncorrected captions, and code-container mismatches. These monitors are useful because the series is large. Their alerts should create review tickets. Their silence should not be interpreted as assurance.

Formulas may assist classification only under declared scope. A decision aid can display thresholds, checklist satisfaction, dependency status, or model-comparison results. It should show

inputs, assumptions, uncertainty, and abstention. It should never output a final controlled scientific verdict without human review. The output should be phrased as “review indicated,” not “truth determined.”

Permitted assistance is powerful precisely because it remains subordinate. The project should not reject tools out of fear. It should use them under provenance, audit, and limited authority so that computational strength increases human accountability rather than replacing it.

Table 28.8. Formula and Artificial Intelligence authority boundary.

Tool use	Permitted role	Forbidden role
Automated literature search	Find candidate sources, contradictions, and missing rival language.	Declare completeness, truth, or consensus.
Language model drafting	Suggest wording, detect repetition, propose summaries under review.	Approve manuscript copy, public status, or canon.
Statistical dashboard	Display diagnostics, uncertainty, dependencies, and abstention flags.	Issue final discovery, defeat, or transition authorization.
Model-recovery pipeline	Compare candidate and rival generators under declared conditions.	Treat construction or fit as evidence for the formal Law by itself.
Archive system	Preserve versions, corrections, failures, and provenance with access controls.	Represent the person, soul, worth, or final inner life.

Tool use	Permitted role	Forbidden role
Formal equation	State a definition, candidate realization, estimator, diagnostic, or decision aid under status label.	Become proof, moral permission, clinical instruction, or public score.

28.8.2 — No Dashboard Authority

No dashboard authority means a visualization organizes evidence for review but does not deliver the verdict. Layout, color, rank order, thresholds, filters, and summary panels are audited so the dashboard does not silently decide what human reviewers later rubber-stamp (UNESCO, 2021b).

No formula may decide personhood. Bearer classification, consciousness uncertainty, artificial-system evidence, nonhuman extension, and boundary-state humility remain expert-governed scientific and ethical questions. A classifier may provide evidence support or a risk flag. It may not declare a being a bearer or non-bearer as public authority.

Apply the non-deployment rule in §9.7 to every dashboard and computational output surface. No display, threshold, rank order, or derived score acquires authority over persons, communities, countries, religions, institutions, or readiness.

No artificial-intelligence system may adjudicate the claim register. It may propose a change request, draft compatibility tables, detect stale artifacts, and summarize dissent. It may not approve the change, close dissent, decide the root handoff, or declare that public status has moved. Approval belongs to a human-governed scientific process with visible responsibility

(Council for International Organizations of Medical Sciences, 2016; Tabassi, 2023; Feuerriegel et al., 2026).

No software system may convert future-testbed observations into evidence by default. A dashboard may organize questions, flag confounds, and track whether a study is protocol-fixed or publicly preregistered. Evidence status still requires the scientific route, adequate measurement, serious rivals, and accountable human review rather than data abundance.

No archive may be treated as a soul or final truth repository. An archive can preserve records, versions, artifacts, corrections, and failures. It cannot preserve the person. It cannot judge consciousness. It cannot authorize care decisions. It cannot become a public dossier. Its role is memory with limits.

Computational outputs remain purpose-limited, reviewable, contestable, and revocable. Scientific status decisions follow the designated human review process across political, donor, institutional, religious, and transition settings.

28.8.3 — No Model-Generated Consensus

No model-generated consensus means artificial intelligence may summarize positions but may not smooth disagreement into agreement. Dissent, unresolved rivals, minority reports, and adverse findings remain visible even when a model can produce fluent prose that sounds balanced. Human review preserves the scientific cost of disagreement rather than translating it into synthetic harmony (Autio et al., 2024; World Health Organization, 2025; Council for International Organizations of Medical Sciences, 2016).

The authority boundary can be stated compactly. Tools generate support. Humans judge status. Formal root changes return to *The Law of Fairness*. Scientific evidence status belongs to *The Science of Fairness*. Applied books receive corrected status within their own domains. Public artifacts carry only the claim their source permits. No surface receives more authority than the route that produced it.

The boundary must be visible in practice. Every artificial-intelligence-assisted change request includes provenance; every automated audit states what it can and cannot detect; every formulaic decision aid includes abstention and human-review fields; every model card identifies prohibited uses; and every public artifact remains correctable. Current governance and reporting guidance supports documented evaluation, model and configuration disclosure, human accountability, risk management, and contestability, but no framework can confer scientific or personal authority on automated output (Tabassi, 2023; Autio et al., 2024; World Health Organization, 2025; Feuerriegel et al., 2026).

This boundary also protects artificial-intelligence systems from being turned into scapegoats. If a model writes a misleading sentence and humans publish it, the responsibility is human. If an automated dashboard overstates status and humans deploy it, the responsibility is human. Tool use does not erase accountability; it makes provenance, evaluation, and contestability more necessary (Tabassi, 2023; Autio et al., 2024; UNESCO, 2021b; World Health Organization, 2025).

The same boundary protects the project from fake humility. It is not enough to say that tools are imperfect. The document must specify where they stop. A tool stops before personhood. It stops before truth. It stops before status. It stops before claim register. It stops before care. It stops before public authority. Those stops are not rhetorical; they are workflow permissions.

A scientific claim system becomes trustworthy when it can be corrected without becoming ownerless. Human-governed updates, versioned registers, dissent, appeal, formal change requests, root handoff, correction propagation, public-artifact control, future-testbed firewalls, and no tool sovereignty form the route. The result is not a perfect system. It is a system that lets imperfection surface before it becomes doctrine.

The final safeguard is not a sentence but a habit. Whenever a result, model, or tool appears to make the Law easier to believe, the project asks what route gave it that authority, what component it touches, what public surface it affects, what dissent remains, what failure memory it creates, and what would make it lose. That habit is the science book's contribution to the active claim register: vulnerability made operational.

28.8.4 — Human Review, Dissent, and Appeal

Human review, dissent, and appeal keep responsibility traceable. People sign the decision, record reasons, disclose conflicts, preserve minority reports, and accept appeal; the presence of computational support never removes the human duty to answer for the update (Council for International Organizations of Medical Sciences, 2016; Tabassi, 2023).

Every substantial tool-assisted decision should leave a tool-use record. The record should state the tool, version if known, input class, output class, human reviewer, permitted use, and rejected use. If a language model helped draft a correction notice, the record should say that. If a static analyzer found stale version strings, the record should say that. If a simulation tool generated benchmark results, the record should say the container and seed policy.

Tool-use records prevent both mystification and scapegoating. The project should not pretend that a human alone did work a tool assisted. It should also not blame a tool for a human decision to publish, approve, or ignore. Provenance lets future reviewers ask whether the tool was appropriate and whether human review was adequate.

Audit includes hallucination, omission, compression, and configuration risk for language tools. A system can invent sources, flatten branch distinctions, omit adverse evidence, merge versions, or change output after an update. Review therefore records model identity, version, access date, instructions, tool settings, source set, generated output, human verification, and rejected material when those details affect the scientific record (Feuerriegel et al., 2026).

Audit should include leakage risk. Tool inputs may include sensitive draft material, participant information, restricted records, or unpublished protocols. The default should be local, controlled, or redacted use unless governance approves otherwise. Convenience cannot override privacy, consent, or

publication control. A tool that improves drafting but leaks restricted context is not acceptable.

Tool auditing is not anti-innovation. It is how the project can use powerful assistance without letting assistance become authority.

28.8.5 — Audit of Automation Bias

Audit of automation bias tests whether reviewers overdefer to technical outputs. The system looks for anchoring, confidence-label effects, interface-driven ranking, selective summarization, prompt framing, and quiet replacement of judgment by tool convenience (Tabassi, 2023; UNESCO, 2021b).

The sovereignty loophole appears when the project says no tool has authority, but then structures workflows so that humans merely ratify tool outputs. If a dashboard selects the status, a language model drafts the public wording, a model chooses the route, and reviewers approve by inertia, the tool has become de facto sovereign. The workflow must force human reasons independent of the output.

One protection is independent human justification. A reviewer should state why the decision is correct in ordinary language, naming the source, evidence, scope, and public consequence. The tool output may be attached, but it cannot be the reason. If the reviewer cannot explain the decision without the tool, the decision is not ready.

Adversarial tool review supplies another safeguard. A second reviewer or system can search for overclaim, stale versions, conflicting artifacts, excluded rivals, root-handoff triggers, and public-risk hazards that the first pass missed. The goal is

complementary scrutiny, not a contest among tools, and no fluent pipeline should become invisible infrastructure (Council for International Organizations of Medical Sciences, 2016).

A third protection is abstention. If the evidence is too ambiguous, the tool should not be forced to classify. If the public wording cannot be made safe at the required compression level, the artifact should not be released. If the register cannot resolve whether a change is root-level or science-level, the route should hold. Sovereignty often enters through the refusal to abstain.

The final protection is revocability. Tool-assisted decisions must be correctable. If later review finds that an artificial-intelligence summary omitted a fatal caveat, the correction route should mark the affected decision and propagate changes. Tool assistance does not create a privileged shield against revision.

Closing the loophole means the project does more than say humans decide. It designs workflows so that humans actually carry the reason, the uncertainty, the correction, and the cost.

28.8.6 — Public Language of Responsibility

Every controlled scientific update should identify the accountable human role or roles, reviewed object, status, scope, uncertainty, conflicts, and current version. Signatures record responsibility and relevant expertise, not prestige (Council for International Organizations of Medical Sciences, 2016; Tabassi, 2023).

When software or artificial intelligence assisted, record its bounded task and version and what humans verified or rejected; authority remains with the reviewers (Tabassi, 2023; Autio et al., 2024; World Health Organization, 2025; Feuerriegel et al., 2026).

Correction notices should state the practical action for readers: use the new version, do not use the old artifact, treat the evidence as narrowed, await review, or recognize that a component has retired. Where a formula or model informed the change, state the local calculation it supported rather than allowing a local diagnostic to become a global adjudicator.

Applied domains may retain independent local value after a scientific correction, but they do not inherit stronger scientific warrant. Older copies remain historical and should point to the current status where feasible.

Chapter 29 — The Open, Staged Research Program

A final science chapter turns formal precision, extensive sources, and careful protocols into an ordered program of discovery. The remaining problems identify the next theorem, measurement, comparison, and humane study that could move the field forward (Fenwick et al., 2020; Skivington et al., 2021). The useful unit of progress is therefore not another topic added to the agenda, but an open question whose resolution would change a later scientific decision.

The preceding Parts now form a research dependency map: define the target, qualify its estimators, identify endpoints independently of the tested residual, specify candidate dynamics, compare explanations, and report the resulting evidence clearly. The map also shows which tasks can proceed in parallel because they do not depend on one another, preventing one unresolved branch from unnecessarily freezing independent work elsewhere in the program.

The practical questions are concrete. Which theorem or counterexample comes first? Which instrument requires qualification? Which simulation gate must pass before human inference? Which study can begin at low burden, which clinical work must wait, and which failure closes the line? A methodologist, ethics board, funder, laboratory, clinician, participant advocate, and critic should all be able to locate their decision. Those roles are complementary rather than interchangeable: resources, clinical access, methodological review, and participant protection cannot substitute for one another's gate.

Stronger terminal claims depend on a model that preserves the hypothesis specified here, qualified representation and measurement, and endpoint and rival designs capable of discrimination within approved burden limits. Each dependency has a stop condition. Terminal work follows the lower-burden formal, measurement, state-classification, and recovery gates. A terminal proposal should therefore identify the earliest unresolved prerequisite on which its interpretation depends; until that prerequisite is resolved, the proposal remains downstream work rather than a reason to bypass the gate.

Ownership remains clear at the handoff. *The Law of Fairness* retains the formal root; *The Science of Fairness* owns protocols, evidence, replication, and scientific verdicts; applied titles may contribute contexts and questions; *The Transition of Fairness* owns sequencing only after its independent authority gates are met. No local success borrows warrant from another domain.

The roadmap proceeds from open theorems and identification through instrument qualification, synthetic recovery, low-burden studies, endpoint methods, multisite replication, and only then stronger terminal tests. Movement is triggered by passed dependencies, not elapsed time; each stage has an owner, output, release consequence, and stop condition. For example, a simulation that shows two routes are indistinguishable can redirect instrument development toward the observation on which their predictions actually diverge.

Each verdict directs the next action: support can justify replication, narrowing a smaller test, No adequate estimate renewed identification work, and Rival-favored further study of

the winning explanation. Defeat can close the strong branch while preserving failure memory. Institutional review should track null-result release, rival investment, correction latency, and stop decisions alongside favorable outputs. Recording the expected consequence of a decision makes it possible to check later whether research investment addressed the uncertainty that originally justified it.

The final chapter treats science as a public trust. It identifies what can be proved, measured, simulated, studied, released, restricted, corrected, redesigned, or abandoned. The volume closes with a program whose ambition is governed by care, independent criticism, evidence, and an executable ability to stop. That stopping capacity is not merely defensive; it preserves resources and credibility for questions that remain genuinely open. That shared structure gives contributors from different disciplines a practical way to work on separate questions while producing results that can be combined coherently.

29.1 — Scientific Case and Dependency Map

The scientific case is a dependency map, not an argument by accumulation. Formal coherence, representation, measurement, endpoint construction, recoverability, rival discrimination, replication, transport, and ethical feasibility are separate gates; a stronger sentence becomes available only when every dependency on its route has passed.

The final map should therefore show both connection and failure: which statement concerns the formal object, measurement relation, endpoint method, candidate mechanism, model comparison, or public verdict, and where that route can break. A good map leaves skeptics precise targets rather than a diffuse program.

Table 29.1. One-view component map for the open scientific program.

Component	Near-term task	Result that changes status
Formal hypothesis	Clarify bridge, origin, endpoint, and reserve assumptions	A proved bridge, a separation theorem, or a formal amendment request changes only the formal component.
Measurement stack	Qualify contexts of use for the candidate momentary-valence and interval-contribution estimators under disability, medication, culture, and missingness	Stable calibration or failure updates measurement status before any terminal inference.

Component	Near-term task	Result that changes status
Endpoint discipline	Prospective consciousness-state and stopping-rule validation	Endpoint independence survives or terminal claims pause.
Rival comparison	Synthetic and held-out model recovery across bridges, frailty, safe control, and observation shutdown	If rivals dominate, Law-specific language narrows or retires.
Replication and verdicts	Multisite and adversarial replication with public correction rules	Support, narrowing, inconclusive evidence, or defeat attach to components rather than the whole program.

29.1.1 — The Received Hypothesis

The received hypothesis is exact in its latent form and cautious in its public form. It concerns a qualifying unified conscious stream, a latent phenomenological ledger, and a terminal boundary condition. The final chapter must therefore restate the hypothesis without turning a formal target into an empirical finding.

The strong form asks whether terminal neutrality belongs to the structure of the stream rather than to a moral accounting system. Its precision is the reason it can be criticized. A vague tendency toward balance would be easier to defend, but it would also be less scientific.

The public program does not begin by observing the latent equality directly. It begins by asking whether measurable

consequence structures appear under independently defined endpoints, explicit observation models, and strong rival comparison. That difference remains the central claim-status firewall of the research program.

The near-term empirical object is not a human soul, a moral score, or a complete life narrative. It is a set of structured predictions about measured dynamics, such as preterminal variance behavior, endpoint windows, reserve-linked signatures, and model-discriminating patterns that can fail (Manski, 2003; Gelman et al., 2020).

The practical record should name this status at every public handoff. A slide, abstract, protocol, or interview may summarize the hypothesis, but it should not compress strong latent closure and public empirical testing into one sentence of certainty. The most dangerous error is not skepticism; it is the friendly shorthand that turns a precise target into an announced discovery.

The hypothesis creates connected research tasks: develop the valence representation, identify its origin, qualify endpoint methods, test candidate dynamics, and compare their explanatory performance.

The final program connects the exact hypothesis to a sequence of empirical comparisons. Future work should identify which components receive support, which require refinement, and which should be retired. That record makes cumulative progress visible.

29.1.2 — Why the Program Is Scientifically Interesting

The program now has a concrete empirical starting point. Experience-sampling studies identify mood-dependent activity choice; laboratory and smartphone studies quantify how expectations and reward outcomes shape reported happiness; cross-modal neural work identifies shared as well as modality-specific affective structure; and engineered biological circuits demonstrate robust integral feedback (Taquet et al., 2016; Rutledge et al., 2014; Chikazoe et al., 2014; Aoki et al., 2019). Lifespan and comparative studies add structured variation in emotional experience and fairness judgments (Carstensen et al., 2011; Blake et al., 2015).

Together, these findings motivate a connected research program. Experience has measurable temporal structure, organisms regulate over time, biological control can represent history, and future opportunity can shape behavior (Fung et al., 1999). A specified PTVC model can bring those components into a joint quantitative account and test the relationships it predicts.

The most informative candidate would derive several outcomes from one completion relation: future signed increments, response timing, action probabilities where an action-mediated route is proposed, and endpoint-support behavior. A reserve-coupled realization would also specify its resource variables and their relation to the proposed dynamics. Simulations would first establish model recovery through the full measurement and observation process. Parameters and measurement relations would then be trained without confirmatory endpoint outcomes and tested across new people, conditions, horizons, and

laboratories. A coherent pattern that transfers with fewer independently tuned relations could offer explanatory economy as well as predictive gain, evaluated for the complete model.

Cumulative history creates two useful comparisons. A cumulative variable may improve prediction beyond current mood and a limited recent-event model. When a flexible rival already receives the same full history, the potential gain is an efficient, transferable representation of that history. Giving both models the same observations and comparable tuning budgets makes these gains interpretable.

The combined evidence can be analyzed jointly, accounting for shared participants, instruments, analysis choices, biological pathways, and cultural ancestry. Cross-modal or cross-species relationships become especially informative when they survive prespecified transformations and improve predictions evaluated on new observations. This offers a practical way to turn recurring patterns into a demanding comparison of explanations.

The research also has benefits at intermediate stages. Better within-person affect measurement, accurate recognition of retained conscious capacities, humane longitudinal observation, and more discriminating dynamic models would each contribute useful knowledge. Researchers can begin with existing records, benign calibration, and fully disclosed benchmarks. The opportunity is substantial: connect established findings through precise predictions and give independent laboratories a clear, worthwhile program to investigate.

29.1.3 — The Most Testable Near-Term Claims

The most testable claims are the ones that do not require observing an entire life or administering a terminal verdict. Early work should focus on representation, sign, context of use, model recovery, and preterminal dynamics in bounded settings where the observation process can be audited (Manski, 2003; Gelman et al., 2020).

Section 29.4.1 develops two early examples: a benign horizon/scheduling-route task and a sleep/affective-reprocessing study. Both illustrate the near-term rule: choose bounded studies that can separate candidate structure from ordinary urgency, scarcity, memory, mood inertia, and regulation before clinical escalation.

A longitudinal ordinary-life calibration cohort can test whether active reports, passive signals, clinical context, and relational events can be fused without erasing disability, culture, medication, and missingness. It is a measurement study before it is a Law study.

Near-term studies place questions where an informative answer is attainable. Their protocols specify the consequences of each result, including channel revision or retirement, changes to sign assumptions, and the context of use supported by calibration.

A consciousness and endpoint method study can test whether state classification and endpoint windows can be defined prospectively without using ledger estimates. If this cannot be done, terminal inference should stop before it reaches vulnerable settings.

The first terminal dynamics pilot is therefore not first in the literal sequence. It becomes scientifically admissible only after representation, momentary-valence estimator qualification, endpoint independence, and model-recovery benchmarks have enough credibility to make the clinical burden justified.

The near-term portfolio should therefore privilege claims that can fail cleanly: representation stability, origin calibration, instrument recovery, endpoint classification, and rival separability. Success at those gates earns the next question; failure saves the program from an expensive and ambiguous test.

29.1.4 — The Strongest Rivals

The rival architecture is already developed in Parts VI and VII. For the final roadmap, the governing requirement is equal-rule generative comparison: adaptation, homeostasis, predictive and safe-control accounts, conditioned bridges, clinical and treatment processes, selection, population composition, and observation artifacts must share the relevant observation and endpoint uncertainties and must be allowed to win (Gelman et al., 2020).

Before a confirmatory protocol launches, publish the rival families, parameter freedom, shared observation model, and held-out win conditions. A rival omitted from the benchmark is not defeated, and a simpler rival that wins receives the scientific status earned by the evidence.

29.1.5 — What Would Change the Case

The case changes only when evidence attaches to a specified component. Representation evidence changes representation status. Endpoint evidence changes endpoint status. Model-

recovery evidence changes design readiness. Replication evidence changes transport confidence. No result should change more than its design can support.

A strong early result would not be a declaration that the Law is true. It might show that a physiological estimator has a stable context of use, that a horizon task separates scarcity from candidate scheduling pressure, or that a synthetic benchmark can distinguish reserve-coupled candidates from bridges under realistic missingness.

Qualification findings guide the timing of later terminal studies. Unresolved sign, instrument transfer, endpoint independence, or model recovery pauses the dependent analysis and identifies the work needed before it resumes.

A mixed result should produce a smaller map, not a confused headline. A mechanism might retire while the measurement program remains useful. A reference class might narrow while the formal problem remains open. A rival might dominate one signature while leaving another undecided (Manski, 2003; Gelman et al., 2020).

The change record should also preserve timing. A result that looked strong before a bridge failure may become historically important but no longer status-bearing. A result that survives a later amendment may need reanalysis rather than inheritance. Scientific memory should protect both the excitement of discovery and the humility of versioned correction.

Public wording must change whenever the component status changes. Words such as discovery, support, narrowing,

inconclusive, unusable, retired, rival-dominant, and defeated should not float above the evidence. They should be tied to a versioned claim, a population, an instrument, and a comparison set.

The case changes most honorably when it becomes easier to state. A result that forces the program to say less, more exactly, may strengthen science even if it weakens the public story.

What changes the case is not accumulated enthusiasm but an evidence-bearing dependency transition. A frozen component passes or fails a protocol-fixed test, a rival becomes more or less adequate, or a reference class narrows; the case changes only by that amount.

29.1.6 — Next Measurement Priorities

The next measurement priorities are a stable valence scale, an empirically anchored origin, longitudinal coverage, and a workable endpoint method. Reserve-based models add the task of identifying and calibrating their resource variables (Manski, 2003).

Extensions to children, nonhuman animals, artificial systems, additional cultural settings, sudden death, coma, dementia, and altered states each create specific bearer-classification and measurement questions. Targeted studies can establish the conditions for those extensions.

Figures, tables, equations, and pipelines organize the work and identify stopping conditions. Their conclusions depend on whether the assumptions survive testing.

Timelines map dependencies. Evidence may shorten a ten-year plan, measurement difficulties may slow it, ethics review may pause it, and a stronger rival may redirect it (Gelman et al., 2020).

Public summaries should pair proposed signatures with open questions about whole-life initial state, origin identification, scalarization, endpoint independence, and cross-species transport. This makes the research agenda accessible beyond the technical chapters.

Applied domains offer varied settings for new questions. City experiments, government observations, religious practices, Workgame dynamics, and ordinary-life reflections can reveal patterns worth studying. Researchers can translate those observations into defined variables, competing predictions, and prospective tests.

An explicit map of open questions keeps the program testable and guides future science.

29.2 — Open Theorems and Formal Verification

Some questions cannot be solved by collecting more data because the target, bridge, or entailment is not yet identified. Open theorems, counterexamples, and formal verification therefore sit on the critical path. They determine whether an attractive construction actually reaches the received claim or merely resembles it.

Open theorems are not ceremonial humility. They are obligations that prevent attractive simulations from being confused with evidence. A model can be implemented, fit, and visualized while still failing to connect to the received latent claim.

The final chapter therefore gives formal problems their own place. They are tasks for mathematicians, statisticians, philosophers of measurement, consciousness theorists, and modelers who are willing to sharpen or break the theory before public language becomes stronger.

Formal work also governs public diagrams. When a figure makes a product-process realization look identical to the received ledger, that equivalence requires a theorem; otherwise the caption identifies it as a candidate bridge. Open mathematical problems therefore have direct consequences for talks, figures, and public summaries.

These problems receive named expert lanes rather than remaining philosophical atmosphere. A theorem register identifies the competence required for review, the artifact that would count as progress, the counterexample that would close the route, and the

public wording that remains unavailable until the obligation is resolved.

The theorem register remains open after publication. Some tasks may be solved, some shown impossible, and some converted into formal amendment candidates. The public record must distinguish solved, open, impossible, superseded, and revised rather than treating every item as inspiration.

29.2.1 — Integral–Product Bridge

The integral-product bridge remains open. Section 7.8.1 states the formal mismatch between the received ledger and the reserve-coupled product. The next deliverable is a theorem or bounded approximation specifying when the product preserves the ledger's domain, increments, initial conditions, endpoint semantics, and relevant transformation class, with its filtration, state variables, reserve process, and observation relation explicit. A separation result should identify when it does not. Empirical use of route coordinates for the terminal phenomenal target should follow that relation or state explicitly which weaker property is being tested (Oberkampff & Trucano, 2002; Oreskes et al., 1994).

29.2.2 — Origin and Representation

A ledger requires more than signed feelings. It requires a representation in which differences, accumulation, and neutrality have scientific meaning. The origin problem asks which evidence and assumptions can identify the relevant neutral point (Krantz et al., 1971; Luce & Tukey, 1964).

The representation problem is not solved by better sensors alone. Even perfect physiological signals would not create a natural unit

of felt valence by themselves. The program must justify which transformations preserve the scientific claim and which transformations change it.

A frozen potential model makes origin calibration an explicit identification problem. Let y contain integrated readings on one provisional cardinal scale, τ their independently qualified exposures, and B the incidence matrix of the fixed state graph. A common rate-origin offset o gives $y = o\tau - B^T\varphi + \varepsilon$. Choose a full-row-rank matrix C spanning the cycle space and write $g = Cy$ and $d = C\tau$. Eliminating the potential gives $g = od + C\varepsilon$. In the noiseless model, o is identified exactly when $d \neq 0$; a tree supplies no cycle constraint.

For centered errors with a fixed positive-definite cycle covariance V and known d , the generalized least-squares estimate is

$$\hat{o} = \frac{d^T V^{-1} g}{d^T V^{-1} d}.$$

Its denominator measures information, so a nonzero but weak duration direction can still yield poor precision. Additional declared nuisance patterns must be removed before assessing rank and information. Noisy exposures, shared edges and uncertain state membership require joint inference. One fitted independent cycle calibrates an origin without testing that calibration; further independent constraints provide overidentification and should include held-out paths.

The cross-sign unit assumption can also be tested within a specified two-channel model. Let P and N be independently defined operational magnitude channels associated with positive

and negative experience; both may be active during a mixed state, and their interpretation remains to be qualified. Write the candidate edge contribution as $aP - bN - o\tau$ with $a, b > 0$. Division by a gives $CP = rCN + \kappa C\tau$, where $r = b/a$ and $\kappa = o/a$. The two parameters are identified only when $[CN, C\tau]$ has rank two; further independent cycles test the relation. Both exercises remain conditional on the proposed potential and observation maps. Agreement with independent sign and scale calibration would strengthen their phenomenal interpretation.

The open theorem here concerns admissible scales. If only ordinal comparisons are meaningful, then additive ledger claims weaken. If interval structure can be justified locally but not globally, then interpretations of the candidate interval contribution estimate and claims of terminal neutrality must narrow by context of use.

The neutral origin must also be distinguished from comfort, silence, absence of report, low arousal, or social compliance. A person who cannot speak, a person who is sedated, and a person who is culturally trained to minimize distress do not create the same origin by producing low observed signal.

This problem also shapes the first-study portfolio. A representation task should not ask participants to confirm a theory; it should expose where different reporting modes, bodily states, and temporal framings produce incompatible origins. The failed origin is not a participant failure. It is a scientific boundary that protects the person from being reduced to a bad scale.

Formal work should produce representation tests that ordinary studies can implement. These tests might compare invariance

under language, disability, medication, developmental state, and within-person calibration rather than assuming all streams inhabit one scalar scale.

If no suitable origin or representation is found, the program should not rescue the strong form by changing the ledger into a metaphor. It should record a representation failure and preserve whatever narrower affective-science results remain.

Progress here means reducing the admissible representation class without choosing it from the completed outcome. A valid result would either identify the origin and sign structure under independent calibration or show that the scalar branch is not presently adjudicable.

29.2.3 — Endpoint–Reserve Synchronization

The endpoint and the reserve variable must not define each other. The endpoint must be established through consciousness-related stopping rules that are not algebraically identical to the ledger estimate. Reserve may approach a limiting condition, but it cannot be used as a disguised ledger clock.

The open problem is synchronization without tautology. If the model needs reserve to decline toward zero near the independently defined endpoint, it must state why that relation should hold, how wide the mismatch can be, and what happens when reserve rebounds, jumps, or is externally supported.

Clinical reality makes this difficult. Ventilation, sedation, analgesia, delirium, infection, organ failure, device support, and sudden events can alter reserve proxies without cleanly

corresponding to consciousness termination. A model that ignores these cases will be fragile exactly where the claim matters most.

A useful theorem would characterize classes of reserve processes and endpoint rules that preserve non-tautological prediction. It would also identify cases where endpoint selection creates apparent closure even when no Law-specific dynamics exist.

Synchronization should be evaluated under counterexamples as well as favorable cases. Sudden death, temporary clinical rescue, palliative sedation, fluctuating delirium, and device-supported survival all test whether reserve and endpoint are being related by biology or by narrative convenience. A theorem that works only in smooth stories is not ready for terminal science.

The theorem should produce empirical design rules. Endpoint adjudication must be prospectively specified, reserve proxies versioned, and desynchronization between reserve and endpoint clocks reported rather than hidden as noise.

Terminal analyses proceed when synchronization studies establish the endpoint-reserve relation under the intended observation conditions. Where that relation remains unresolved, the program can continue studying preterminal regulation as its own specified target.

The theorem target should separate genuine state-coupled synchronization from retrospective alignment. Its value is practical: it tells protocol designers which timing relations can be tested and which apparent completions are mathematical artifacts.

29.2.4 — Closure Modes and Random Endpoints

Closure can mean several different mathematical things. It may mean almost-sure latent equality in an idealized process, equivalence-band concentration in measured estimators, convergence in probability, bounded terminal error, or pathwise compression under a shrinking reserve. These are not the same claim (Kallenberg, 2002).

Random endpoints complicate the problem. A stopping time can condition observed paths, select survivors, truncate data, or change the distribution of what is observed near the boundary. A closure theorem must separate genuine dynamics from the statistical effects of stopping.

A taxonomy of closure modes helps organize terminal results. Because several mechanisms can produce a measured equivalence window, the analysis specifies the observation model, endpoint rule, and rival matrix. Their joint predictions identify which comparisons can distinguish the candidate explanations.

The Brownian bridge and Doob-transform rivals belong inside the formal problem. They show how endpoint conditioning can create apparent movement toward a boundary. Any claimed closure mode must be compared with these conditioning mechanisms under the same observation constraints (Doob, 1957; Revuz & Yor, 1999).

Published examples should include cases in which closure modes agree and cases in which they diverge. They must show how equivalence-band neutrality can occur without exact latent

closure, how terminal concentration can arise through selection, and why pathwise closure is stronger than a favorable ensemble average. Distinction by example prevents future slogan drift.

A strong result would state which closure modes are implied by which candidate realizations and which observable signatures distinguish them. A weaker result may show that several modes remain observationally equivalent under humane sampling.

Report the closure mode supported by the analysis, the alternatives it distinguishes, and the additional information required to resolve the remaining modes.

A concrete classification separates a fixed deadline from an endpoint that waits for the state. In one declared clock, consider an absolutely continuous ledger and a noisy contribution rate,

$$dL_t = V_t dt, \quad dV_t = u_t dt + \sigma dW_t, \quad 0 \leq t < T,$$

where T is a deterministic positive finite deadline, $\sigma > 0$, initial states are square integrable, W is Brownian in the full information filtration and u includes all progressively measurable drift affecting V . Exact $L_{T-} = 0$ almost surely is impossible if $E \int_0^T u_t^2 dt < \infty$. To see why, write the final h -window remainder as $L_{T-} = m + C + Z$, where m is known at $T - h$, $C = \int_{T-h}^T (T - s) u_s ds$ and Z has conditional variance $\sigma^2 h^3/3$ and conditional mean zero. Exact closure requires $C - E[C | \mathcal{F}_{T-h}] = -Z$. Conditional variance and Cauchy–Schwarz then imply

$$E \int_{T-h}^T u_s^2 ds \geq \sigma^2 \quad \text{for every } 0 < h \leq T,$$

contradicting finite expected total quadratic effort as h decreases to zero. This effort is a mathematical control quantity, with no assumed conversion into metabolic energy. The restriction concerns the specified fixed-deadline innovation model; it does not impose those dynamics on every PTV route.

Exact completion is nevertheless constructible with ordinary stochastic feedback. Start at $L_0 = V_0 = 0$, put $\tau = T - t$, taper the diffusion to $\sigma_t = \sigma_0 \tau / T$ and choose

$$u_t = -\frac{5(L_t + \tau V_t)}{\tau^2}.$$

For $M = L + \tau V$, the equation becomes $dM = -5Mdt/\tau + (\sigma_0/T)\tau^2 dW$. Its solution gives $E[u_t^2] = (5\sigma_0^2/T^2)\tau[1 - (\tau/T)^5]$, hence $E \int_0^T u_t^2 dt = 25\sigma_0^2/14$. Finite absolute drift integral ensures a continuous endpoint extension; M tends to zero and τV tends to zero, so $L_{T-} = 0$ almost surely. The feedback gains remain singular even though expected quadratic effort is finite. This is a mathematical realization with vanishing relevant innovations, not evidence that an organism implements it.

A random hitting endpoint supplies a different ordinary construction. With $L_0 = l > 0$, $V_0 = 0$ and constant drift $u = -a < 0$ under persistent $\sigma > 0$, $L_t = l - at^2/2 + \sigma \int_0^t W_s ds$ eventually becomes negative almost surely. Its first zero is finite and continuity gives exact pre-endpoint closure, with bounded drift control. In a complete-stream account, l would represent a preceding prefix. Identifying that hit with the stream endpoint remains an independent scientific obligation. Together the constructions direct measurement toward relevant innovation

strength, correction dynamics and independently classified endpoint rules, rather than treating every convergent-looking trace as the same mechanism.

29.2.5 — Stochastic Reserve and Markov Closure

The reference reserve model is useful because it is simple, but biological reserve need not behave as a smooth deterministic clock. Acute events, treatment, fatigue, infection, sleep, and medication motivate investigating stochastic, multidimensional, or regime-switching reserve candidates, while measurement changes require a separate observation model (McEwen & Wingfield, 2003; Inouye et al., 2014). These sources support the biological and clinical motivation, not the validity of a particular latent-reserve model.

A stochastic reserve extension rebuilds the dynamics rather than quoting the finite-variation shortcut. If reserve has its own martingale component or shares shocks with the normalized process, the product calculation includes bracket terms and potentially different terminal conditions. Those terms are part of the candidate mechanism, not a technical footnote.

A smooth state-potential realization must accommodate the process's actual noise. In one common clock, suppose $dS_s = b(S_s)ds + G(S_s)dW_s$ and $dL_s = v(S_s)ds$. For a C^2 potential Φ , Itô's formula and uniqueness of the semimartingale decomposition show that the pathwise identity $dL = -d\Phi$ requires

$$G^\top \nabla \Phi = 0, \quad v + \mathcal{A}\Phi = 0,$$

along the supported process, $ds \times \text{Pr}$ almost everywhere, with the usual localization and integrability assumptions. The generator is $\mathcal{A}\Phi = b \cdot \nabla\Phi + 1/2 \text{tr}(GG^\top \nabla^2\Phi)$. Noise can coexist with exact accounting when it acts in directions that leave the potential unchanged. A nonconstant smooth potential is impossible on a connected open region where these supported identities extend pointwise and the diffusion directions span the whole state space.

Instantaneous rank deficiency is not sufficient protection. For sufficiently smooth noise fields and potential, successive commutators of noise directions must also annihilate Φ ; if those directions together span the region, Φ is constant there. Drift directions cannot be added to this test without an additional argument. This identifies a precise research target: a coordinate responsive to the signed contribution while protected against the relevant fluctuations. A coarse noisy assay does not establish the noise geometry of the complete biological state, and jump or hybrid models require their own calculation.

Markov closure is also open. A system may be Markovian in an expanded hidden state while appearing non-Markovian in measured variables. The program needs to know which state variables must be included for closure-like signatures to be generated and distinguished from rivals.

A formal result here would identify minimal state conditions: reserve dimensions, normalized affective process, observation intensity, endpoint hazard, treatment state, and latent confounders. It would also specify when the process class becomes too flexible to be discriminating.

The extension should be constrained before data are seen. If stochastic reserve is added only after a negative result, the revision risks becoming a rescue move. If it is specified before testing, with parameter ranges and predicted failures, it can improve the model while preserving empirical content. Timing is part of the theorem's public credibility.

This matters for model recovery. If stochastic reserve can mimic nearly any observed trajectory, it becomes a language of accommodation rather than a source of risky prediction. The open program should prefer parsimonious, constrained generators that can lose.

The best outcome may be a family of nested realizations. The finite-variation reference remains the clean baseline, stochastic reserve becomes a formally labeled extension, and failure of both under fair comparison becomes evidence against that realization rather than an invitation to unbounded complexity.

The Markov program earns a place only if it yields distinctive, recoverable consequences under realistic observation. A convenient state augmentation that reproduces the endpoint but erases falsifiability is not a solution; it is a relabeling.

29.2.6 — Formal Amendment Candidates

Some future work may discover that the received formal statement needs repair. That possibility remains visible, but no repair enters the active scientific record before formal acceptance. A formal amendment candidate is a proposal under governance, not an invisible rewrite.

Amendment candidates might concern the representation of valence, the product realization, reserve dimensionality, endpoint clocks, scalarization, or whole-life initial state. Each candidate should state the old claim, the proposed new claim, the reason for change, and the predictions it improves or sacrifices.

A progressive amendment solves an independently identified problem and creates new risky predictions. A degenerating rescue move appears after failure only to preserve a favored conclusion. The program must keep those categories distinct before results arrive.

Historical results remain attached to the versions that generated them. Reanalysis under a new model is not a silent correction of the old record. It is a new analysis with its own version, assumptions, and public status (Crossref, 2025). A cross-version table should distinguish reproduced findings, newly derived findings, and findings rendered incomparable by the amendment.

Amendment candidates should also include a public-cost statement. A repaired theory may be more accurate but less simple, less universal, or less connected to earlier figures. The audience deserves to know when an elegant public explanation has been sacrificed for scientific truth, because that sacrifice is one of the signs that correction is real. The cost statement should also identify which prior empirical results remain valid under the amendment and which require reanalysis.

The formal-law book maintains the root statement. The science book supplies evidence, proposed amendments, and implications for formal change review. A concordance between the two books

can then show whether the scientific amendment changes the root claim, only its testable bridge, or both.

A formal amendment may someday make the program stronger or smaller. The final chapter leaves that route open because a theory that cannot be repaired honestly cannot be tested honestly. Any amendment must preserve the failed premise, counterexample, proposed repair, and new empirical obligations together, so formal change cannot masquerade as continuity. Fresh obligations should be prospectively testable, ensuring that formal repair increases empirical exposure rather than only logical flexibility.

Table 29.2. Open formal-problem register.

Problem	Minimum deliverable	Failure consequence
Integral-product bridge	Theorem, separation result, or formal amendment packet	Candidate realization loses authority to speak for the received ledger.
Origin and representation	Scale and origin conditions with sensitivity tests	Ledger and candidate interval-contribution estimator claims narrow to contexts where representation survives.
Endpoint-reserve synchronization	Non-tautological relation between endpoint clocks and reserve processes	Terminal inference pauses or becomes a smaller preterminal program.
Random endpoints	Convergence taxonomy: stopping and conditioning	Endpoint-conditioned rivals remain undefeated.

Problem	Minimum deliverable	Failure consequence
Stochastic reserve	General product dynamics and identifiability limits	Reserve family narrows or becomes non-discriminating.
Formal amendments	Versioned change request with costs and predictions	Old headline cannot silently continue after bridge failure.

29.3 — Identification and Measurement Problems

Identification and measurement establish which records answer the intended terminal question. The analysis specifies sign, origin, unit, exposure rule, stream boundary, endpoint, observation process, and the relation between measured and latent quantities (American Educational Research Association et al., 2014; Manski, 2003).

The section orders blockers that can invalidate a terminal claim even when the dataset is large and technically impressive. Its purpose is to make measurement more informative by preventing procedural sophistication from substituting for identification.

The core rule is simple: a model may estimate only what its design has identified. More channels, more sampling, and more computation do not repair an unidentified origin, an invalid sign, a context mismatch, or missingness that is part of the event being studied.

The measurement agenda identifies what each improved instrument can estimate, its qualified conditions, and the circumstances requiring no estimate. Those specifications make the instrument's contribution clear.

Identification also protects against technological overconfidence. Future sensors may improve, but a better sensor can still measure the wrong construct more precisely. The program therefore prefers an explicit construct failure to impressive but uninterpretable signal quality.

The identification register defines overreach. Using a candidate momentary-valence estimator outside its context of use, treating a missing terminal window as neutral, or collapsing noncompensable states into a scalar without support becomes a visible violation of the program's own standards.

29.3.1 — Sign and Neutral Origin

The sign problem asks whether a measured change points toward burden or relief. The neutral-origin problem asks where zero sits. Both are prior to any ledger estimate, because a running total cannot be meaningful if its contributions can flip meaning across context (American Educational Research Association et al., 2014; Little & Rubin, 2019).

Self-report anchors help but do not solve the problem alone. Reports are shaped by language, expectation, disability, culture, medication, fatigue, social demand, and memory. Physiological anchors help but remain nonspecific because arousal, effort, pain, fear, and salience can share channels.

The first study should therefore create bounded tasks in which sign can be cross-checked. A horizon and candidate scheduling route task, an affective reprocessing task, and ordinary-life micro-reports can test whether the same modeled direction survives across report, behavior, physiology, and time.

Negative controls and artifact challenges are essential. A proposed negative control requires an independently justified absence of the relevant causal relation; device looseness, motion, sensor drift, speech impairment, and clinical routines must also be tested for recording artifacts and possible genuine effects on

experience. A system that assigns a confident valence sign to every channel change has failed (Lipsitch et al., 2010).

Sign disagreements are expected rather than anomalous. A trembling hand, a quiet face, a reduced heart-rate signal, and a calm verbal report may point in different directions. The first response is not fusion but interrogation of context, because disagreement often marks the place where measurement is learning its limits.

A useful deliverable may be a hierarchy of anchors: within-person origins, context-specific neutrality bands, state-specific uncertainty, and decision rules for when a sign can be assigned.

If sign and origin remain unstable, ledger claims should stop while affective-measurement research continues where it has independent value. The result identifies the calibration problem that further work must solve before cumulative claims can responsibly resume.

Sign and neutrality are anchored outside the terminal record, with their uncertainty propagated into the final estimate. The measurement protocol identifies the conditions for a qualified estimate and returns no estimate when those conditions remain unmet.

29.3.2 — Candidate Momentary-Valence Instrument Context of Use

The candidate momentary-valence estimator is not a universal meter of inner life. It is a proposed estimator under a context of use. That context must specify population, state, language,

device, cadence, care regime, endpoint relation, clinical exclusion, and intended inference (Goldsack et al., 2020).

A context of use can be narrow at first. It might cover consenting adults in ordinary-life calibration, then a specific palliative population, then a carefully defined preterminal window. Each expansion requires evidence rather than rhetorical continuity.

Measurement qualification should test calibration transfer. A model trained on healthy adults should not silently travel to advanced cancer, dementia, autonomic neuropathy, chronic pain, traumatic stress, or medication regimes. Transport is an empirical question that targeted validation can answer.

The context must also specify abstention. When channels decouple, report is unavailable, medication changes, or device quality fails, the candidate instrument should return uncertainty or no estimate rather than a confident number. No estimate is a valid scientific output (Lakens, 2017; American Educational Research Association et al., 2014).

Context of use is written in the language of future exclusion. If the estimator has not been qualified and supported in delirium, chronic pain, autonomic neuropathy, or a given language group, those conditions remain outside scope rather than appearing as small-print uncertainty. A boundary written before use is protection; a boundary discovered after overreach is repair.

Model cards, device-version records, calibration logs, sensor-quality tags, and site-specific performance document the estimator's qualified uses.

Terminal-dynamics studies begin after the candidate instrument establishes its context of use. If qualification remains unmet, the next step is measurement refinement or retirement of that estimator.

29.3.3 — Rate, Additivity, and Scalarization

A ledger requires contributions over time. That means the program must identify whether lived experience can be represented as a rate, whether interval contributions are additive enough to support a candidate interval contribution estimate, and whether multiple dimensions can be responsibly scalarized.

The rate problem appears whenever sparse reports are stretched across unobserved intervals. A painful minute, a fearful hour, a sedated afternoon, and a socially quiet evening cannot be integrated by clock time alone unless the model states smoothness, bandwidth, and error assumptions.

Temporal additivity concerns partitions of the same realized stream. Memory, anticipation, trauma, and physiological recovery may change the valence rate, so two separate brief burdens need not equal one longer episode. Those differences do not by themselves refute temporal additivity. The candidate interval contribution estimate must be tested for consistent accumulation across partitions of the same history.

Scalarization may fail for noncompensable states. Pain relief, fear reduction, dignity, fatigue, grief, and confusion may not collapse into one axis without loss. The program should test whether vector-valued representations preserve more truth than a single

running score (American Educational Research Association et al., 2014; Little & Rubin, 2019).

A good measurement program should also compare what is lost when the representation is simplified. If a vector model retains grief, fatigue, pain, fear, and effort separately while a scalar model predicts one signature better, the choice should be tied to the estimand. Scientific elegance is not the same as human fidelity.

The first deliverable is a representation battery. It should compare scalar, vector, ordinal, and interval models under bounded tasks, ordinary-life sampling, and safe perturbations. The aim is to find where additivity holds, where it only approximates, and where it should be abandoned.

When rate, additivity, or scalarization tests favor a richer representation, record that finding and revise the scope of cumulative claims accordingly.

The decisive question is whether the chosen rate and scalarization preserve the contrasts the claim needs. When the proposed representation fails partition consistency or cannot support the required scalar comparisons, the analysis should widen the identified set or retire that representation branch.

29.3.4 — Candidate Remaining-Support Construct Validity

Reserve is scientifically useful only if it means more than frailty, illness severity, remaining time, or signal quality. The open program must identify what reserve is, how it differs from these neighboring constructs, and when it should be vector-valued rather than scalar (Lakens, 2017; American Educational Research Association et al., 2014).

Section 20.1.2 identifies the candidate dimensions behind a reserve construct. Construct validation must test whether a scalar or vector reserve adds discriminating validity beyond frailty, prognosis, remaining time, and signal quality for the declared estimand.

Construct validity requires discriminant evidence. A reserve proxy should not merely predict death, device dropout, or care intensity. It should help explain the specific dynamics the candidate realization says reserve should create, such as changing innovation amplitude or conditional relaxation.

Medication and clinical intervention are central. Analgesia, sedation, oxygen, dialysis, ventilation, nutrition, infection control, and palliative care can alter reserve proxies. A model that treats care as nuisance may distort both science and ethics (Little & Rubin, 2019; Manski, 2003).

Reserve should also be tested against interventions. If palliative care improves a reserve proxy, the model must know whether it has measured capacity, comfort, treatment, or observation quality. This matters because care should not be modeled as a contaminant that interferes with the theory. Care is part of the environment in which any humane science must operate.

A reserve-qualification protocol should compare candidate reserve dimensions, test shared sensors, estimate measurement error, report treatment sensitivity, and declare when reserve is too confounded for Law-specific interpretation.

If reserve construct validity fails, the product realization may retire while other parts of the program continue. That is exactly

why the final chapter separates components rather than letting a single elegant equation control the whole research agenda.

Remaining support becomes scientific only if it predicts constrained continuation under held-out conditions better than ordinary resources, prognosis, and opportunity measures. Without that incremental validity, the construct should be treated as an evocative label, not a mechanism variable.

29.3.5 — Unity and Endpoint Classification

Endpoint classification is not a clerical detail. The terminal claim depends on identifying when the relevant conscious stream has ended, not when a body, biography, legal status, monitor, or family narrative reaches a convenient boundary.

Unity classification must handle sleep, anesthesia, delirium, coma, dementia, dissociation, sedation, sudden death, return, and low-signal states. It should produce confidence classes and abstention windows, not binary certainty where the evidence is weak.

The endpoint method study must be independent of ledger estimates. It should use consciousness-state markers, clinical adjudication, prospectively specified windows, and blinded review channels that are not algebraically identical to the predicted neutrality measure.

False endpoints are especially costly. Prematurely declaring an endpoint can create tautology, erase return, or assign terminal meaning to a reversible state. Delayed endpoints can miss the relevant window and create post hoc selection (Manski, 2003; Lakens, 2017).

Endpoint validation should publish unresolved classes. Some states may remain beyond responsible classification, and those states should be named. The program becomes safer when it says that certain low-signal, ambiguous, or reversible conditions are not eligible for terminal inference under current methods, even if that makes the test less dramatic.

Its concrete output is a prospective endpoint protocol with versioned rules, open-channel windows, return handling, confidence classes, and independent adjudicators. That protocol should first be tested in nonterminal or simulated state transitions before entering palliative settings.

An unresolved endpoint method pauses terminal-neutrality inference while measurement and consciousness research continue. Care proceeds according to participants' needs.

Classification error here changes the unit and boundary of the claim itself. The program therefore needs calibrated abstention, alternative routing sets, and explicit false-ending controls before any residual estimate can carry complete-stream language.

29.3.6 — Observation and Missingness Models

Observation is part of the data-generating process. Reports arrive when a person can respond, devices record when they are worn, clinical visits occur under care regimes, and terminal data may disappear precisely when the event of interest becomes most important (Little & Rubin, 2019; Manski, 2003).

Missingness near endpoints can create false trajectories. A quiet final day may mean comfort, sedation, delirium, exhaustion,

family privacy, sensor loss, staff triage, or the ethical decision not to measure. The model must not impute meaning by default.

The open program should model observation intensity, dropout, device adherence, care transitions, family refusal, medication changes, and site routines jointly with the outcome. A smooth path drawn through gaps can become a false theorem if missingness is informative.

Ethically feasible randomized variation in harmless prompt timing, device redundancy, or backup reports can reveal observation bias without increasing burden. The goal is to study missingness while minimizing measurement itself (Lakens, 2017; American Educational Research Association et al., 2014).

Some data are absent because the right decision was not to ask, measure, enter the room, or turn a family scene into research. A humane model treats this ethical silence as design information. Each study needs a charter for planned and unplanned missingness, ethical nonmeasurement, terminal shutdown, data quarantine, and unusable estimates.

If missingness dominates the signature, that is a result: the humane observation window may be too narrow for the claim, requiring the program to stop or move to less vulnerable designs.

The observation model must allow for informative disappearance. The estimand should specify how relevant intercurrent events are handled, while estimation and sensitivity analyses address sedation, fatigue, withdrawal, device failure, death, and selective nonresponse. Missing observations must never be coded as neutral experience merely because they are absent.

Table 29.3. Identification and measurement bottlenecks.

Bottleneck	Early test	Decision consequence
Sign and neutral origin	Bounded anchor tasks and within-person sensitivity bounds	No signed ledger until direction and origin survive.
Candidate momentary-valence estimator context of use	External validation across state, site, device, and medication	Estimator remains local or abstains outside context.
Rate and additivity	Cadence and representation battery	Candidate interval-contribution estimator claims narrow if interval structure fails.
Reserve validity	Vector versus scalar reserve qualification	Product realization narrows or retires if reserve is confounded.
Endpoint classification	Independent consciousness-state protocol	Terminal inference pauses if endpoint independence fails.
Observation and missingness	Joint visit, dropout, device, and care-transition models	Unusable evidence remains visible rather than imputed into closure.

29.4 — First Study Families and Simulation Gates

The first empirical portfolio begins with studies that can change a decision at relatively low scientific and ethical cost. Representation, momentary-valence estimation, unity and endpoint classification, generative model recovery, sleep and reprocessing, and humane preterminal dynamics enter only after their prerequisite simulations and qualification gates pass.

The minimal portfolio includes bounded representation and sign work, a longitudinal calibration cohort, consciousness and endpoint-method studies, a generative benchmark challenge, and a humane preterminal protocol. Sleep and affective-reprocessing work can serve as a lower-burden bridge when its target, report process, and rival explanations remain explicit.

Stage Zero is a bounded existing-data challenge that can begin before new participant recruitment. Its first commission tests which accumulation statistics and predictive distinctions survive realistic measurement. The openESM resource introduced in Chapter 17 supplies a starting inventory, subject to each dataset's access, license, consent scope, variables, cadence, and participant overlap (Siepe et al., 2026). Freeze that inventory and distinguish exploratory datasets from protected confirmation records.

Before integration, qualify the observation scale, exposure weights, and missing-window bounds. Where cardinality, cross-sign comparability, or neutral origin is unresolved, report an observed affect-process statistic. Audit every centering, differencing, detrending, filtering, interpolation, and rescaling step. Pass known constant, slow-changing, and cumulative

signals through the identical pipeline: whole-record centering forces a zero total, and differencing changes a sum into an endpoint difference. Any resulting cancellation must be attributed to the transformation before being interpreted biologically.

Compare cumulative variance over prespecified window lengths using Sections 10.6.2 and 21.5.3, then evaluate Section 23.3.4's history comparison against strong current-state and memory models. Release synthetic generators for ordinary accumulation, genuine cancellation, multiscale memory, integral feedback, endpoint conditioning, origin drift, shared error, and informative observation loss. Give competitors identical available histories, observation procedures, and tuning resources. Freeze the primary score, practical-gain threshold, missingness sensitivity, and dependence-respecting uncertainty before confirmation; transport the comparison to an independent cohort without outcome-driven retuning.

The commission returns an access-and-measurement inventory, executable rival-recovery benchmark, observed-range accumulation estimates, protected predictive comparison, and a specification for the next informative measurement. Assign a time and resource ceiling, an owner for each output, and an independent reproduction task. A favorable result earns a focused replication or calibration investment through its prespecified effect and uncertainty. Failed recovery or inadequate separation identifies the design change needed before expansion. These outputs support the five study families below without asking a first nonterminal dataset to decide whole-stream closure.

29.4.1 — Study One: Representation and Sign

The first study asks whether signed contributions can be identified without terminal settings. It uses bounded tasks that vary horizon, candidate scheduling pressure, effort, relief, anticipation, and recovery while collecting reports, behavior, and physiological channels under prospectively specified models (Nosek et al., 2018; Cook et al., 2006).

The horizon and scheduling-route task belongs here. Participants face benign choices in which remaining opportunity and competing priorities vary without deliberately inducing suffering, distress, deprivation, or sleep disruption for Law-specific evidence. The task compares ordinary urgency, scarcity, and avoidance with the candidate route's separately specified predictions.

A sleep and affective reprocessing study can accompany or follow the task. It asks whether affective episodes show measurable next-day adjustment that cannot be reduced to report memory, mood inertia, or simple arousal. The study is valuable because it is relatively benign and temporally structured.

Study One is designed to resolve representation: sign, interval structure, rate behavior, and the first pass at scalar versus vector models. A success would not validate terminal neutrality. It would justify a more serious measurement qualification phase (Cranmer et al., 2020; Center for Open Science, 2025).

The study should also predefine what it will not ask. It should not use trauma induction, deprivation, humiliation, or high-stakes loss to create cleaner signals. The purpose is not to stretch people

until sign becomes visible. The purpose is to discover whether humane, bounded variation is enough to identify the representation the program needs.

A failure would be decisive for downstream design. If sign flips by context, if the same event produces incompatible scales, or if reports and physiology cannot be reconciled even locally, the program should stop ledger claims and continue as representation research.

Study One has a moderate, ethically manageable burden. It should minimize deception, avoid harm induction, preserve exit rights, record fatigue, and publish negative results because a failed sign study can prevent later misuse.

Study One earns completion when it reduces the representation set enough to make later measurements interpretable. If positive and negative channels cannot be linked without outcome-dependent choices, the portfolio stops at the representation gate.

29.4.2 — Study Two: Momentary-Valence Estimator Qualification

The second study builds the physiological estimator only after representation has enough local stability. It should not ask whether the Law is true. It should ask whether the candidate instrument can estimate relevant affective-state contributions within a defined context of use (Goldsack et al., 2020).

The core design is a longitudinal ordinary-life calibration cohort. Participants provide active reports, bounded event annotations, sleep and activity context, selected passive signals, medication and health covariates, and periodic recalibration. The cohort

should include variation in age, disability, chronic illness, language, and device access.

Study Two addresses transport across ordinary life. A laboratory estimator that fails during grief, fatigue, work stress, pain flare, caregiving, or medication change is not ready for clinical inference. Ordinary life is not easier than the lab; it is where measurement learns humility.

Use the deployment-matched validation scheme in §17.7: leave-person-out, leave-site-out, or leave-device-version-out tests for those transport claims, and temporally ordered splits for prospective within-person prediction. Study Two must state its intended generalization and prevent dependence or preprocessing leakage (Center for Open Science, 2025; Nosek et al., 2018).

The ordinary-life cohort should have a participant-facing explanation that is honest about uncertainty. Participants should know that the study is qualifying a research estimator, not reading their true ledger. Return information should emphasize patterns, confidence, and data-quality lessons rather than personal status, virtue, resilience, or deficit.

A success qualifies a bounded estimator and creates a versioned model card. A failure returns the program to channel design, person-specific baselines, vector representation, or abstention rules. Either outcome improves public safety by preventing unqualified body-reading.

Study Two imposes a substantial longitudinal burden because repeated measurement consumes attention and privacy. Cadence must therefore be justified by participant bandwidth and decision

value, with meaningful return information that never becomes a score, rank, or authority-laden interpretation.

Study Two should return a context-of-use decision for the candidate momentary-valence estimator, not a universal instrument claim. Qualification requires recovery, calibration, uncertainty, burden, and failure reporting strong enough that later studies know exactly what the estimator can and cannot support.

29.4.3 — Study Three: Unity and Endpoint Validation

The third study asks whether consciousness-state and endpoint methods can be qualified and evaluated independently of the ledger. This is a prerequisite for terminal inference because a terminal prediction cannot define its own endpoint and still count as an independent test.

The early version uses nonterminal analogues before clinical endpoints. Sleep transitions, anesthesia recovery, sedation changes, delirium windows, and independently evaluated disorders-of-consciousness protocols can test classification logic without treating dying participants as the first method-development population.

Study Three addresses unity and endpoint classification, including any prospectively declared independence branch. It estimates false-positive endings, false-negative continuity, ambiguous windows, return handling, and confidence classes, while keeping endpoint adjudicators blinded to ledger estimates and outcome expectations.

The design requires clinical and consciousness-science review. It should incorporate neurologists, palliative clinicians,

anesthesiologists, disability advocates, statisticians, ethicists, and family advisors before any terminal extension is considered (Council for International Organizations of Medical Sciences, 2016).

The endpoint method study should also test public-description risk. It should examine whether consent forms, summaries, and diagrams are understood as state-classification tools rather than as predictions about a person's final meaning. Misunderstanding by readers is a data point about artifact safety, not a communications footnote.

A success creates a prospective endpoint protocol with uncertainty bands and abstention categories. A failure stops terminal claims and redirects the program toward consciousness-state science. It should not be reinterpreted as a spiritual or poetic endpoint.

Study Three concentrates its burden in specialist clinical work. It requires clinical access, state labels, careful consent, and protection against public misunderstanding; that burden is justified only if it prevents greater harm in later terminal research.

Study Three is allowed to end in abstention. If unity or endpoint classes cannot be distinguished with acceptable error and humane burden, that finding blocks complete-stream adjudication while preserving narrower longitudinal work.

29.4.4 — Study Four: Generative Benchmark Challenge

The fourth study is not a human study at all. It is an open simulation and model-recovery challenge that asks whether the proposed analyses can recover true generators under known

conditions before they are trusted with real-world ambiguity (Center for Open Science, 2025; Nosek et al., 2018).

The benchmark library should include reserve-coupled candidates, OU processes, fixed and random Brownian bridges, Doob transforms, frailty, sedation, observation shutdown, adaptation, predictive or reinforcement-learning controllers, and any prospectively defined cross-species route or future-regime extension. Endpoint selection, subgroup mixtures, none-of-the-models generators, ordinary developmental and learning processes, and deliberately defective allocation or observation pipelines belong in the same challenge set. Before confirmatory testing, the model must specify its prediction, experimental unit, ordinary null, information set, and prespecified model-recovery, calibration, and false-positive criteria under realistic observation conditions.

For the delayed-treatment comparison, simulate both the primary strict-pre-endpoint and any separately declared endpoint-inclusive branch. Include streams that end before, at, or after scheduled treatment onset, with terminal contributions assigned only under the appropriate branch convention. Distinguish the complete-remainder restriction from stronger pre-treatment localization. Null simulations should include realistic finite-sample imbalance, ordinary later compensation with no early arm difference, and development or survival selection. Any selection or reweighting used to enforce closure must be checked for induced dependence between assignment and the pre-assignment prefix.

The implementation challenge includes route-cue leakage, route-to-contingency coding errors, one-shot versus learned choice, no-choice and observation-loss outcomes, allocation leakage, parental and batch structure, density and position effects, handling and scoring artifacts, censoring, and multiplicity. Permuted and placebo assignments must preserve the actual randomization scheme; placebo labels are generated independently of outcome values after ascertainment and do not determine treatment. Simulate cancellation, crossover, non-delivery, and other regime changes. When a prediction depends on actual regime realization, test its prespecified causal or partial-identification strategy rather than treating later adherence as randomized.

The benchmark should retain the terminal fork defined in Section 19.2, including general and the phenomenally silent idealization. Apply the declared selector to determine whether compatibility restrictions produce the claimed observable choice pattern. Compare first choices, repeated choices with learning, and continuation-only analogues separately. Candidate and rival implementations must expose their local or global information assumptions; hidden mapping information must not be supplied silently as an ordinary pre-choice covariate. The terminal case remains a theoretical and computational comparison, not an empirical lethal protocol.

Advance a confirmatory design when it meets prespecified recovery and error criteria for the candidates actually tested, with unresolved or open-set cases reported explicitly. Successful recovery establishes separability within the simulated conditions,

not the truth of the generator in nature. Empirical work then tests the preregistered prediction under independent scientific and welfare review.

Every analysis model should fit every generator. The report should include parameter bias, coverage, false equivalence, false defeat, open-set detection, calibration, convergence failures, computation time, and held-out scores under person, site, endpoint, and device-version splits.

Study Four asks whether the candidate can be separated from ordinary rivals. If a Law candidate cannot be distinguished from ordinary rivals under realistic observation noise, missingness, and endpoint uncertainty, then human confirmatory studies are premature no matter how good the prose sounds (Cook et al., 2006; Cranmer et al., 2020).

The benchmark includes deliberately defective pipelines to test detection of endpoint-label leakage, tuning on test outcomes, and weak-rival comparisons. Their known defects provide explicit checks of the analysis safeguards.

Successful model recovery establishes that the proposed design can distinguish important generators under the tested conditions. The public benchmark report records recovery and confusion patterns, and confirmatory recruitment begins after the design meets its prespecified separability requirements.

Study Four is computationally and adversarially demanding rather than participant-intensive. It is therefore a high-priority early investment because it can prevent unnecessary clinical work and give critics a formal role before data collection begins.

The generative challenge is successful only when the pipeline can recognize worlds in which PTVc is absent. Open-set failure, rival confusion, and observation-floor artifacts must be reported before the same pipeline is trusted on human data.

29.4.5 — Study Five: Humane Preterminal Dynamics

The fifth study is the first confirmatory comparative protocol that approaches terminal relevance without treating final moments as a spectacle. It should be attempted only after representation, momentary-valence estimator qualification, endpoint methods, and model recovery have passed their gates (Nosek et al., 2018; Cook et al., 2006).

The study may begin with a preterminal or palliative feasibility cohort rather than an end-of-mind inference. It should monitor comfort, observation burden, family burden, staff burden, device adherence, medication transitions, and clinical events as part of the scientific design.

Study Five asks whether humane preterminal observation reveals prospectively specified signatures beyond rivals. Candidate signals may include variance behavior, reserve-linked changes, endpoint-window concentration, and model-specific residuals, but only within the qualified context of use.

The design compares well-developed models of frailty decline, sedation, observation shutdown, terminal scripts, Brownian bridge conditioning, safe control, adaptation, and selection under shared evaluation rules (Cranmer et al., 2020; Center for Open Science, 2025).

Keep a family and staff burden dashboard within the research team, not in public. It supports stopping decisions, not publicity. Rising research load, excessive staff documentation, or strained family privacy must permit reduced cadence or stopping.

Success would support independent replication and expansion to the next justified reference class. An unsuccessful test would identify the formal, measurement, or protocol work needed before terminal research proceeds, while preserving the care-first design lessons.

Because this study carries the highest human burden, it comes last and remains limited to humane, low-burden, immediately stoppable observation. Its purpose is to test local dynamics and measurement transport against rivals, not to recruit terminal lives as proof.

29.4.6 — Portfolio Decision Points

The first studies form a portfolio with decision points, not a ladder that climbs automatically. A failed prerequisite may pause later work, redirect methods, or retire a mechanism before additional burden is imposed (Cook et al., 2006; Cranmer et al., 2020).

Representation and sign qualification govern whether ledger estimators are built; estimator transport governs the populations in which later work may proceed; and endpoint validation governs whether terminal claims are allowed at all. Failure at any gate is published rather than bypassed (Center for Open Science, 2025; Nosek et al., 2018).

The synthetic challenge determines whether the planned model comparison has demonstrated adequate recovery and separability

under its tested conditions. Failure blocks that confirmatory comparison; it does not automatically reclassify every human study as exploratory. Separately justified calibration, descriptive, or feasibility studies may retain their own prospectively specified questions and decision rules.

Decision points belong in protocols, funding agreements, and public status pages. Each converts evidence into permission, redesign, pause, or retirement, making the portfolio successful only when every outcome is genuinely available.

Table 29.4. First-study portfolio and decision value.

Study track	Primary uncertainty resolved	Further research questions
Horizon and queue task plus safe affective anchors	Sign, scale, horizon sensitivity, queue pressure, and representation limits	How do horizon-dependent dynamics relate to independently defined stream endpoints?
Sleep and affective reprocessing study	Temporal adjustment and next-day ledger movement under benign observation	Which sleep-linked changes generalize across populations, nights, and measurement channels?
Longitudinal ordinary-life calibration cohort	Candidate momentary-valence estimator context of use, calibration transfer, missingness, and cadence	How far does calibration transfer across states, populations, and instruments?

Study track	Primary uncertainty resolved	Further research questions
Consciousness and endpoint method study	Prospective endpoint independence and unity classification	How can qualified endpoint methods be linked to longitudinal affect measurements?
Generative benchmark challenge	Model recovery, open-set adequacy, and design separability	How do recoverable models perform on prospectively collected observations?
Humane preterminal dynamics pilot	Preterminal signatures under rival comparison and clinical burden monitoring	Which preterminal signatures replicate across qualified sites and care settings?

29.5 — Staged Roadmap and Value of Information

A staged roadmap is a dependency order, not a promise of progress by date. Each stage begins only after the objects it depends on are sufficiently identified, recoverable, safe, and transportable for the next inference. Value of information compares expected decision change with cost, burden, delay, opportunity cost, and the value of learning from a negative result (Claxton, 1999).

Early stages therefore concentrate on formal and measurement work. Fragile terminal claims wait until representation, candidate momentary-valence estimator qualification, endpoint architecture, model recovery, and humane feasibility have earned enough support to justify greater burden.

The plan also names opportunity cost. Funding, clinical time, participant attention, privacy, statistical labor, adversarial review, and public trust are finite. A fair research program spends them where the result can actually change status.

The roadmap also needs public patience. A program may appear slow precisely because it refuses to spend clinical vulnerability before formal and measurement gates pass. The plan explains that restraint as design rather than apologizing for it.

Annual review tests whether the roadmap's assumptions still hold. A ten-year sequence is a dependency hypothesis, not a destiny map. Each review asks whether the next stage retains decision value, whether a lower-burden alternative has emerged, and whether failure elsewhere has changed the order.

The resource plan keeps later funding responsive to earlier results. Resources can move to measurement, palliative care, comparison models, participant support, or public correction when those uses offer greater research or care value.

29.5.1 — Stage One: Formal and Measurement Lock

The first two years should prioritize formal proof obligations, representation batteries, candidate momentary-valence estimator context-of-use work, synthetic fixtures, and governance of code and data. This foundational stage creates the instruments and comparisons on which later discoveries depend (Claxton, 1999; Fenwick et al., 2020).

Formal teams should work on the integral-product bridge, origin and representation, endpoint-reserve synchronization, random endpoints, stochastic reserve, and formal amendment candidates. Their outputs should be versioned documents, not oral consensus.

Measurement teams should develop the sign and neutral-origin battery, ordinary-life calibration plan, channel taxonomy, missingness charter, and abstention rules. These are prerequisites for any claim that a measured ledger contribution means what it says.

The first open simulation challenge should also begin here. A synthetic benchmark can expose nonseparability before human recruitment. It should include critic-designed rivals from the start rather than after favorable results appear (Skivington et al., 2021; Center for Open Science, 2025).

The year-one artifact list should be concrete: versioned formal notes, a representation test battery, synthetic generators,

containerized analysis environments, a first data dictionary, and a public status vocabulary. These artifacts make the program real without creating the illusion that empirical validation has already begun.

The main gate at the end of year two is readiness for carefully bounded human calibration and state-method work. Formal and measurement checks identify the preparations needed for that next stage.

The resource logic is straightforward: early technical work is cheaper than late clinical error. The program should spend computation, mathematics, and critique before it spends terminal vulnerability.

Stage One should end with a locked formal and measurement packet or with a documented reason that no such packet is available. It is the cheapest place to discover that a later human study would be uninterpretable.

29.5.2 — Stage Two: State and Endpoint Validation

Years two through four should build the consciousness-state and endpoint infrastructure. The goal is independent classification of state and endpoint candidates. The program should test sleep, anesthesia, sedation, delirium, and recovery cases before any terminal endpoint is treated as a scientific boundary (Fenwick et al., 2020; Skivington et al., 2021).

The advisory structure becomes broader here. Consciousness scientists, clinicians, palliative teams, patient advocates, disability experts, statisticians, and ethicists should review state definitions, confidence classes, and abstention conditions.

Apply the purpose separation defined in §26.5.6 to operational records, research data, derived features, model-training corpora, and public summaries. In Stage Two, endpoint reanalysis under new versions must remain visible.

The endpoint study should produce false-ending rates, false-continuity rates, return handling, low-signal rules, and prospectively specified windows. Those outputs become inputs to preterminal protocol design only after independent review (Center for Open Science, 2025; Claxton, 1999).

This stage should also rehearse disagreement. Clinicians, consciousness researchers, families, disability experts, and statisticians may classify edge states differently. Premature consensus would erase the uncertainty the study needs to understand; the task is to learn where agreement is reliable, where dissent must remain visible, and where abstention is the only responsible category.

The gate at the end of this stage is endpoint readiness. If endpoint classification remains too uncertain, terminal inference stops while ordinary-life and nonterminal measurement work may continue.

Stage Two requires sustained clinical and institutional coordination. That cost is justified only when endpoint work prevents more serious downstream misuse by refusing to let the theory select its own boundary.

State and endpoint validation belong after measurement because misclassified bearers and endings cannot be repaired by a larger

sample. This stage earns progression only when uncertainty is narrow enough to support the next protocol's language.

29.5.3 — Stage Three: First Protocol and Replication

Years three through five overlap with endpoint validation because the first humane protocols can begin in ordinary-life and nonterminal settings. The aim is to prospectively specify designs that can produce interpretable evidence rather than impressive data volume (Skivington et al., 2021; Center for Open Science, 2025).

The first confirmatory protocol should define estimands, observation models, rival matrices, missingness handling, model-recovery prerequisites, endpoint rules, analysis versions, and public language before data collection. Registered Reports are attractive because methods receive review before outcomes and publication protection does not depend on direction.

Replication should begin modestly. A direct replication of representation and momentary-valence estimator qualification may matter more than a dramatic clinical pilot. A failed early replication can save the program from building on a fragile first result.

Independent analysis teams should receive staged access. One team can validate preprocessing, another can fit prospectively specified models, and a third can run adversarial checks. The separation reduces self-confirming pipelines without treating ordinary collaboration as suspect (Claxton, 1999; Fenwick et al., 2020).

The first confirmatory protocol should secure publication rights for null, adverse, mixed, and No adequate estimate outcomes. If the design is worth running, a clean negative result is worth preserving. The system must not make positive findings public while keeping failures as private lessons for insiders.

The gate at this stage is replication quality. A first protocol that works only under one analyst, one device version, one site, or one subgroup does not justify stronger public claims. It becomes a local finding or a method-development signal.

Stage Three's principal cost is coordination. The program should fund neutral analysis, critic participation, and negative-result publication before larger recruitment because scientific trust is infrastructure, not an afterthought.

The first protocol and its replication should be modest enough to fail without consuming the program. Its purpose is to test recoverability and transport under independent implementation, not to deliver a public verdict on the strong form.

29.5.4 — Stage Four: Mechanism and Transport

Years five through seven should test mechanism and transport only after early gates have survived. This stage asks whether signatures travel across populations, sites, care regimes, cultures, diagnoses, device versions, and states without collapsing into ordinary rivals (Center for Open Science, 2025; Claxton, 1999).

Mechanism work should compare reserve coupling, interoception, candidate scheduling pressure, sleep repair, adaptation, predictive processing, safe control, and frailty under

shared observation models. It should retire mechanisms that lose rather than giving every mechanism a protective interpretation.

Transport work should be reference-class explicit. A result in consenting adults with stable devices does not travel to advanced illness, nonverbal states, childhood, nonhuman animals, or artificial systems by analogy. Each reference class needs measurement invariance and endpoint comparability.

Multisite cohorts can enter here if harmonization has passed. Site heterogeneity should be treated as a finding, not a nuisance. A negative site may defeat universality or reveal a boundary condition that makes the Law-specific claim smaller (Fenwick et al., 2020; Skivington et al., 2021).

Mechanism and transport work should not be evaluated only by average performance. It should ask who is harmed by error, which subgroup fails, which site reverses, and which clinical context changes meaning. The transport question is moral as well as statistical because unjustified travel of a model places interpretive risk on other people.

The gate is transportable component support. If mechanisms change by site, device, culture, or diagnosis, public language must narrow to the supported reference class. If rivals explain the transported result better, Law-specific scope contracts.

Stage Four pays for breadth. Expansion should occur only where another site, population, or measurement system can change a component status; more sites are not better when they merely multiply unmodeled heterogeneity.

Mechanism and transport work should begin only after a stable signal survives equal-budget rivals. At this stage, a route may be favored, retired, or split by context; none of those outcomes automatically changes the terminal target.

29.5.5 — Stage Five: Terminal and Comparative Work

Only after earlier stages survive should the program attempt more demanding terminal and comparative work. Even then, the question should remain component-specific. The aim is not a public declaration of the Law; it is a carefully bounded test under humane conditions (Claxton, 1999; Fenwick et al., 2020).

Terminal-dynamics studies should be comfort-first, opt-in, low-burden, and clinically subordinate. They require prospectively specified windows, independent endpoint adjudication, medication and care-transition models, family burden monitoring, and stop authority outside the hypothesis team.

Comparative work should be adversarial. Reserve-coupled candidates, bridges, frailty models, sedation models, observation shutdown, safe control, adaptation, and selection-conditioned generators should all face the same data and the same endpoint constraints.

The most informative result may be narrowing. A preterminal signature might hold in one diagnosis, one care regime, or one endpoint class while failing elsewhere. That is not a public disappointment; it is scientific resolution (Skivington et al., 2021; Center for Open Science, 2025).

Even at this stage, the program should prefer designs that can stop early for futility or burden. Sequential monitoring should consider

not only statistical evidence but also staff fatigue, participant distress, family privacy, and endpoint uncertainty. A mature terminal study has more exit doors than entrance rhetoric.

Year ten closes with theory-level synthesis, not a victory ceremony. The program asks whether evidence supports components, narrows reference classes, retires mechanisms, or defeats the strong form. The answer may be mixed.

Terminal and comparative work follows earlier qualification because it requires substantial resources, identification, and ethical review. It proceeds when the question has no less burdensome adequate design and the study preserves the quality of participants' care.

29.5.6 — Resources, Opportunity Cost, and Value of Information

The resource plan counts participant time, privacy exposure, family attention, clinician and analyst labor, computation, ethics work, communication risk, and the opportunity cost of studying this hypothesis instead of other urgent problems (Fenwick et al., 2020; Skivington et al., 2021).

Funding reserves support negative results, adversarial replication, stewardship, cybersecurity, accessibility, participant care, staff training, and public correction. These are scientific costs, not disposable overhead.

Expertise spans mathematical biology, affective and consciousness science, palliative medicine, longitudinal statistics, causal inference, computational psychiatry, reinforcement

learning, open science, governance, disability science, and communication.

Fund low-burden tests that can defeat prerequisites before burdensome studies that add ambiguity. Synthetic nonseparability may make clinical data collection unnecessary (Center for Open Science, 2025; Claxton, 1999).

Critics, palliative clinicians, data stewards, and participant advocates review resource decisions because they can see costs the hypothesis team may underestimate.

Public schedules may report released artifacts, persistent preregistrations, passed benchmarks, and narrowed components, but cannot promise validation by date or treat sunk resources as entitlement to a favorable result.

Opportunity cost is ethical cost. The program becomes smaller when reality demands it because no hypothesis is owed participants, clinicians, or public attention.

Value of information compares expected decision change with money, time, burden, privacy, and alternatives. The next study is the one most likely to close a consequential uncertainty responsibly, not the most visible one.

Table 29.5. Ten-year dependency and resource plan.

Stage	Primary deliverables	Gate before expansion
Years 1-2	Formal obligations, representation battery, candidate momentary-valence estimator context of use, synthetic fixtures	Formal and measurement lock.
Years 2-4	Unity and endpoint validation, state-classification protocol, data separation	Endpoint independence and abstention rules.
Years 3-5	First prospectively specified protocol, ordinary-life replication, independent analysis	Replication quality and model separability.
Years 5-7	Mechanism comparison, transport tests, multisite harmonization	Component support across reference classes.
Years 7-10	Humane terminal and comparative protocols, adversarial replication, synthesis	Status update, narrowing, suspension, or defeat.
Always	Failure logs, public correction, staff and participant burden audit	Stop when burden exceeds decision value.

29.6 — Release, Pause, Redesign, and Stop Conditions

Release, pause, redesign, and stop conditions are the executable form of the gates developed earlier in the book. Here the action rule is simple: a failed prerequisite blocks the dependent inference; a correctable failure returns the program to the affected component; repeated or indispensable failure can retire a route or the strong empirical program.

Formal failure pauses confirmatory escalation when the target, notation, bridge, or endpoint relation is unstable. Measurement failure suspends residual claims in contexts where sign, origin, calibration, missingness, or transport cannot support the intended estimand. Endpoint failure blocks complete-stream language when the stopping or adjudication rule cannot be prospectively justified independently of the tested ledger estimator. Separability failure blocks human work undertaken for the affected confirmatory model comparison when candidate and serious rivals cannot be distinguished under realistic observation. Ethics, privacy, security, or burden failure pauses or stops the affected study or release pathway when care, meaningful refusal, data protection, family or staff burden, or participant protection becomes unacceptable.

These gates are noncompensatory. Success at one gate cannot pay for failure at another. Public artifacts inherit the same ceiling: a diagram, model card, website, or donor summary must be narrowed or withdrawn when the underlying component loses status.

For each failure, record four things: the failed prerequisite, the dependent claims blocked, the knowledge that remains valid, and the condition for responsible reopening. Repeated rival victory or identification failure should trigger the predeclared escalation rule: shift effort toward the better rival, narrower component science, or retirement analysis rather than another protected iteration.

Table 29.6. Release gates, pause rules, and useful stop knowledge.

Gate	Pause or stop condition	Useful knowledge retained
Formal	Bridge, notation, origin, endpoint, or amendment route remains unstable	Which object cannot yet be tested.
Measurement	Sign, rate, calibration, candidate momentary-valence estimator context, or abstention fails	Which estimator or representation should retire or narrow.
Endpoint	Prospective endpoint independence cannot be validated	Which consciousness-state methods need repair.
Separability	Rivals are observationally indistinguishable under realistic data	Which signatures lack empirical content.
Ethics and burden	Unacceptable care or privacy risks, coercion, or disproportionate participant, family, or staff burden	Which questions should remain inaccessible.

Gate	Pause or stop condition	Useful knowledge retained
Repeated loss	Rivals win or bridges fail across independent attempts	Which Law-specific claims should pause, narrow, or be defeated.

Table 29.7. Runnable artifacts and release order.

Artifact	Earliest release condition	Reason for restraint
Synthetic generators and fixtures	After formal object and rival envelope are versioned	Prevents benchmarks from protecting only the favored model.
Study-registration, protocol, and analysis-plan templates	After measurement and endpoint contexts of use are declared	Prevents protocols from hiding unqualified estimands.
Code containers	After dependency and data dictionary are frozen for a release	Makes replication possible without silent software drift.
Model cards and candidate momentary-valence estimator summaries	After external validation and abstention rules exist	Prevents estimators from becoming public inner-life scores.
Clinical protocol materials	After ethics and burden gates pass independently	Protects participants, families, and staff before recruitment.
Public diagrams and captions	After hostile-quotation and crop audits	Prevents uncertainty from becoming a slogan.
Failure logs and correction pages	At first failed gate or retired component	Preserves negative knowledge and blocks repeated overclaim.

After a gate failure, keep the affected artifacts versioned, identify which public objects are withdrawn or superseded, preserve

technically reusable infrastructure, and state the condition for responsible reopening. This keeps correction prospective and prevents an obsolete analysis or status claim from regaining authority merely because its files remain available.

29.7 — What Every Verdict Teaches

Chapter 27 defines the verdict taxonomy in full; this roadmap summarizes the consequence of each class. A result changes only the component, reference class, instrument, endpoint, or route it actually reaches. Replicated component support can justify transport or a stronger next test; partial support narrows the public claim; inconclusive evidence names the remaining uncertainty; instrument or endpoint failure returns work to the failed prerequisite; and rival victory redirects effort to the better explanation. One gate-valid counterexample can reject a declared set-universal [SET-ALL] branch when its stated identification and inferential prerequisites hold. A demonstrated formal contradiction defeats the branch whose stated assumptions entail it. Neither result should be borrowed automatically across a distinct target modality such as a probability-one [P1] branch. If indispensable representation, endpoint, or identification requirements fail beyond independently justified repair, or no ethical discriminating design remains, the strong empirical program may be retired without implying that the latent target is false.

Two protections remain essential. First, no local support becomes whole-Law support, and no route failure becomes automatic target defeat. Second, historical findings remain attached to the versions that generated them so later repairs do not silently inherit evidential credit.

Table 29.8 provides the public-language summary. Every status update should name the object changed, reference class, evidence type, surviving uncertainty, and next decision.

Table 29.8. Verdicts and public language.

Verdict	What it teaches	Public wording discipline
Replicated component support	A specified dependency survived independent tests	Name the component, context, and limits.
Partial or reference-class support	A claim is smaller than hoped but more exact	State the population, instrument, endpoint, and transport question.
Inconclusive evidence	A valid analysis did not decide the question	Name the bottleneck and the next decision-relevant design.
Instrument or endpoint failure	The apparatus is not valid for the intended inference	Repair or retire the instrument before status language advances.
Mechanism retirement or rival victory	A rival or ordinary mechanism explains the signature better	Reduce Law-specific scope and credit the rival.
Target defeat or empirical-program retirement	The exact target is contradicted under its declared prerequisites, or the empirical program is retired after its distinct, testable content is exhausted	Correct public artifacts and preserve useful scientific knowledge.

29.8 — Final Posture: From Architecture to Testing

PTVC is now specified as a scientific hypothesis with a defined formal target and a staged set of testable component questions involving representation, measurement, mechanisms, rivals, endpoints, and verdict rules. That architecture defines a research program. It does not establish that the terminal regularity exists, and it does not by itself determine whether large-scale empirical investment is warranted.

The next question is narrower: which formal, measurement, simulation, or low-burden empirical task has enough decision value to justify the next stage? A study earns priority when it can materially change a component's status, separate serious alternatives, or show that a prerequisite cannot be met. Early work should therefore favor high-information tests that reduce uncertainty before more burdensome designs are considered.

If a terminal regularity exists, a staged program may eventually reveal its scope. If it does not, the same architecture should make that failure legible while preserving useful work on measurement, endpoints, missingness, model recovery, and humane research design.

The opportunity is therefore both ambitious and staged. Laboratories can enter through the component closest to their expertise. Psychometricians can strengthen the measurement bridge. Consciousness researchers can improve bearer and endpoint classification. Statisticians can develop identification, missingness, transport, and model-recovery methods.

Computational scientists can test candidate dynamics and strong rivals. Clinical researchers can determine which low-burden observations are feasible in relevant populations. Independent teams can replicate and extend the results.

A research program becomes especially compelling when its central question is large but its next experiments are concrete. The Law of Fairness now has that structure. The task ahead is to turn the architecture into datasets, simulations, instruments, preregistered comparisons, and independent results.

29.8.1 — What Can Be Tested Next

Near-term work should target dependencies that can change the program at relatively low cost: the integral-product bridge, neutral origin and representation, estimator qualification, endpoint qualification independent of the ledger, and generative model recovery. A reproducible predictive advantage, a validated measurement bridge, or a counterexample can each change the next decision.

Convergent results across independent component tests would justify stronger follow-up; failed recovery, unresolved identification, or inadequate separability would justify redesign, narrowing, or pause. The scientific case for each study should therefore be made at the component level, using expected information gain, burden, opportunity cost, and the availability of lower-cost alternatives, rather than by the importance of the headline hypothesis.

29.8.2 — A Program Built for Independent Investigation

Independent investigation is essential because useful work does not require accepting PTV C in advance. A laboratory can take one defined component, apply its own methods, compare serious alternatives under common rules, and report what the data show.

Different teams can attack different dependencies: measurement and transport, partial identification and missingness, generative benchmarks, or state and endpoint classification. Their results become cumulative only when the assumptions and scope of each component remain visible.

The book also provides unusually rich infrastructure for such collaboration: explicit definitions, study families, model libraries, rival classes, failure modes, reproducibility requirements, versioning rules, evidence states, and public reporting standards. Those materials lower the cost of beginning serious work because researchers need not invent the entire scientific architecture before asking their first question.

A mature research field is created when multiple groups can disagree productively while working on the same answerable problems. The Science of Fairness is intended to make that possible.

29.8.3 — Every Strong Result Moves the Program Forward

The program is structured so that scientific progress can occur at many levels. A stronger measurement relation can improve future studies. A better endpoint method can make previously inaccessible questions testable. A successful model-recovery benchmark can identify which comparisons are genuinely

discriminating. A replicated component can justify transport or a more demanding next protocol.

Positive evidence is especially valuable when it survives independent pressure. A prospectively specified result that transports across sites, remains stable under measurement and missingness sensitivity, and outperforms serious rivals can materially advance the relevant PTVC component. Replication then turns an interesting result into a foundation for the next stage.

The staged architecture allows confidence to grow cumulatively. Researchers do not need one enormous experiment to carry the entire hypothesis. A sequence of well-designed studies can progressively qualify the representation, measurement, endpoint, model, and consequence layers needed for stronger tests.

This creates a practical path from the present book to a mature empirical program. Each credible result can reduce uncertainty, improve the next design, and bring the central question within closer scientific reach.

29.8.4 — Humane Design Makes the Research Stronger

The scientific ambition of the project and its humane design reinforce one another. Low-burden measurement, participant choice, clinically appropriate observation, careful privacy practice, and independent stop authority improve both the ethics and the interpretability of the resulting data.

This is especially important for research involving illness, altered consciousness, or terminal settings. The goal is to discover the strongest evidence that can be obtained within ordinary duties of care. That constraint encourages better questions, better

instruments, less intrusive observation, more realistic missing-data models, and study designs capable of functioning in the environments they claim to describe.

Many foundational studies can occur far from terminal settings. Measurement qualification, simulation, formal verification, model recovery, longitudinal affect studies, sleep research, natural experiments, and prospective prediction can establish much of the infrastructure first. By the time more demanding clinical questions are approached, the program can arrive with better instruments, stronger models, and clearer reasons for collecting each observation.

Humane design is therefore part of the program's scientific strength. It also makes the resulting evidence easier to interpret because observation remains subordinate to care, participant choice, and clinically appropriate stopping.

29.8.5 — Research Value Beyond a Single Test

The program has value beyond any single experiment when its component questions produce reusable methods, discriminating predictions, or clearer failure boundaries. A research group can contribute by solving one difficult component well, including by showing that a proposed measurement, route, or distinction does not survive testing. The broader scientific value should be judged by what remains usable after results narrow or reject the founding hypothesis.

29.8.6 — The Next Step Is to Test It

Further progress now depends on implementation: formal proofs or counterexamples, measurement qualification, synthetic recovery, preregistered comparisons, and independent replication. Each task should begin only when its prerequisite gates are met and should use prospectively specified stop rules when additional work is no longer expected to change the scientific decision enough to justify its cost or burden. The next phase is therefore not a general call to validate the Law, but a sequence of component tests that can support, narrow, redirect, or retire parts of the program.

Table 29.9 converts that architecture into immediate handoffs. It identifies who can advance each component and the boundaries that keep the resulting work scientifically interpretable.

Table 29.9. Final scientific handoff.

Next action owner	What is handed off	What is not handed off
Formal-law route	Bridge proofs and representation or formal amendments	Silent revision of the Law in scientific prose.
Measurement science	Momentary-valence estimators: qualify, calibrate, define use and abstention	Authority to score persons or read inner life directly.
Consciousness and endpoint science	Unity classification; endpoint windows; false-ending checks	Endpoints defined by predicted neutrality.

Next action owner	What is handed off	What is not handed off
Model-recovery and rival teams	Synthetic challenges, rival generators, and open-set tests	A weak rival space that protects the favored model.
Palliative and clinical partners	Humane feasibility, comfort-first protocols, and stop authority	Sacrificing care for data.
Public-communication stewards	Versioned status, correction logs, artifact withdrawal	Slogans that turn uncertainty into certainty.
The wider series	Questions, contexts, and domains for scientific care	Scientific validation or proof; transition authorization.

Together, those contributions can turn the architecture in this volume into evidence. The immediate priorities are to test the representations, qualify the instruments, strengthen endpoint methods, build capable rivals, run recovery simulations, and replicate results. Future status should follow those outcomes: components may gain support; PTVC may narrow in scope or remain unresolved; the strong empirical program may be retired. The scale of the question should not decide the verdict.

Glossary

A

Abstention: A decision to withhold a positive or negative verdict while specified identification, measurement, endpoint, model, or data-quality requirements remain unresolved.

Action-mediated closure: A candidate route in which the consequences of available actions produce the proposed closure relation.

Active inference: A family of models in which an organism can reduce expected mismatch by updating expectations and by acting on or selecting its environment so preferred or viable states become more likely. See also: Predictive processing; Reinforcement-learning reward signal; Viability kernel.

Ad hoc patch: A change introduced after an adverse result mainly to preserve a preferred conclusion, such as moving the endpoint, recentering the origin, inventing an unseen interval, or excluding a bearer. A legitimate successor must have independent support, create new prospective tests, and leave the earlier result visible. See also: Correction and withdrawal; Endpoint independence.

Adjudicability: The property that a declared target can be validly evaluated under fixed bearer, representation, origin, domain, endpoint, observation, bridge, and inference rules. If the target cannot be defined, identified, or bounded, the result is No adequate estimate; if a required protocol or implementation gate failed, the evidence is Unusable. Neither outcome is support.

Adverse case: A gate-valid case for which the branch-matched inferential object supports the registered Target-adverse conclusion. Exclusion of zero by a deterministic identified set

guaranteed to contain the truth under maintained assumptions yields a deductive counterexample; exclusion by a confidence or posterior object yields only its coverage- or posterior-qualified conclusion. Favorable population averages cannot cancel the case.

Affective valence: The positive, negative, or neutral felt character of conscious experience. In this series, valence concerns how experience feels from within, not merely preference, behavior, reward, arousal, or verbal report.

AI sovereignty: Institutional authority assigned to an artificial intelligence system over a person's inner life, worth, standing, or eligibility, a use prohibited by the project. Research systems remain assistive tools under accountable human review. See also: Human-worth score prohibition; Testimony-like output; Latent cumulative object.

Almost-sure attainability: The existence of at least one admissible policy that reaches a declared target with probability one from a stated information state. It differs from closure under a fixed law, success under every policy, and limit-sure attainability, where probabilities can approach one without any single attaining policy. See also: Limit-sure attainability; Probability-one closure; Reachability.

Almost-sure closure: See Probability-one closure.

Alternative endpoint branches: Prospectively declared architectures including state coupling, first hitting, absorption, endpoint atoms, singular timing or support, continued experience beyond a protocol boundary, and endpoint-inclusive value. Each

specifies its endpoint, representation, bridge, and testing assumptions. See also: Endpoint atom; First-hitting and absorption routes; State-coupled timing.

Applied lens and formal Law: The applied lens asks bounded present questions about burden, options, care, and repair. The formal Law concerns an exact truth-level condition over one complete qualifying stream. See also: Care before proof and interpretation; Law of Fairness; Target-route distinction.

Arousal: The activation, wakefulness, or energetic mobilization dimension of experience. High or low arousal can accompany welcome, burdensome, mixed, or neutral states. See also: Felt valence; Observation channel and observation model.

Atom at zero: Positive probability mass located exactly at zero in a terminal-residual distribution. Its presence is distinct from concentration within a finite band: a small atom can coexist with a widely dispersed remainder, and strong near-zero concentration can occur without an atom. Probability-one closure requires all mass at zero under the declared law.

Attainability: The existence of at least one admissible route or policy capable of reaching the target from a specified state. Attainability alone does not show that the route will be selected, that it works under partial observation, or that every admissible path closes.

Attrition mechanism: The process by which participants leave, pause, become unreachable, lose access, enter treatment, withdraw permission, or die during longitudinal research, thereby changing who remains visible. Attrition is both a selection

problem and an ethical signal about burden, access, trust, and study design. See also: End of observation; Informative missingness; Longitudinal research trace.

Auxiliary assumption: An assumption needed to connect a theoretical claim to an observation, estimator, or test. A failed prediction may reflect the target hypothesis, an auxiliary assumption, or both, so confirmatory work must state these assumptions in advance.

B

Balance: Book 1's accessible term for exact intrastream terminal valence closure.

Baseline drift: A change over time in a person's use of a rating scale, neutral point, comparison standard, or reporting habit. Unmodeled baseline drift can create an appearance of convergence or closure without a corresponding change in latent phenomenal valence.

Bearer: The truth-level subject or unit to which qualifying felt experiences belong and within which the proposed accumulation is evaluated. Its identity is established through the declared stream and routing criteria. See also: Maximal qualifying conscious stream; Ownership; Stream identity.

Behavioral nonresponse: The absence of expected command following or another observable response under a particular assessment. Motor, sensory, language, medication, arousal, task, and environmental barriers can block expression, so nonresponse alone does not settle whether experience is present or whether a

conscious stream has ended. See also: Felt availability; Low-unity state; Unknown category.

Biological death: The end of biological life. It is not identical by definition to the truth-level endpoint of a conscious stream. The Law formulation used in this series separately includes a biological-death admissibility condition under which biological death may not occur before the declared closure condition has been satisfied for the relevant stream. A qualifying conscious stream may permanently end after satisfying closure while biological processes continue without consciousness, including under artificial life support; such continued nonconscious biological persistence does not extend the completed stream. This additional condition does not identify the truth endpoint, a route to closure, or any particular biological or behavioral marker. See also: Branch; Endpoint-inclusive branch; Truth-level endpoint.

Bipolar branch: A representation branch that keeps positive and negative phenomenal components separate so they may coexist rather than being forced into one momentary net value. It is not interchangeable with the primary additive branch, and results transfer between them only through a justified bridge on a common identified domain. See also: Generalized Terminal Neutrality; Primary additive branch; Scalarization.

Blinded bearer adjudication: A procedure for deciding among bearer or routing models while withholding, as far as possible, the downstream result each classification would help produce. Fixed criteria, independent reviewers, visible disagreement, and outcome separation reduce post hoc routing in favor of the theory. See also: Bearer; Routing; Unknown category.

Blinding: A design safeguard that withholds selected information from participants, investigators, coders, analysts, or adjudicators when that information could bias conduct or interpretation. The form of blinding must fit the study and its ethical limits.

Boundary hypothesis: A hypothesis about a limiting, terminal, or otherwise sharply delimited property of a process rather than a claim about its ordinary moment-to-moment path. PTVC is a candidate boundary hypothesis because it concerns a stream's terminal signed residual.

Branch: A prospectively declared version of a target, model, or test whose bearer, representation, origin, domain, endpoint architecture, target geometry, modality, and reference class are fixed. Transfer between branches uses an explicitly justified bridge.

Bridge: A stated relation, with assumptions, scope, uncertainty, and failure conditions, that licenses movement between distinct objects or levels, such as measured to latent or protocol endpoint to truth-level endpoint.

C

Calibration: The process of relating a measurement system to an independently justified reference so that its origin, scale, uncertainty, and interpretation are known.

Candidate boundary hypothesis: A testable proposal about a specified terminal boundary, evaluated through its representation, measurements, and predicted consequences. See also: Falsifiability; Law of Fairness; Lawhood.

Candidate mechanism: See Candidate route.

Candidate realization: A formula or model proposed as one route-level realization linking received PTVC objects to observable consequences. It carries the formula-status label CR. See also: Candidate route; Formula-status code; Route state.

Candidate route: A proposed mechanism, policy structure, dynamical construction, or mathematical path by which the terminal target might be satisfied. A route can receive support or fail independently of the target hypothesis.

Candidate sentience escalation: A protocol-governed increase in protection when a candidate system's organization, activity, behavior, or welfare signal exceeds the assumptions under which ordinary review was approved. It may trigger verification, monitoring, reduced exposure, independent review, pause, or retirement without declaring consciousness or personhood. See also: Precaution without personhood; Testimony-like output; Theory-derived indicator.

Candidate signature: A prospectively specified observable pattern predicted by a candidate route, such as horizon-sensitive choice, recovery after perturbation, or narrowing variance. It is a testable clue rather than a unique fingerprint, and it gains weight only through transport, adequate measurement, and serious rivals under common rules. See also: Negative control; Nonunique explanation; Predictive fit versus explanation.

Care-before-interpretation rule: The ethical sequence that addresses urgent care, relief, safety, consent, privacy, and dignity before theoretical interpretation.

Care before proof and interpretation: The governing sequence that responds to present pain, fear, danger, illness, or grief with reachable care and protection. Care remains evidence-based, proportionate, revisable, and independent of PTVC's scientific status. See also: Ethical floor; No harm for proof; Outcome independence.

Causal locus: The place in a system where a causal influence is proposed to operate, such as experience generation, action selection, routing, endpoint timing, observation, or reporting. Distinguishing loci helps prevent one process from being mistaken for another.

Channel qualification: The staged process by which a report, sensor, behavior, contextual record, or other observation channel earns a defined research role through technical verification, analytical validation, construct validation, burden review, and specified performance thresholds. See also: Calibration; Multichannel estimate; Observation channel and observation model.

Claim ceiling: The strongest inference supported by a channel, design, model, comparison, or public artifact under its identification, uncertainty, scope, and safeguards. See also: Detachable-excerpt ceiling; Public-artifact limit.

Closure: The satisfaction of a declared terminal target. On the primary additive PTVC branch, closure means that the finite positive and negative phenomenal masses within one qualifying stream are exactly equal; equivalently, its terminal signed residual is zero.

Coercive measurement: Inner-life measurement conducted where authority, dependency, crisis, or structural pressure makes disclosure or monitoring a practical condition of care, work, education, benefits, liberty, opportunity, or standing. A tool is not voluntary when refusal brings penalty, suspicion, or reduced access. See also: Consent, refusal, and withdrawal; Human-worth score prohibition; Participation without surveillance.

Comfort-first observation: A terminal-research order of authority in which routine care, symptom relief, privacy, family presence, and clinical judgment determine whether and when observation may occur. Data collection stops when it interferes with treatment, rest, touch, conversation, spiritual practice, or requested quiet. See also: Care before proof and interpretation; End of observation; Protocol endpoint.

Common-action requirement: Under partial observation, an action or policy must be selected from the information actually available. For probability-one closure, its probability of completion must equal one for almost every compatible latent state under the declared conditional state law. A robust guarantee over every observationally indistinguishable state is stronger and requires its own feasibility and selection premises. State-specific actions that cannot actually be selected do not satisfy either requirement.

Comparative consciousness evidence: Species-appropriate evidence that combines behavior, learning, neurobiology, ecology, affective organization, and motivational tradeoffs into a converging case about possible experience. Human resemblance may inform a bridge but is neither necessary nor sufficient, and

welfare protection need not wait for a complete theory. See also: Precaution without personhood; Theory-derived indicator; Unknown category.

ComparatorStatus: See Scientific verdict axes.

Comparison without forced equivalence: Comparing traditions or ideas through a precise shared question, function, image, or difference while preserving their distinct histories, doctrines, registers, and internal disagreements. See also: Controlled vocabulary transfer; Meaning as optional; Spiritual resonance is not scientific support.

Compensability: A route-specific question about whether a present formal discrepancy remains answerable through safe, realistically available paths before a declared horizon closes. See also: Future optionality; Noncompensable risk; Viability kernel.

Complete felt history: See Complete strict-pre-endpoint felt history.

Complete strict-pre-endpoint felt history: Every qualifying phenomenal contribution owned by one stream before, but not at, its independently defined truth-level endpoint. Completeness is relative to declared bearer, representation, ownership, and domain rules, not to a remembered biography, selected episode, observation window, or final survey. See also: Endpoint-inclusive branch; Maximal qualifying conscious stream; Truth-level endpoint.

Complete strict-pre-endpoint phenomenal domain: The entire qualifying field of conscious experience belonging to one stream before, but not including, its truth-level endpoint. The primary

PTVC target is defined over this complete domain, not merely over a sampled terminal window.

Completion potential: A candidate mathematical function whose decrease, boundary behavior, or terminal value characterizes a proposed route to closure.

Component support: A verdict that one declared component, such as a representation, instrument, endpoint bridge, candidate signature, or route, survived its applicable validity gates and serious rivals within a bounded reference class. Preliminary component support is an initial result; replicated component support requires independent confirmation under compatible rules. See also: Claim ceiling; Replication; Target-route distinction.

Conditional support: The set of values, states, actions, or outcomes that remain possible after conditioning on specified information. Claims about exact closure must distinguish support restrictions from high probability or average behavior.

Conscious stream: A temporally connected sequence or field of qualifying conscious experience treated as one unit under declared identity and routing criteria.

Consent, refusal, and withdrawal: A continuing, practical consent relationship in which information is understandable, alternatives are genuine, retaliation is absent, stopping remains possible, and data consequences are clear. Separate choices may govern participation, monitoring, linkage, reuse, model training, disclosure, continued contact, and deletion. See also: Data

minimization and deletion; Measurement without ownership; Participation without surveillance.

Constraint does not imply design: A distinction between structural relations that limit possible histories and hypotheses about how those relations originated. Each origin hypothesis requires its own explanatory model and evidence. See also: Constraint without a judge; Spiritual resonance is not scientific support.

Constraint without a judge: An impersonal structural or boundary relation governing admissible complete histories. PTVC proposes exact terminal zero in this structural sense while leaving the realizing mechanism open. See also: Candidate boundary hypothesis; Constraint does not imply design; No moral desert, debt, or payment.

Construct-estimand distinction: A construct is the experience-related concept a study intends to represent. An estimand specifies the exact population, time, endpoint, treatment, and analysis quantity it seeks to learn. A cohort mean, individual probability, and path-level endpoint therefore pose different questions. See also: Estimator; Observation channel and observation model; Reference class.

Construct validity: The degree to which a measure, manipulation, or model captures the intended latent construct rather than a neighboring one. For valence research, behavior, reward, arousal, language, and neural activity may inform measurement without being identical to felt valence.

Controlled vocabulary transfer: Use of a technical term across fields with its source meaning, local role, evidential basis, and specialist references made clear. See also: Claim ceiling; Comparison without forced equivalence; Testimony-like output.

Correction and withdrawal: The accountable process of detecting a problem, assessing it, containing harm, correcting the record, propagating the change, documenting it, reviewing controls, and withdrawing or retiring affected claims, comparisons, routes, tools, and public artifacts. Superseded versions remain visible enough to preserve the scientific record. See also: Ad hoc patch; Public-artifact limit.

Counterfactual reachability: Whether a target could be reached under one or more alternative admissible actions or policies from a specified state. Counterfactual reachability does not establish what actually occurred or what a partially informed agent could select.

Craving capture: The narrowing of attention and immediately reachable options when a learned cue, urge, withdrawal state, or expected relief becomes unusually salient. It can constrain lived choice and future optionality. See also: Future optionality; Lived choice; Reinforcement-learning reward signal.

D

Data as trace: A report, waveform, image, note, gesture, archive, or model output is a context-bound record produced through an observation process. Its interpretation uses the relevant measurement model and provenance. See also: Latent cumulative object; Observation channel and observation model; Provenance.

Data-generating process: The full process that produces the observed data, including latent states, dynamics, routing, selection, measurement, missingness, and reporting. A valid analysis must consider whether more than one process can generate the same observations.

Data minimization and deletion: The discipline of collecting and retaining only the least revealing data needed for a declared question, while governing removal or restriction across raw records, features, backups, shared copies, outputs, and trained-model influence. Deletion promises must accurately state their technical reach and residual limits. See also: Consent, refusal, and withdrawal; Provenance; Record-regime separation and no-dossier rule.

Decision rule: A prespecified mapping from evidence to an outcome such as support, adverse result, narrowing, abstention, or route retirement. Decision rules should be fixed before outcome inspection whenever confirmatory status is claimed.

Defeat condition: A prospectively specified result that counts against a target, route, measurement claim, or auxiliary assumption under stated validity and inference rules.

Desert-based fairness: The question of when praise, reward, blame, or sanction properly follows from what a person chose and did. Its legitimate use is narrow and evidence-based. See also: External justice; No moral desert, debt, or payment; Procedural fairness.

Detachable-excerpt ceiling: The evidential scope a headline, quotation, caption, slide, social post, translation, donor summary,

or AI explanation retains when encountered apart from its source. Accurate, concise wording identifies the result being communicated. See also: Claim ceiling; Portable safeguard; Public-artifact limit.

Dignity firewall: The project's grounding of dignity, rights, care, safety, treatment, privacy, and relief in ethical principles independent of PTVC's scientific status.

Dimensionality of valence: The question whether phenomenal valence can be represented on one signed dimension or requires multiple dimensions. The primary additive PTVC branch uses a signed representation, but that representation remains an empirical and conceptual commitment to be tested.

Direct identification: Identification obtained from assumptions and observations that determine the target without relying on a route merely because it fits. Direct identification is distinct from selecting one convenient model among several observationally equivalent alternatives.

Dream-as-felt-experience window: An interval of conscious experience during sleep that may belong to the felt history of a stream even when waking recall omits it. Studies relate that interval to sleep stage, reports, and the adopted continuity model. See also: Complete strict-pre-endpoint felt history; Dream-report chain; Reversibility and return rule.

Dream-report chain: The sequence connecting experience during sleep, awakening, the memory trace available afterward, and the report given to another person. Each transition can select,

reorder, or reshape what enters the record. See also: Data as trace; Informative missingness; Response shift.

E

Empirical band: See Finite-band compatibility and measured equivalence.

End of observation: The last time usable data are obtained because a channel fails, monitoring stops, communication is lost, privacy is requested, or another practical event occurs. It is an observation boundary that may precede the protocol endpoint and truth-level endpoint and creates missingness rather than terminal truth. See also: Protocol endpoint; Truth-level endpoint; Observation window.

Endpoint: The boundary at which a qualifying conscious stream ceases for purposes of the truth-level target. The endpoint must be defined by the stream model and cannot simply be replaced by biological death, loss of contact, device shutdown, or the last available report.

Endpoint atom: Positive probability mass assigned by a declared endpoint-time or marked-endpoint law to a particular time or point. It specifies endpoint timing or marking, distinct from probability mass at a terminal residual of zero. See also: Atom at zero; First-hitting and absorption routes; State-coupled timing.

Endpoint bridge: The independently validated relation connecting an observed or protocol endpoint, possibly an interval, to the truth-level endpoint required by the claim while carrying error, return, revision, confounding, and competing-event

uncertainty. See also: Protocol endpoint; Reversibility and return rule; Truth-level endpoint.

Endpoint conditioning: Selecting, observing, conditioning, or reweighting trajectories according to where they end. This can change the apparent earlier drift or dispersion and supplies an explicit statistical model for comparison. See also: Candidate signature; Endpoint independence; Random-endpoint obstruction.

Endpoint coupling: A candidate route in which endpoint timing or endpoint conditions depend on the evolving stream state. Tests compare the predicted relationship with alternative accounts of endpoint timing and pre-endpoint dynamics.

Endpoint firewall: See Endpoint independence.

Endpoint-inclusive branch: A prospectively declared branch that assigns a specified phenomenal contribution exactly at the endpoint. Its temporal domain includes a point excluded from the primary strict-pre-endpoint branch, so comparison between the branches requires the corresponding domain and representation bridge. See also: Complete strict-pre-endpoint felt history; Exact terminal closure; Truth-level endpoint.

Endpoint independence: Two noninterchangeable conditions must be distinguished. Prospective endpoint independence fixes the endpoint branch, evidence source, selection rule, and adjudication procedure without using a ledger estimate or terminal residual to choose the endpoint. Probabilistic path-endpoint independence states, under a specified reference law, that endpoint time is independent of the sigma-field generated by

the pre-endpoint ledger path; it is a premise of the independent-diffuse-endpoint theorem. The first condition does not imply the second. See also: Ad hoc patch; Protocol endpoint; Random-endpoint obstruction.

Endpoint marker: An observable event or signal used to estimate or bound a truth-level endpoint. A marker can be informative without being identical to the endpoint itself.

Endpoint uncertainty and ambiguity: Multiple defensible interpretations of endpoint identity, timing, or interval under the declared evidence and rules. Prospective adjudication represents that uncertainty and states when it yields No adequate estimate. See also: Endpoint bridge; No adequate estimate; Truth-level endpoint.

Equal-budget comparison: See Rival model and equal-budget comparison.

Equivalence band: A prespecified finite interval around a reference value within which effects are treated as practically equivalent for a stated purpose. An equivalence result around zero supports only the declared finite-band claim; it does not establish exact zero.

Error budget: An explicit accounting of uncertainty from sampling, instruments, calibration, sign, origin, timing, missingness, model choice, transport, and construct identification across the evidence chain. Separating these sources identifies which additional data or methodological changes could improve the result. See also: Calibration; Noise floor; Partial identification.

Estimand: The precisely defined quantity an analysis seeks to learn, including its population, unit, time domain, conditioning, and scale. The estimand is not the same as the estimator used to calculate it.

Estimator: A rule or procedure for using observed data to estimate an estimand. An estimator may be biased, uncertain, inconsistent, or nonidentifying even when its numerical output is close to zero.

Ethical burden too high: A typed outcome in which a scientifically coherent question is not ethically available because the required burden, privacy exposure, dependency, deception, bystander risk, or lasting effect is disproportionate. Consent, payment, technical sophistication, or promised decisiveness cannot cure the design; it must be redesigned or left unanswered. See also: No harm for proof; No adequate estimate; Safe perturbation.

Ethical floor: The nonnegotiable safeguards that keep present pain a claim on care, reject earned suffering and cross-stream payment, forbid harmful testing, protect consent and refusal, place relief before interpretation, and allow meaning to be declined. These protections hold under every scientific outcome. See also: Care before proof and interpretation; No harm for proof; Outcome independence.

Every-continuation closure: Every continuation in a prospectively declared nonempty admissible continuation class satisfies closure. The claim says nothing about paths outside that class and is not implied by probability-one closure or support

containment. If the class is empty or undefined, closure is unavailable rather than vacuously established. See also: Probability-one closure; Reachability; Support containment.

Evidence ladder: A map of evidential dependencies and branch-specific implications. Descriptive convergence, finite-band equivalence, an atom at zero, probability-one closure, and set-universal closure are not interchangeable; some require additional bridges and are not ordered by a single strength scale. Each result states its target and what further inference it licenses.

Exact closure: The truth-level condition that one qualifying stream's terminal signed residual is exactly zero. Exact closure is not interchangeable with near-zero measurement, mean-zero aggregation, an interval containing zero, or practical equivalence.

Exact terminal closure: See Exact closure.

Exact zero: See Exact closure.

Experienced exposure and unity gate: Experienced exposure is the declared measure of how qualifying phenomenal experience contributes across a stream and may differ from calendar time. The unity gate states when felt contribution is treated as active and owned by the stream. See also: Complete strict-pre-endpoint felt history; Maximal qualifying conscious stream; Ownership.

External justice: Rights, capabilities, opportunities, material conditions, duties, institutions, protection, and remedy grounded in the project's independent ethical and legal principles. See also: Outcome independence; Procedural fairness; Hidden burden and hidden relief.

F

Failed upstream gate: An unmet prerequisite, such as representation, origin, bearer, endpoint, observation, measured-to-latent bridge, or transport, that determines which downstream conclusions remain available. See also: Measured-to-latent bridge; No adequate estimate; Scientific verdict axes.

Falsifiability: A scientific claim's specification of observations or evidence objects that could count against it under prospectively declared validity requirements and decision rules. See also: Candidate boundary hypothesis; Gate-valid counterexample; Strong-form defeat.

Falsification: A result that conflicts with a prespecified claim under the study's stated assumptions and validity gates. Falsification must identify which target, route, or auxiliary claim is affected rather than overgeneralizing from one failed component.

Felt availability: The modest claim that something is occurring for a conscious stream even when the experience cannot be spoken, deliberately used, remembered later, or organized into a clear self-story. It separates possible experience from an observer's access to evidence about it. See also: Behavioral nonresponse; Low-unity state; Observation channel and observation model.

Felt valence: The evaluative character of qualifying conscious experience as lived from within. Under a declared scalar signed representation it is positive, negative, or neutral relative to an independently justified origin; a bipolar branch preserves co-

occurring positive and negative components. See also: Arousal; Bipolar branch; Neutral origin; Primary additive branch.

Finite-band compatibility and measured equivalence: Latent finite-band compatibility requires the complete nonempty latent compatibility object to lie wholly inside a prospectively calibrated latent acceptance set. Measured equivalence requires the complete nonempty measured compatibility set to lie wholly inside the appropriate bridge-defined measured region. Partial overlap or merely including zero is unresolved. See also: Exact terminal closure; Measured-to-latent bridge; Terminal residual compatibility object.

Finite signed phenomenal measure: A finite signed measure representing positive and negative phenomenal valence over a qualifying stream's complete strict-pre-endpoint domain. Finiteness permits well-defined positive and negative Jordan masses and a terminal signed residual.

Finite soft-guidance ceiling: Under the registered finite power-weighting route, any retained positive probability mass on actions with completion probability below one prevents probability-one completion. This is a probability-mass result; topological-support containment and set-universal closure require separate premises.

Finiteness: On the primary finite branch, each complete positive and negative phenomenal magnitude is finite. This is a per-stream condition; different streams may have different finite totals. See also: Positive and negative phenomenal magnitudes; Primary additive branch; Gross experience.

Firewall: An explicit boundary that prevents evidence or language in one domain from being used to justify an unsupported conclusion in another. The series uses scientific, ethical, legal, institutional, and spiritual firewalls.

First-hitting and absorption routes: A first-hitting route uses the first entry into a prospectively declared set. An absorption route additionally keeps the process within that set afterward. Relating either event to the truth-level endpoint uses a separately specified endpoint bridge. See also: Endpoint atom; Endpoint bridge; State-coupled timing.

Fission-and-fusion routing rule: Under the book's primary formal convention, genuine fission ends the parent stream and begins each qualifying child stream, while genuine fusion ends the prior streams and begins a new one. Earlier phenomenal balances are neither duplicated among descendants nor pooled into the fused stream. See also: Bearer; Routing; Stream identity.

Fitness, feeling, and moral worth: The distinction among reproductive propagation, the valenced quality of a bearer's experience, and the ethical standing owed to that being. Each is evaluated through its appropriate biological, experiential, or ethical framework. See also: Comparative consciousness evidence; External justice; Viability kernel.

Formal or latent phenomenal ledger: On the primary additive branch, the latent cumulative signed phenomenal-value process through time. See also: Latent cumulative object; No moral desert, debt, or payment; Terminal residual.

Formula-status code: The labels attached to formulas in the technical synopsis: R = received definition; CR = candidate realization; OE = operational estimator; DC = design criterion; and OC = open conjecture. They classify a formula's role, not its empirical support.

Future optionality: The meaningful future paths a person can realistically reach through available time, bodily capacity, material conditions, relationships, information, institutions, treatment, support, and action. These conditions can widen or narrow the available paths. See also: Compensability; Craving capture; Lived choice.

G

Gate-valid counterexample: An adverse case that passes the declared bearer, representation, origin, domain, endpoint, observation, bridge, and inference gates for the tested branch. Deductive exclusion requires a deterministic truth-containing object guaranteed under maintained assumptions to exclude the target. Confidence or posterior objects support only their registered coverage- or posterior-qualified adverse conclusions, not literal universal refutation. See also: Falsifiability; Set-universal closure; Strong-form defeat.

Gate-valid stream: A qualifying stream that satisfies the prespecified inclusion, endpoint, measurement, data-quality, and model-validity gates required for the declared test. Only gate-valid cases may carry the evidential status assigned by that test.

Generalized Terminal Neutrality: A broader family of terminal-zero conditions defined by a declared functional, measurable

output space, and distinguished zero when scalar addition would lose relevant structure. It is a separate branch and is not PTVC unless a justified bridge connects its zero condition to the additive positive-negative decomposition. See also: Bipolar branch; Primary additive branch; Scalarization.

Gross experience: On a declared additive scalar representation, the complete positive-plus-negative phenomenal variation before cancellation. Its value can differ across streams with the same terminal residual. See also: Outcome independence; Phenomenal magnitude; Terminal residual.

Gross negative valence: The total magnitude of negatively valenced phenomenal mass within one stream, evaluated separately from positive valence.

Gross positive valence: The total positively valenced phenomenal mass within one stream, evaluated separately from negative valence.

H

Hedonic adaptation: The changing emotional impact of a gain, loss, or continuing condition as novelty, attention, expectations, comparison, routine, and context change over time. Adjustment varies across events, people, domains, measures, and times. See also: Opponent process; Response shift.

Held-out transport: Testing whether a prospectively specified model or result travels to data, settings, populations, channels, periods, or endpoint regimes reserved from model development and tuning. See also: Measurement invariance; Model recovery; Reference class.

Hidden burden and hidden relief: The observation that visible advantage may coexist with distress and visible hardship with joy, competence, love, meaning, or peace. It motivates direct attention to experience alongside external conditions. See also: External justice; Measurement without ownership; Per-stream claim.

Hidden cumulative object: See Latent cumulative object.

Hidden-state model: A model in which the process of interest contains latent states that are inferred from observable signals. Such a model must distinguish state dynamics, observation error, routing, selection, and missingness.

Homeostasis and allostasis: Homeostasis regulates variables within workable ranges, while allostasis anticipates changing demands by adjusting operating levels, mobilizing resources, and redistributing physiological cost. These processes provide measurable architectures for studying regulation, recovery, and resource use. See also: Mean reversion; Opponent process; Viability kernel.

Human-worth score prohibition: No estimate of burden, mood, pain, resilience, contribution, regulation, apparent balance, or unity may measure or rank human worth, credibility, trustworthiness, holiness, competence, deservingness, or eligibility. The prohibition applies to labels, visuals, dashboards, proxy scores, and model outputs. See also: AI sovereignty; Coercive measurement; Record-regime separation and no-dossier rule.

I

Identification: The ability of the available data and stated assumptions to distinguish the target quantity or model from alternatives. More data cannot resolve nonidentification when competing explanations remain observationally equivalent under the design.

Identified set: The set of every target value compatible with the observed data, admissible measurement models, and declared assumptions. It is not a confidence interval: partial identification and sampling uncertainty are separate layers and may both need reporting. See also: Partial identification; Terminal residual compatibility object.

Inconclusive evidence: Evidence from a valid analysis that does not resolve the declared estimand within the prespecified uncertainty and sensitivity bounds. It is neither support nor Unusable evidence.

Independent neutral-origin calibration: A procedure that identifies the valence zero point using evidence and rules independent of the completed record's terminal residual.

Inference: Reasoning from observations and assumptions to conclusions about latent quantities, models, mechanisms, or populations. Every inference inherits the limits of its measurements, design, identification conditions, and auxiliary assumptions.

InferenceStatus: See Scientific verdict axes.

Informative missingness: Missing observations whose occurrence relates to burden, state, access, treatment, refusal, shutdown, or another factor relevant to the inference, so visible records may differ systematically from what disappeared. A missing report is not zero, neutrality, noncooperation, or absence of experience. See also: Attrition mechanism; Missingness; Observation channel and observation model.

Institutional administration limit: Courts, governments, employers, insurers, schools, platforms, clinicians, families, and religious bodies have no authority to possess or administer the latent cumulative object as a fact about worth, credibility, eligibility, fault, care priority, spiritual standing, or terminal status. Bounded research estimates cannot create that authority. See also: Human-worth score prohibition; Latent cumulative object; Record-regime separation and no-dossier rule.

Interoceptive prediction: The anticipation and interpretation of bodily signals such as heartbeat, breathing, pain, fatigue, hunger, nausea, temperature, and arousal through expectations, context, uncertainty, attention, and action. See also: Active inference; Predictive processing; Prediction error and valence.

Interval contribution estimate: An operational estimate $\widehat{\Delta L}_{i,[a,b]}$ of accumulated measured contribution over a declared interval, constructed from a versioned momentary estimator and exposure/time rule with propagated uncertainty. See also: Momentary valence estimator; Phenomenal ledger.

Intrastream: Evaluated within one conscious stream at a time. The term fixes the scope of the proposed equality and excludes

netting across people, households, families, populations, species, institutions, or ensembles, even when experiences are causally connected or socially interdependent. See also: Nontransferability; Per-stream claim; Routing.

Intrastream closure: Closure evaluated within one qualifying conscious stream. Positive valence in one stream cannot cancel negative valence in another, and no population total substitutes for a stream-level target.

Invariance under positive rescaling: The property that multiplying a valid signed valence representation by a positive constant leaves its sign structure and exact-zero closure status unchanged. This does not license arbitrary nonlinear transformations or shifts of the neutral origin.

J

Jordan decomposition: The representation of a finite signed measure as the difference between mutually singular positive and negative measures. Their total masses provide the positive and negative phenomenal quantities compared by the primary additive PTVC target.

Jordan masses: The total positive and total negative masses produced by the Jordan decomposition of a finite signed phenomenal measure. Exact closure requires equality of these two masses within the same qualifying stream.

L

Last conscious experience: The final qualifying experience before a truth-level stream endpoint, when such a final experience

is well-defined. PTVC does not require this last experience itself to feel neutral and does not equate it with the last observed report.

Latent cumulative object: The unobserved formal representation of signed qualifying felt experience accumulated within one stream across its declared domain. Reports and instruments constrain it through a measurement model. See also: Formal or latent phenomenal ledger; Measured-to-latent bridge; Terminal residual.

Latent valence: The unobserved phenomenal valence attributed to experience itself and investigated through models linking reports, behavior, physiology, and neural signals.

Law of Fairness: The series' public name for the proposed idea that each qualifying conscious stream may satisfy exact terminal valence closure, together with the wider inquiry built around it. In scientific use, it remains a candidate hypothesis rather than an established law of nature.

Lawhood: The scientific aspiration to discover a general structural condition on completed qualifying streams. Its evaluation uses identified objects, invariance, prediction beyond construction data, capable comparisons, replication, explicit scope, and prospective decision rules. See also: Candidate boundary hypothesis; Falsifiability; Claim ceiling.

Ledger: See Formal or latent phenomenal ledger.

Limit-sure attainability: The property that policies can make the probability of closure arbitrarily close to one, even though no single admissible policy need achieve probability-one closure. Within the same fixed environment and nonempty admissible

policy class, it is weaker than almost-sure attainability and does not establish closure under an arbitrary fixed law or every admissible continuation.

Lived choice: The capacity to form purposes, choose among meaningful options, revise, refuse, and act with others from within real bodily, social, historical, and material conditions. Reversibility and opportunities for review and repair can help guide decisions under uncertainty. See also: Craving capture; Future optionality; Target-route distinction.

Local return and terminal closure: The separation between movement toward a familiar range during an episode or observed interval and a proposed exact cumulative condition at the independently defined end of one complete qualifying stream. See also: Hedonic adaptation; Mean reversion; Pathwise closure.

Longitudinal ledger: A model-based representation of accumulated signed phenomenal valence across a stream.

Longitudinal research trace: A repeated sampled record created through changing instruments, schedules, contexts, purposes, and permissions. It can reveal trajectories and within-person change but remains a borrowed trace rather than a biography, complete phenomenal history, or ownership of the person. See also: Attrition mechanism; Consent, refusal, and withdrawal; Response shift.

Low-unity state: A state in which ordinary access, responsiveness, integration, or evidence of unified experience is reduced or uncertain, as in sleep, anesthesia, coma, delirium, or severe brain injury. It may be a pause, altered-state branch, or

unresolved interval rather than the end of a stream. See also: Behavioral nonresponse; Reversibility and return rule; Truth-level endpoint.

M

Maximal qualifying conscious stream: A qualifying stream extended as far as the adopted routing and identity criteria permit, with the complete resulting domain retained for analysis.

Mean reversion: A local statistical or control tendency for an extreme observation to move toward a typical range because of feedback, stable dynamics, regression, sampling noise, treatment, or changed context. See also: Homeostasis and allostasis; Local return and terminal closure; Nonunique explanation.

Mean-zero result: A finding that an expectation or sample average equals or approaches zero. It describes the aggregate, in which positive and negative individual residuals can cancel.

Meaning as optional: The freedom to make, receive, revise, postpone, refuse, or live without an encompassing religious, spiritual, philosophical, or secular interpretation of experience, grief, suffering, or the Law. Nonbelief, doubt, silence, and exit retain full dignity and may never become barriers to care or belonging. See also: Care before proof and interpretation; Comparison without forced equivalence; Spiritual resonance is not scientific support.

Measured-to-latent bridge: The independently justified relation that allows a result on a measured estimand to constrain the declared latent phenomenal target, with scope, uncertainty, and failure conditions carried forward. It is separate from the

observation model, endpoint bridge, estimator, and route; without it, evidence remains on the measured scale. See also: Endpoint bridge; Estimator; Latent cumulative object.

Measurement invariance: The tested stability of a measurement relation across the people, groups, languages, devices, sites, times, or contexts for which a comparison is proposed. Its results identify supported comparisons and opportunities for further calibration. See also: Calibration; Held-out transport; Response shift.

Measurement model: A formal account of how latent valence or related states generate reports, behavior, physiology, neural signals, or other observations. It includes scale, origin, error, drift, and possible response-process distortions.

Measurement reactivity: Change in experience, behavior, disclosure, or the observation process caused by measurement itself, including repeated prompts, wearables, interviews, monitoring, and study expectations. Reactivity must be minimized, estimated, or carried into interpretation because it can alter both the target interval and the evidence collected. See also: Informative missingness; Observation channel and observation model; Consent, refusal, and withdrawal.

Measurement without ownership: Experience may be described, compared, and modeled without transferring ownership to a clinician, researcher, institution, record, or algorithm. Measurement creates responsibilities for purpose limitation, consent, privacy, correction, uncertainty, and stopping, not authority over a person's inner truth, worth, eligibility, or care.

See also: Observation channel and observation model; Consent, refusal, and withdrawal; Human-worth score prohibition.

Mechanism retirement: See Route retirement.

Metrology: The discipline of measurement, including units, calibration, traceability, uncertainty, comparability, and error. It provides the tools for making PTVC's quantitative predictions empirically interpretable.

Missingness: The process by which observations are absent, censored, truncated, or unavailable. Missingness near endpoints may be informative, and treating it as random without support can bias terminal conclusions.

Modal reachability ladder: A family of nonequivalent, scope-dependent claims, including existence of a closing continuation, positive-probability completion, fixed-law probability-one closure, limit-sure attainability, almost-sure attainability, support containment, and closure of every admissible continuation. These claims do not form one unconditional total order. Within the same fixed environment and nonempty admissible policy class, almost-sure attainability implies limit-sure attainability; a support-containment claim additionally requires a declared topology. Every implication must preserve the carrier, completion event, policy scope, and relevant assumptions. See also: Almost-sure attainability; Every-continuation closure; Support containment.

Model ambiguity: Model-ambiguous means two or more adequate declared models remain practically indistinguishable under the common rules. Open-set inadequate means no declared model is adequate. No adequate estimate means that the target or

estimand is undefined or cannot be identified or bounded under the available data and maintained assumptions, including because ethically permissible evidence is insufficient. A failed protocol or implementation gate yields Unusable evidence. See also: No adequate estimate; Rival model and equal-budget comparison; Scientific verdict axes.

Model-ambiguous: See Scientific verdict axes.

Model governance: Accountable rules for choosing a model's target, data, loss function, constraints, interventions, permitted uses, review process, correction route, and verdict. See also: Decision rule; Human-worth score prohibition; Scientific verdict axes.

Model recovery: A simulation-based check of whether an analysis can distinguish candidate model families when their generating identities are known. Parameter recovery separately tests estimation of parameters under a specified generator. Both are evaluated under realistic observation conditions; success in one does not establish success in the other.

Momentary valence estimator: A versioned, context-bound operational estimator $\hat{v}_i(t)$ of a valence-rate-like contribution from declared observation channels under a measurement model. See also: Interval contribution estimate; Measurement model.

Motivation: The internal or external factors associated with action selection. A policy describes a mapping from information or state to actions; it should not be equated with the person's consciously experienced motive.

Multichannel estimate: A versioned, purpose-bounded estimate formed through an explicit model relating channels such as report, behavior, physiology, neural data, and context to a declared construct and estimand. See also: Error budget; Observation channel and observation model; Provenance.

N

NAE: See No adequate estimate.

Narrowing: A transparent reduction in the surviving reference class, target branch, measurement version, endpoint class, or claim strength after a limitation or adverse result. A narrowed claim receives a new scope or version and does not count as confirmation of the unchanged original. See also: Reference-class narrowed; Verdict.

Near-zero band: A finite interval around zero used to describe limited measurement resolution, uncertainty, or practical closeness.

Negative control: A condition, timing, procedure, or outcome that should not show the proposed signature if an explanation is specific. Matched non-horizon tasks, sham procedures, impossible timing, and alternate outcomes can expose generalized arousal, demand, leakage, selection, or analytic flexibility. See also: Candidate signature; Nonunique explanation; Safe perturbation.

Net valence: Positive phenomenal mass minus negative phenomenal mass within a specified stream and domain.

Neutral origin: The identified zero point separating positive from negative phenomenal valence in the adopted representation. Its location must be justified independently rather than chosen to make terminal records balance.

No adequate estimate: A prespecified inference status used when the target or estimand is undefined or cannot be identified or bounded under the available data and maintained assumptions, including because the evidence needed to identify it is ethically unavailable. A valid but unresolved analysis is Inconclusive evidence; evidence from a failed protocol, consent, endpoint, measurement, provenance, computation, or participant-protection gate is Unusable evidence. The reason and affected estimand are recorded. See also: Abstention; Decision rule; Model ambiguity.

No moral desert, debt, or payment: PTVC does not assign moral entitlement or an obligation to suffer. Under exact closure, a genuinely nonzero accumulated balance requires an equal and opposite signed remainder within the same stream. This is conditional accounting, not a known personal balance, a fixed quota of suffering, or a method for choosing future rewards. Care and responsibility retain their independent ethical grounds. See also: Constraint without a judge; Desert-based fairness; Outcome independence.

No harm for proof: The prohibition on inflicting, prolonging, intensifying, staging, ignoring, or leaving suffering unrelieved in order to test, demonstrate, dramatize, or promote PTVC. It covers unsafe self-testing, delayed care, coerced disclosure, vulnerable participants, and plausible synthetic suffering; principled

abstention remains available. See also: Care before proof and interpretation; Ethical floor; Stop authority.

No-neutrality-by-fiat: The rule that origin, baseline, sign, scalarization, endpoint, smoothing, missingness treatment, weights, and exclusions may not be chosen after outcome inspection to manufacture apparent neutrality. Deviations require visible exploratory or sensitivity status.

No personal endpoint testing: No person should try to test the Law by approaching danger, loss of consciousness, treatment refusal, self-harm, deprivation, violence, or death. Such acts create risk but cannot identify the bearer, complete domain, endpoint, missingness process, origin, or measured-to-latent bridge required for valid evidence. See also: Care before proof and interpretation; No harm for proof; Truth-level endpoint.

No-score rule: See Human-worth score prohibition.

Noise floor: The smallest distinction an observation system can reliably resolve under declared conditions. Rounding, censoring, preprocessing, and random or systematic noise help determine that resolution. See also: Calibration; Error budget; Finite-band compatibility and measured equivalence.

Noncompensable risk: The modeled risk that, under specified conditions and uncertainty, an action or state closes essential paths faster than remaining channels can reopen them. It is a route- or continuation-level diagnostic. See also: Compensability; Future optionality; Viability kernel.

Nonidentification: A condition in which different target values or models are equally compatible with the available observations

and assumptions. Reporting a single precise estimate under nonidentification creates false certainty.

Nontransferability: The rule that valence belonging to one conscious stream cannot be credited to, debited from, or used to balance another stream.

Nonunique explanation: Several mechanisms generate the same observed trajectory, endpoint concentration, rebound, report, compression, or return pattern. Additional observations, interventions, or model comparisons can investigate the differences among them. See also: Candidate signature; Mean reversion; Model ambiguity.

Null model: A specified alternative under which the distinctive PTVC target or route is absent. A useful null model makes concrete predictions and is tested alongside serious rivals rather than serving as a vague absence of effect.

Null outcome: A result that does not support the tested effect or distinction under the declared analysis. A null outcome may be informative, inconclusive, or adverse depending on power, identification, and the prespecified decision rule.

O

Objective functions versus experience: The distinction between a modeler's rule for ranking selected outcomes and the lived experience the model seeks to investigate. A measurement relation states which aspects of experience the chosen objective represents. See also: Model governance; Reinforcement-learning reward signal; Viability kernel.

Observation: A recorded report, behavior, physiological measure, neural signal, event, or other data item interpreted through the relevant observation model.

Observation channel and observation model: An observation channel is recorded evidence such as report, behavior, physiology, neural activity, or context. The observation model states how a latent construct and nuisance conditions can generate or alter that output, including sampling, timing, error, and channel failure. Neither the channel nor its model is the experience. See also: Informative missingness; Measured-to-latent bridge.

Observation model: See Observation channel and observation model.

Observation process: See Observational process.

Observation shutdown: The process or protocol event in which one or more observation channels close because a device is removed or fails, a report is skipped or becomes impossible, privacy or consent changes, care takes priority, staff capacity changes, or contact is lost. Shutdown creates structured missingness and can mimic terminal compression; it is not the truth-level endpoint. Complete shutdown may determine the end of observation. See also: End of observation; Informative missingness; Observational process.

Observation window: The finite span during which a study records data. Its relation to the complete stream is specified through the observed interval, any missing prefix or remainder, and the applicable measurement and endpoint bridges. See also:

Complete strict-pre-endpoint felt history; End of observation; Protocol endpoint.

Observational process: The mechanism by which latent experience and system states become recorded data, including measurement error, reporting, censoring, sampling, and missingness. It must be modeled separately from the target process.

Open-set inadequate: See Scientific verdict axes.

Opponent process: A temporal counterprocess in which an initial state recruits a later afterstate whose strength and timing may change with repetition, helping explain relief, recovery, tolerance, withdrawal, fatigue, and rebound. See also: Hedonic adaptation; Local return and terminal closure.

Origin problem: The inability to interpret exact zero unless the neutral origin is independently identified. A constant shift in a valence rate changes the accumulated ledger in proportion to included exposure, so post hoc centering can manufacture closure. See also: Independent neutral-origin calibration; Neutral origin.

Outcome independence: Care, rights, dignity, privacy, repair, ordinary causation, and independently supported knowledge retain their own grounds across changes in PTVC's scientific status. See also: Care before proof and interpretation; Ethical floor; Strong-form defeat.

Ownership: The prospectively specified rule assigning each qualifying phenomenal event or contribution to its bearer without omission, double counting, or cross-stream transfer. Ownership

answers whose experience a contribution is, while routing governs continuity through time and transitions; data ownership is a different legal and institutional question. See also: Bearer; Nontransferability; Routing.

P

Palliative sedation: A clinically governed process used proportionately to relieve otherwise refractory suffering, with varying drugs, depths, durations, routes, and circumstances. It is treatment rather than a standardized consciousness manipulation or clean terminal signal, and research must never delay relief, alter indicated titration, or prefer observability over comfort. See also: Comfort-first observation; End of observation; Protocol endpoint.

Partial identification: A condition in which the evidence restricts a target to a set or interval while leaving more than one value possible under the maintained assumptions.

Partial observation: A decision or inference setting in which the relevant latent state is not fully observed. Closure claims in such settings must respect common-action and selection requirements rather than assuming state-specific knowledge.

Participation without surveillance: A research architecture that keeps participation voluntary through purpose separation, data minimization, practical privacy controls, ordinary nonparticipation, correction, and eventual deletion. A person may contribute selected observations without granting permanent access, hidden inference, public ranking, or ownership of the life described. See also: Consent, refusal, and withdrawal; Data

minimization and deletion; Record-regime separation and no-dossier rule.

Past-fixity: Later experience may add to the future portion of a stream but cannot retroactively change what earlier experience was. This temporal discipline permits formal future complementarity while forbidding moral or phenomenal repricing of the past, including claims that later joy makes earlier abuse acceptable. See also: Outcome independence; Formal or latent phenomenal ledger; Reserve coupling.

Pathwise closure: Closure evaluated on complete individual trajectories. The stated quantifier distinguishes one realized path, probability-one closure, support containment, and closure of every admissible path. See also: Complete strict-pre-endpoint felt history; Probability-one closure; Set-universal closure.

Per-stream claim: A claim evaluated for each separately routed maximal qualifying conscious stream as its own unit rather than for a population, household, country, species, or group average. See also: Intrastream; Maximal qualifying conscious stream; Population mean and expected neutrality.

Per-stream terminal valence closure (PTVC): On the primary additive branch, the candidate boundary hypothesis that every separately routed maximal qualifying conscious stream in the declared reference class carries a finite signed phenomenal measure over its complete strict-pre-endpoint domain whose positive and negative Jordan masses are exactly equal; equivalently, its terminal signed residual is zero.

Phenomenal ledger: See Formal or latent phenomenal ledger.

Phenomenal magnitude: The represented amount of positive or negative felt experience assigned to a stream under a declared valence representation. Positive and negative gross magnitudes are evaluated separately from their signed net difference. See also: Felt valence; Gross experience; Positive and negative phenomenal magnitudes.

Phenomenal measure: A measure assigned to conscious experience itself for purposes of representing valence across a stream. It is conceptually distinct from clock time, event count, memory strength, neural activity, or report frequency.

Phenomenal time: A measure or ordering of experienced duration within a conscious stream. It need not coincide uniformly with external clock time and should not be inferred solely from the number of observations.

Phenomenal valence: The felt positive, negative, or neutral character of conscious experience considered as phenomenal rather than merely behavioral, computational, motivational, or linguistic.

Policy: A rule mapping available information or state to actions, possibly probabilistically.

Policy mixture: A probabilistic combination of actions or component policies. Average cancellation across components does not establish exact closure on each realized path.

Policy-mixture exactness: The requirement that exact closure under a randomized policy be secured on the relevant realized branches, not merely in expectation through cancellation among closing and nonclosing actions. Under the applicable support

conditions, every action retained with positive probability must be closure-compatible.

Policy-support condition: A condition requiring the support of a selected policy to contain only actions or continuations compatible with the declared exact closure claim. Assigning very small but positive probability to a nonclosing option does not satisfy exact support restriction.

Population mean and expected neutrality: Expected neutrality means that the terminal residual has expectation zero under a named probability law and information set, when that expectation exists. A sample or cohort mean estimates a population quantity under further assumptions. Either can arise through cancellation while every individual stream remains nonzero. See also: Per-stream claim; Probability-one closure; Set-universal closure.

Portable safeguard: A local, operative protection placed on the exact surface or workflow where a high-risk fragment can be encountered or acted upon. A distant disclaimer is insufficient when the nearby claim could imply personal prediction, cross-person balancing, human scoring, machine ownership, or delayed care. See also: Detachable-excerpt ceiling; Public-artifact limit; Stop authority.

Positive and negative phenomenal magnitudes: On the primary additive branch, the nonnegative complete-stream totals of the positive and negative parts of the signed phenomenal measure. PTVC proposes that these two quantities are finite and exactly equal within each qualifying stream. See also: Finiteness; Gross experience; Terminal residual.

Positive-probability completion: Under a prospectively frozen continuation regime and its declared induced law, the completion event has probability strictly greater than zero, optionally conditional on a stated prefix and admissible action or policy. This weak reachability claim does not imply likelihood, probability one, an attaining policy, support containment, or every-continuation closure. See also: Modal reachability ladder; Probability-one closure; Reachability.

Positive rescaling: Multiplication of a valence representation by a positive constant. Exact zero and sign are preserved under positive rescaling, whereas shifting the origin or applying arbitrary nonlinear transformations can change the target.

Precaution without personhood: Proportionate, revisable protection under uncertainty, including monitoring, reducing avoidable harm, preserving reversibility, pausing, or redesigning when plausible welfare risk is serious. Protection can strengthen while consciousness, ontology, law, and personhood remain unresolved, without treating precaution as proof. See also: Candidate sentience escalation; Comparative consciousness evidence; Unknown category.

Prediction error and valence: The distinction between mismatch under a predictive model and the positive, negative, or neutral quality of felt experience. Surprise and valence can interact without being the same quantity: expected harm can remain painful, surprise can be welcome, and mean-zero prediction error does not imply neutral experience. See also: Felt valence; Interoceptive prediction; Predictive processing.

Predictive fit versus explanation: Predictive fit is a model's ability to forecast held-out observations. Explanation additionally relates its variables and dependencies to the process that generated those observations. See also: Candidate signature; Held-out transport; Model recovery.

Predictive processing: A family of accounts in which perception, bodily interpretation, and action depend on generative models, expected signals, prediction errors, uncertainty, and estimated reliability. See also: Active inference; Interoceptive prediction; Prediction error and valence.

Preregistration: Public preregistration records the hypotheses, estimands, gates, measures, exclusions, models, analyses, and decision rules in a timestamped external registry with a persistent identifier before the relevant outcomes are inspected. An internal advance specification is prospectively specified, not publicly preregistered. Deviations remain visible and receive the status appropriate to their timing and purpose. See also: Protocol-fixed and prospectively specified; Registered Report.

Preterminal compression: A candidate signature in which within-stream dispersion narrows before a declared endpoint under a prospectively specified relation. Comparison models include sedation, frailty, sensor floors, selective missingness, pooling, mean reversion, treatment, and endpoint conditioning. See also: Candidate signature; Endpoint conditioning; Noise floor.

Primary additive branch: The branch that represents qualifying phenomenal valence as one finite signed scalar measure with a

justified neutral origin and additive consistency across disjoint parts of a stream. Its positive and negative parts yield complete-stream magnitudes, and their difference yields the terminal residual. See also: Bipolar branch; Generalized Terminal Neutrality; Signed representation.

Probability-one closure: Closure with probability one under a specified probability law, and under a specified policy when the model includes one. It permits measure-zero exceptions and is distinct from set-universal closure, which requires closure for every admissible realization.

Procedural fairness: Fairness in rules and decision paths, including knowable standards, voice, understandable reasons, consistency, limited bias, respectful treatment, correction, and appeal. See also: Desert-based fairness; External justice; Consent, refusal, and withdrawal.

Process evidence: Evidence about a specified route, mechanism, state transition, or selection process.

Protocol endpoint: A prospectively specified operational event, adjudicated interval, stopping region, or governed proxy used by a study to locate or approximate a relevant boundary. It may be usable, uncertain, revisable, or ethically unavailable and is distinct from both the truth-level endpoint and end of observation. See also: End of observation; Endpoint bridge; Truth-level endpoint.

Protocol-fixed and prospectively specified: A choice is protocol-fixed or prospectively specified when it is recorded in the study protocol before the relevant outcome is inspected. This

timing status does not guarantee that the choice is valid or the study succeeds, and it is not public preregistration without a prior external timestamped record. See also: Endpoint independence; Preregistration; Rival model and equal-budget comparison.

Provenance: The documented lineage of a trace or derived output, including who collected it, for what purpose and authority, under which prompt, device, language, setting, burden, transform, model version, missingness state, uncertainty, and correction history. Provenance limits interpretation rather than merely decorating a record. See also: Data as trace; Public-artifact limit; Record-regime separation and no-dossier rule.

Psychometrics: The theory and practice of measuring latent psychological or experiential constructs, including reliability, validity, scaling, response processes, and measurement invariance.

PTVC: See Per-stream terminal valence closure (PTVC).

PTVC core notation: On the primary additive branch, v_i is the finite signed phenomenal measure on the declared measurable space; V_i^+ and V_i^- are its Jordan masses; $L_i^{\text{phen}}(t)$ is the latent phenomenal ledger; T_i^* is the truth-level endpoint; and $Z_i^* = v_i(\Omega_i) = V_i^+ - V_i^- = L_i^{\text{phen}}(T_i^* -)$ is the terminal residual. On the absolutely continuous chart, $r_i(t) = g_{\theta,i}(t)q_i^{\text{exp}}(t)v_i^{\text{real}}(t)$. The relation $L_i^{\text{rc}}(t) = c_{LU}U_i(t)Y_i(t)$ is a candidate realization, and hatted quantities are operational estimators, not identities with the latent target. See also: Candidate realization; Formula-status code; Phenomenal ledger.

Public access-permission distinction: Public availability for accountability, education, criticism, scholarship, or communication does not itself authorize profiling, consequential judgment, redistribution, linkage, or general model training. Visibility is not surrender, de-identification is not guaranteed anonymity, and access for one purpose is not standing authority for another. See also: Consent, refusal, and withdrawal; Data as trace; Record-regime separation and no-dossier rule.

Public-artifact limit: Every detachable project surface, including a summary, caption, guide, model output, slide, translation, or post, preserves an accurate account of its source, result, audience, reviewer, and correction route. See also: Detachable-excerpt ceiling; Portable safeguard; Correction and withdrawal.

Public safety floor: Care, dignity, rights, welfare, relief, refusal, and protections under uncertainty guide every stage of the research. Participation remains voluntary, care takes priority, and scientific outputs describe study questions and findings. Human-worth scoring, created suffering, compulsory belief, personal endpoint testing, delayed care, and hidden-object administration are prohibited.

Q

Qualifying conscious stream: A conscious stream that meets the declared scope, identity, routing, inclusion, and validity conditions for the target being tested. The criteria must be stated independently of whether the stream appears to close.

Queue model: A constructive candidate route that represents unresolved signed valence and asks whether admissible future transitions can remove the remaining residual.

Queue System: Book 1's accessible name for the Queue model, a possible action-mediated route to closure.

R

Random-endpoint obstruction: Under a specified reference law and declared positive-probability eligible event, suppose a jointly measurable pre-endpoint ledger extension exists on an interval I , endpoint time T is independent of the sigma-field generated by that ledger path on I , and T has a conditional Lebesgue density positive almost everywhere on I . If the ledger is zero at T with probability one, then it is zero with probability one for Lebesgue-almost every time in I . A ledger that is nonzero with positive probability on a positive-measure subset of I is therefore incompatible with probability-one closure on this branch. State-coupled timing, endpoint atoms, singular support, continued experience, routing changes, and endpoint-inclusive value require separate analysis.

Reachability: Whether at least one admissible continuation from a state can reach the declared target. Reachability does not guarantee selection, common feasibility under partial observation, probability-one success, or universal success.

Record-regime separation and no-dossier rule: Research, clinical, employment, educational, civic, legal, family, spiritual, platform, and public records must retain separate purposes, identifiers, access roles, retention rules, consequences, and

correction paths rather than being joined into a master profile. Inferred reconstruction can breach this boundary even without copying a forbidden field. See also: Data minimization and deletion; Human-worth score prohibition; Public access-permission distinction.

Reference class: The prospectively declared domain over which a claim and its quantifier range, specified by eligible streams or cases together with the representation, endpoint regime, population, setting, and measurement architecture. It is not automatically the enrolled sample or analyzed cases; outcome-driven exclusions define a new claim. See also: Held-out transport; Maximal qualifying conscious stream; Set-universal closure.

Reference-class narrowed: See Scientific verdict axes.

Registered Report: A publication format in which a study's question, methods, and analysis plan receive peer review before results are known, with publication not conditioned on obtaining a preferred outcome.

Reinforcement-learning reward signal: A formally specified signal used to update action values or policies from outcomes. Its interpretation follows the model's definition, which may concern relief, safety, access, or another specified result. See also: Active inference; Objective functions versus experience; Predictive processing.

Remaining capacity: The set or amount of admissible future change still available before an endpoint. A closure route must

show that remaining capacity is sufficient and selectable under the actual information and support constraints.

Repair is not moral payment: Responding to actual harm through safety, truth, apology, restitution, accountability, prevention, and remedy. These actions address present needs and future protection. Their genuinely felt effects enter the relevant stream's balance, but preventing a particular harm does not require that harm to reappear. PTVC fixes a terminal difference, not a quota of suffering. See also: External justice; No moral desert, debt, or payment; Outcome independence.

Replication: A new test designed to determine whether a result, measurement relation, or model distinction recurs under prespecified conditions. Replication should include adverse and null outcomes rather than only successful demonstrations.

Representation: A mathematical or conceptual encoding of phenomenal valence, time, state, or route that preserves the distinctions required by the stated research target.

Reserve: A route-level variable representing remaining capacity, flexibility, or corrective potential before an endpoint.

Reserve coupling: A candidate relation between accumulated residual and remaining capacity or future transition structure.

Response shift: A change in a person's standards, priorities, values, or understanding of a question after illness, disability, adaptation, treatment, trauma, grief, or aging, altering what the same response scale means over time. A changed answer can reflect changed experience, changed measurement, or both. See

also: Calibration; Longitudinal research trace; Measurement invariance.

Reversibility and return rule: A prospectively specified rule under which reliable return of unified access can defeat an earlier classification as a final endpoint, while nonreturn alone cannot prove absence of experience or identify the exact ending. Protocols must state return evidence, revision timing, and its effect on classification. See also: Endpoint bridge; Low-unity state; Protocol endpoint.

Reversible pause: See Reversibility and return rule.

Rival dominance: A verdict that an adequate protocol-fixed rival explains the declared signatures with better held-out performance and fewer strained assumptions under common data, flexibility, and scoring rules. It must state which route, component, or target interpretation loses standing and does not by itself decide unrelated branches. See also: Rival-favored; Theory-level defeat.

Rival-favored: See Scientific verdict axes.

Rival model: A concrete alternative explanation capable of generating overlapping observations. Strong tests compare PTVC targets and routes against serious rivals involving measurement, reporting, adaptation, selection, endpoint structure, and ordinary statistical effects.

Rival model and equal-budget comparison: A rival is a serious alternative able to generate the relevant pattern without the target or proposed route. Equal-budget comparison gives candidates and rivals common raw variables, observation and missingness pipelines, data splits, scoring rules, and comparable prospectively

bounded flexibility, while allowing that no declared model is adequate. See also: Model ambiguity; Model recovery; Scientific verdict axes.

Route: A proposed process or construction through which a target might be reached, with its own state variables, assumptions, and predictions.

Route-failed: See Scientific verdict axes.

Route-favored: See Scientific verdict axes.

Route retirement: A prespecified decision to stop treating a proposed mechanism or route as viable after decisive failure, poor recovery, nonidentification, or superior rival performance. Retiring a route need not settle the target hypothesis.

Route state: A latent or observed variable defined within a candidate mechanism and used to describe its dynamics.

RouteStatus: See Scientific verdict axes.

Routing: The prospectively specified treatment of continuation, pause, restoration, fission, fusion, copying, replacement, and unresolved continuity, including where prior and later phenomenal contributions are assigned. Routing governs transitions through time and is distinct from ownership, compensation, and causal influence. See also: Fission-and-fusion routing rule; Ownership; Stream identity.

S

Safe perturbation: A reversible, low-burden intervention that changes a declared local feature, such as feedback, delay, expectation, opportunity, or a mild stimulus, to test a named

causal contribution. Its meaning depends on target engagement, spillovers, controls, stopping, and the stated causal estimand. See also: Candidate signature; Negative control; No harm for proof.

Scalarization: A prospectively justified mapping from a richer or multidimensional experiential state to one signed scalar quantity for a named purpose and domain. It is a substantive bridge rather than harmless formatting, and weights selected because they produce closure manufacture the result. See also: Bipolar branch; Generalized Terminal Neutrality; Signed representation.

Scientific verdict axes: Four non-overwriting reporting fields preserve different conclusions: TargetStatus records what the evidence says about the declared target branch; RouteStatus records the status of a candidate route; ComparatorStatus records the absolute adequacy and relative performance of declared rivals; and InferenceStatus records whether the target is identified, partially identified, inconclusive, unusable, or unavailable. Labels such as Target-adverse, Route-failed, Route-favored, Rival-favored, Model-ambiguous, Open-set inadequate, Reference-class narrowed, and No adequate estimate must be assigned only to the relevant field, with branch, reference class, and inferential type retained. No field overwrites another. See also: Decision rule; Model ambiguity; Target-route distinction.

Scope firewall: A statement of conclusions that do not follow from PTVC. The hypothesis does not imply free will, monotonic movement toward zero, frequent zero crossings, conscious ledger awareness, that every urge serves closure, that pain is morally owed payment, or that suffering is morally deserved.

Selection condition: A requirement governing which available action or continuation is actually chosen. The existence of a closing option is insufficient when the selection process can retain nonclosing options with positive support.

Separately routed: Governed by a trajectory or transition structure that is not pooled with another stream for purposes of the terminal target. Separate routing supports the rule that one stream cannot balance another.

Set-universal closure: Closure for every admissible realization, path, or member of the declared set. It is stronger than probability-one closure because measure-zero exceptions are not permitted.

Severe test: A test that had a high probability of exposing a claim's error if the claim were false in the specified way. A result is not strong evidence merely because it is statistically significant or compatible with the preferred model.

Shortening horizon: A reduction in remaining time, opportunity, revision, access, or other route-relevant room for future action, affecting the continuations that remain available. See also: Future optionality; Reachability; Reserve.

Signed representation: A representation that assigns positive and negative directions relative to a justified neutral origin and supplies the declared scale and aggregation rules needed for the target branch. See also: Felt valence; Neutral origin; Primary additive branch.

Signed residual: The cumulative positive phenomenal mass minus the cumulative negative phenomenal mass over a specified

domain. The terminal signed residual is evaluated at the truth-level stream endpoint.

Skepticism as dignity: The protection of organized doubt, exact criticism, nonbelief, and refusal as honorable ways of engaging with a consequential public hypothesis. Comprehension is not assent, and care, standing, participation, intelligence, belonging, or moral worth may never depend on enthusiasm for the Law. See also: Meaning as optional; Falsifiability; Outcome independence.

Spiritual resonance is not scientific support: A relation of meaning occurs when a person or tradition recognizes a neighboring pattern. A relation of evidence requires a defined hypothesis to survive valid measurement, serious rivals, uncertainty, and possible defeat. Tradition, ritual, beauty, testimony, dream, prayer, or transformation may matter without validating PTVC. See also: Comparison without forced equivalence; Meaning as optional; Falsifiability.

State-coupled timing: An endpoint branch in which endpoint timing or hazard depends on prospectively specified current biological, consciousness, ledger, or route-state variables while the endpoint ontology and adjudication remain fixed independently of desired closure. Dependence is allowed, but the state relation cannot be invented after outcome inspection. See also: Endpoint atom; First-hitting and absorption routes; Random-endpoint obstruction.

Stop authority: Preassigned power held by an accountable person or independent reviewer to pause a study, system, publication, or artifact when a declared safety or rights boundary

is crossed. Effective authority can interrupt activity, contain harm, trigger care, and require correction or withdrawal rather than merely advise. See also: Correction and withdrawal; No harm for proof; Portable safeguard.

Stream: In formal PTVC contexts, shorthand for a Maximal qualifying conscious stream. In broader discussion, see Conscious stream.

Stream identity: The criteria that determine which experiences belong to the same conscious stream. Biological continuity, memory, body, legal identity, and data linkage may inform the analysis but are not automatically decisive.

Strong-form defeat: Defeat of the strong universal branch can occur by two routes. Deductive branch-matched refutation requires an independently verified maximal qualifying stream for which a deterministic identified set, guaranteed to contain the truth under the maintained bearer, representation, origin, domain, endpoint, observation, bridge, and inference assumptions, excludes the registered exact target. Governed scientific withdrawal can also follow repeated adequate conjunction failures or repairs that exhaust distinctive empirical content; only the first route is deductive refutation. Confidence or posterior objects support only their registered qualified adverse verdicts. See also: Falsifiability; Gate-valid counterexample; Set-universal closure.

Support condition: A restriction on the values, actions, paths, or outcomes that retain positive possibility under a model or policy.

Exact claims often require excluding nonclosing support, not merely making it unlikely.

Support containment: Under a declared topology, the support of the relevant probability law lies inside the completion event or target set. This topological modality is not every-continuation closure, positive probability at a point, or proof that an unsampled possibility is absent from support. See also: Every-continuation closure; Modal reachability ladder; Probability-one closure.

T

Target: The truth-level property a hypothesis asserts. For the primary PTVC branch, it is an exact zero terminal signed residual within each qualifying stream.

Target-adverse: See Scientific verdict axes.

Target modality and geometry: The exact mathematical form and quantifier of a declared target, including whether it is an exact singleton, finite band, distributional atom, probability-one event, support condition, every-continuation property, or set-universal claim. Evidence and defeat must be matched to that form rather than borrowed across nearby claims. See also: Exact terminal closure; Modal reachability ladder; Terminal residual compatibility object.

Target-route distinction: The target hypothesis states the terminal relation to be evaluated, while a candidate route proposes one optional process that might realize or reproduce its consequences. Evidence updates the object tested; a proved entailment specifies when a route result also changes a target

assessment. See also: Candidate route; Scientific verdict axes; Claim ceiling.

Target-route separation: See Target-route distinction.

TargetStatus: See Scientific verdict axes.

Terminal neutrality: Book 1's accessible term for a zero terminal signed residual over the whole qualifying stream. It does not mean that the final conscious moment is emotionally neutral.

Terminal residual: The signed total of phenomenal valence over a qualifying stream's complete strict-pre-endpoint domain, evaluated at its truth-level endpoint. The primary PTVC target states that this residual is exactly zero.

Terminal residual compatibility object: A branch-matched nonempty object representing residual values allowed by declared representation, endpoint, observation, missingness, bridge, and uncertainty assumptions. It retains its inferential type: deterministic identified set, confidence region, credible region, or sensitivity envelope. Only a deterministic guaranteed truth-containing object supports deductive exclusion; confidence and Bayesian objects license only registered coverage- or posterior-qualified conclusions. A point estimate is not such an object. See also: Finite-band compatibility and measured equivalence; Partial identification; Target modality and geometry.

Terminal signed residual: See Terminal residual.

Terminal window: A finite observed period near a presumed endpoint, used to investigate specified temporal or process relations.

Testimony-like output: Language or behavior from an artificial system that has the form of a first-person report but is generated under a particular model, prompt, memory state, tool set, training regime, and sampling process. It is evidence about configured output, not self-authenticating testimony that a subject feels what is said. See also: AI sovereignty; Candidate sentence escalation; Theory-derived indicator.

The Law: See Law of Fairness.

Theory-derived indicator: An observable property selected because a stated theory connects it to recurrent processing, global availability, higher-order representation, agency, embodiment, metacognition, or another proposed feature of consciousness. See also: Candidate sentence escalation; Comparative consciousness evidence; Testimony-like output.

Theory-level defeat: A branch-specific verdict reached when a declared target is contradicted under its own prerequisites, or when repeated adequate conjunction failures, persistent rival superiority, or outcome-dependent repairs exhaust the claim's distinctive empirical content. It is distinct from local route failure and from nonidentification; the defeat record must state the branch, evidence, assumptions, and surviving claims. See also: Strong-form defeat; Route retirement; Rival dominance.

Truth-containing object: An inferential object linked to the target under a declared guarantee or calibration. A deterministic identified set may be guaranteed to contain the truth under maintained assumptions; a confidence region has repeated-sampling coverage and a credible region has posterior probability,

neither of which is an unconditional realized-case guarantee. Excluding zero licenses only the conclusion appropriate to the object's inferential type. See also: Terminal residual compatibility object.

Truth-containing residual set: See Terminal residual compatibility object.

Truth-level boundary: See Truth-level endpoint.

Truth-level endpoint: The actual boundary of the qualifying stream in the target model. It is conceptually distinct from any observed marker, last report, terminal window, loss of contact, or biological event used to estimate it.

U

Unity gate: See Experienced exposure and unity gate.

Unity Index: A proposed research estimator that organizes separately reported evidence about access, report, memory, agency, embodiment, continuity, and coherence under a declared construct, with explicit assumptions and uncertainty. See also: Blinded bearer adjudication; Human-worth score prohibition; Unknown category.

Universal branch: See Set-universal closure.

Universal quantifier: A claim applying to every member of a declared class. Because the primary PTVC branch is per-stream and universal over qualifying streams, a valid adverse case cannot be repaired by averaging across the class.

Unknown category: A reason-coded classification outcome used when available evidence cannot justify one bearer, consciousness,

or boundary classification over serious alternatives under declared rules. Unknown identifies unresolved classification; it differs from a negative finding, equal probability, zero, and No adequate estimate. See also: Bearer; No adequate estimate; Precaution without personhood.

Unusable evidence: Evidence for which a necessary protocol, consent, endpoint, measurement, provenance, computation, or participant-protection gate failed. A statistic may exist, but it cannot update the affected claim. The report must identify the failed gate, affected estimand, and any permitted narrower use. It is distinct from Inconclusive evidence and No adequate estimate.

V

Valence: The felt positive, negative, or neutral character of conscious experience.

Valence density: A representation of signed phenomenal valence per unit of an adopted base measure, such as phenomenal time. Its interpretation depends on the validity of both the valence scale and the base measure.

Valence ledger: Book 1's metaphor for the cumulative signed phenomenal measure within one stream.

Verdict: The declared evidential conclusion produced by a prespecified decision architecture, such as support, adverse result, narrowing, abstention, or route retirement. A verdict must state its target and scope.

Viability: The possibility of remaining within declared constraints over the specified horizon under an admissible

continuation or policy, with any probabilistic guarantee stated explicitly. Maintaining access to closure is an additional completion-specific requirement when it is included among those constraints.

Viability kernel: The set of modeled states from which at least one admissible continuation satisfies a route's declared constraints. It marks where a future remains formally workable but does not mean that a continuation is likely, humane, accessible, desirable, or supported by resources a person actually has. See also: Compensability; Noncompensable risk; Reachability.

Z

Zero-containing interval: An uncertainty or identification interval that includes zero. Any nonzero members remain alternative values under the interval's stated interpretation.

Zero crossing: A time at which a cumulative or instantaneous signed quantity passes through zero. PTVC does not require monotonic movement, frequent zero crossings, or any particular number of crossings before the endpoint.

Publicly Preregistered Single-Study Result, 2403–2404

Purpose Limits and Participant Return, 1507–1517

Q

Qualifying Bearers and Unified Streams, 347–348

Queue Failure, Scope, and Retirement, 1613–1616

R

Random Assignment and Delivered Exposure, 1713–1715

Random Endpoint Times, 1992–1994

Random endpoints and endpoint surprise, 514–526, 1099–1127, 1381–1404

Random Endpoints and the Non-Atomic Obstruction, 514–526

Random-Terminal-Time Bridges, 2240–2242

Rate, Additivity, and Scalarization, 2603–2604

Reachable Actions Versus Chosen Actions, 1697–1698

Realization and Mechanism Components, 2393–2394

Realization Claim, 99–100

Reanalysis After Major Change, 1504–1506

Reappraisal and Memory Updating, 1270–1272

Rebinding After Recovery, 923–925

Recall Delay and

Reconstruction, 1257–1259

Received Definitions, 248–251

Recency and Kernel Models, 655–657

Reciprocity, Cooperation, and Punishment, 679–682

Recorded Reasons, 2484–2485

Recovery Across Noise and Missingness, 2205–2207

Recovery Before Human Data Verdicts, 2207–2209

Recurrence and Causal Continuity, 893–895

Recurrence as Hypothesis Generator, Not Validation, 690–692

Recurrent and Higher-Order Accounts, 965–966

Red Teams and Challenge Logs, 2274–2283	Release, Correction, and Retirement, 66–66
Redundant Signatures, 2232–2233	Release, Pause, Redesign, and Stop Conditions, 2635–2637
Reference Class, 1153–1154	Release Is Not an Update to the Claim Register, 2378–2378
Reference Class and Horizon, 2124–2125	Removal of Outdated Proof Language, 2530–2532
Reference Classes, Modal Scope, and Past-Fixity, 399–406	Repair Initiation and Recovery, 1794–1795
Reference classes and modal scope, 93–104, 399–406, 2433–2444	Repeated Anchor Events, 789–790
Reference Classes and Scope, 237–238	Repeated Assignment and Adaptive Regimes, 1720–1721
Reference Classes Before Universality, 400–401	Repeated Conjunction Failure, 2459–2460
Reference-Class Discipline, 101–104	Repeated-Night Within-Person Design, 1302–1305
Reference-Class Fragmentation, 2103–2105	Replication, Verdicts, and Scientific Updating, 2295–2647
Refusal, Family Welfare, and Clinical Communication, 1130–1131	Replication Before Status Upgrade, 37–39
Registered Public Report, 1222–1222	Replication Disagreement, 2368–2369
Registered-Report Review, 2313–2313	Report and Command Following, 896–897
Reinforcement Learning and Policy Adaptation, 1968–1979	Reported Quantity, Decision Rule, and Abstention, 722–723
Relaxation and Innovation Estimands, 1182–1184	

Repositories, Provenance, and Access, 2343–2353	Research Value Beyond a Single Test, 2645
Representation and Measurement Interfaces, 416–498	Researcher Degrees of Freedom, 2190–2191
Representation and the Neutral Origin, 433–442	Reserve and Disease Severity, 1348–1350
Representation Before Integration, 267–269	Reserve and Horizon Proxies, 1341–1354
Representation Before Intervention, 1654–1656	Reserve and Recovery, 1272– 1273
Representation Before Measurement, 433–434, 610–622	Reserve as a Multi-Domain Capacity State, 1342–1343
Representation Claim, 95–96	Reserve Construct Invalidity, 579–580
Representation Component, 2389–2390	Reserve Failure Conditions, 1353–1354
Representation Failure as a Result, 464–465	Reserve Is Not One Biomarker, 1346–1348
Representation Failure as Scientific Result, 621–622	Reserve Over Time, 1350– 1351
Representation Families and Invariance, 392–393	Reserve Proxies, 1172–1173
Representation Narrowing, 2439–2440	Reserve Realization Retirement, 2447–2448
Reprocessing as Candidate Function, 1247–1249	Reserve-Coupled Candidate, 2213–2215
Research Labor and Training, 2356–2356	Reserve-Coupled Joint Restriction, 1931–1932
Research Question First, 701– 702	Reserve-coupled route and completion geometry, 556– 563, 1341–1380, 1524–1647
Research Redirection, 2026– 2026	Reserve-Horizon Interaction, 1364–1366
	Reserve-Linked Drift, 287–289

Residual and Calibration	Return Without Recall, 1114–
Diagnostics, 2253–2256	1115
Residual Dependence and	Reverse Causation and
Sensitivity Analysis, 1078–	Feedback, 1803–1804
1079	Reviewing Authority Remains
Resources, Opportunity Cost,	Open, 2480–2481
and Value of Information,	Revision, Versioning, and
2632–2634	Audit, 1067–1068
Response and Device Drift,	Rising Delay Sensitivity and
1499–1501	Boundary Rate, 1356–1359
Response Shift, 811–812	Risk Pruning and Dispersion
Restricted and Public Layers,	Compression, 1361–1363
2291–2292	Risk-Sensitive and Robust
Resuscitation,	Control, 1983–1984
Autoresuscitation, and	Risky Prediction, 105–107
Recovery, 1111–1112	Rival and Negative-Result
Retention and Deletion, 2350–	Burden, 51–52
2351	Rival Dominance, 1928–1929,
Retirement and Deletion, 775–	2451–2452
777	Rival Explanations of
Retirement and Replacement	Narrowed Action Sets, 1709–
by Better Causal Objects,	1711
1748–1750	Rival Model Stewards, 2340–
Retirement of	2341
Nontransportable Scales,	Rival Models, Inference, and
862–863	Adversarial Tests, 1850–
Retirement to Heuristic or	2294
Metaphor, 134	Rival models and adversarial
Retrospective Smoothing,	tests, 282–300, 564–575,
1101–1102	1850–2294
Return, Resuscitation, and	Rival Set and Recovery, 309–
False-Ending Controls,	311
1109–1118	

Rival Sleep Science, 1250–1252
 Rival Victory Under Equivalence, 2134–2135
 Rival-Equal or Rival-Better Prediction, 582–583
 Rival-Unique Predictions, 1880–1882
 Rivals by Signature, 296–298
 Rivals Match or Win, 1216–1217
 Robustness Is Not Replication, 2173–2176
 Root Ownership and Scientific Use, 356–358
 Root-Book Authority, 2519–2520
 Route Failure, Retirement, and Frontier Theorems, 1637–1647
 Route State, Filtration, and Observability, 1327–1329
 Route Verdict Logic, 1411–1413
 Route-Failed as Scientific Progress, 1638–1639
 Route-Favored, Partial, and Replicated Results, 2410–2419
 Routing Corrections to Each Title, 2527–2528

S
 Safe and Constrained Control Baselines, 1980–1989
 Safe Control and Harm Avoidance, 1700–1702
 Safe Interoceptive Perturbation, 1827–1829
 Scalar and bipolar valence representation, 359–389, 443–465, 623–647
 Scalarity and Non-Scalar Alternatives, 447–449
 Scalarization and Identified Sets, 636–647
 Scalarization Weight Families, 458–460
 Schrödinger Bridges and Entropic Steering, 1572–1575
 Science Constrains Claims, Not Governance, 2555–2556
 Scientific, Legal, and Spiritual Boundaries, 1133–1134
 Scientific Authority and Domain Boundaries, 198–208
 Scientific Case and Dependency Map, 2574–2583
 Scientific Deviation Audit, 2364–2365

Scientific Error Versus Ethical Error, 945–946	Selectors, Policies, and Interventions, 551–553
Scientific Estimand and Target Contrast, 716–717	Semi-Competing Risks, 1487–1489
Scientific Evidence and Open Questions, 2517–2519	Sensitivity Across W, 640–642
Scientific Jurisdiction and Synopsis, 1–332	Sensitivity and Partial Identification, 2164–2176
Scientific Seriousness Before Support, 16–16	Sensitivity to Anchors and Priors, 848–849
Scientific Status Is Governed Here, 22–24	Sensitivity to Missing-Not-at-Random, 1467–1469
Scientific Updating and Claim Revision, 2470–2569	Sensitivity to Origin and Sign, 2142–2143
Scientific updating and correction, 2384–2397, 2470–2583	Sensitivity to Weight and Kernel Choice, 461–463
Scope, Provenance, and Failure Memory, 2493–2494	Sensor Fusion Without Sovereignty, 1454–1455
Scope Withdrawal and Outer Limits, 2102–2110	Sensor Placement, Missingness, and State Aliasing, 1562–1563
Sedation, Delirium, and Rapid Decline, 1124–1125	Separate Consent and Data Doors, 2550–2551
Sedation and Analgesia, 834–835	Sequential Evidence and Optional Stopping, 2176–2185
Sedation and Delirium Are Clinical Realities, 164–166	Sequential Evidence and Replication States, 2398–2409
Selection and Experienced Welfare, 2031–2041	Sequential Validity and Review, 2408–2409
Selection on Survival and Observation, 1995–1996	Serious Rival Matrix, 1407–1409

Set-Point and Baseline
 Accounts, 1861–1862
 Severe Tests and
 Underdetermination, 105–
 118
 Severe-Test Reporting, 113–
 116
 Shadow Prices as One Analytic
 Example, 1740–1750
 Shared Core Protocol, 2310–
 2311
 Shared Data-Generating
 Interface, 2009–2010
 Shared Disease and Sensor
 Confounding, 2246–2247
 Shared-Confound Analysis,
 1074–1075
 Shrinking Innovation and
 Variance Structure, 567–568
 Sign, Cross-Sign Units, and
 Scalarity, 443–451
 Sign and Neutral Origin,
 2600–2601
 Sign Identification, 443–444
 Sign Orientation, 799–801
 Signed Arithmetic Reference
 Dynamics, 558–559
 Signed Phenomenal Measure,
 359–361
 Signed Reachability Under
 Finite Opportunity, 1531–
 1533
 Simulation of Closure, 2096–
 2097
 Single-Site Results Are
 Preliminary, 1224–1225
 Site and Era Effects, 1498–
 1499
 Site Effects, Heterogeneity,
 and Transport, 2326–2333
 Site Shift, 2263–2265
 Site-Specific Supplements,
 2311–2312
 Sleep, Anesthesia, and Covert
 Activity, 838–839
 Sleep, Dreams, and Affective
 Reprocessing, 1236–1321
 Sleep, Dreams, and Reversible
 Low Access, 972–982
 Sleep and Reversible Loss of
 Access, 917–919
 Sleep Architecture and Affect,
 1245–1247
 Sleep as Auxiliary Evidence,
 1241–1252
 Sleep Stage, Physiology, and
 Measurement, 1289–1300
 Sleep Stage and Access, 973–
 974
 Social and Environmental
 Interventions, 1389–1392
 Social Comparison and
 Relative Position, 682–684
 Soft Gate $g_0(t)$, 905–906

Soft Unity Gates and Threshold Families, 901–914	Staged Roadmap and Value of Information, 2624–2634
Somatic Markers and Action Readiness, 1766–1767	State, Action, Reward, and Return, 1970–1971
Sparse Windows and Unobserved Time, 1428– 1429	State, Demand, and Control, 1600–1603
Species-Specific Candidate Instruments, 2070–2072	State, Increment, and Cumulative Estimands, 2120–2121
Species-Specific Expression, 1019–1020	State, Report, and Memory, 1864–1866
Specific Consent by Use, 174– 176	State Dependence and Nonlinearity, 1744–1745
Split, Fusion, Pause, and Continuation, 354–356	State Evidence Dossier, 1036– 1037
Split Access and Hemispheric Partition, 930–932	State Mean Reversion, 1900– 1901
Split Points and Descendant Streams, 1083–1084	State Prefixes and Future Cones, 1529–1531
Staff Burden and Participant Support, 2354–2362	State Recovery and Accumulated Experience, 1867–1869
Stage Five: Terminal and Comparative Work, 2631– 2632	State Versus Rate, 616–617
Stage Four: Mechanism and Transport, 2629–2631	State-Coupled, Hitting, and Absorbing Alternatives, 522– 523
Stage One: Formal and Measurement Lock, 2625– 2626	State-Dependent Calibration, 790–791
Stage Three: First Protocol and Replication, 2628–2629	Stationary and Nonstationary Starts, 1901–1903
Stage Two: State and Endpoint Validation, 2626–2628	Statistical Elegance as Rescue, 2191–2192

Statistical Narrowing, 2441–2442
 Statistical Tendency, 77–78
 Status, Notation, and Dimensions, 241–264
 Status-Labeled Cross-Book Notice, 2524–2527
 Status-Labeled Release, 2374–2375
 Steepening Relaxation, 566–567
 Stewardship of Superseded and Retired Claims, 2496–2498
 Sticky and Reflected Boundaries, 1588–1589
 Stochastic Reserve and Markov Closure, 2593–2595
 Stop, Withdraw, and Remain Silent, 168–171
 Stream identity, partition, and fusion, 870–954, 1080–1088
 Stream Origin and Initial Ownership, 1080–1081
 Stream Routing, Origin, Maximality, and Junctions, 1080–1088
 Strict-Pre-Endpoint and Endpoint-Inclusive Domains, 407–408
 Strict-Pre-Endpoint Domain and Posthumous Records, 1057
 Strong Rival Set, 1188–1189
 Strong-Form Component, 2395–2397
 Strong-Form Pressure, 2020–2021
 Study Families and Data Schema, 1301–1313
 Study Families and First Tests, 1136–1517
 Study Five: Humane Preterminal Dynamics, 2620–2621
 Study Four: Generative Benchmark Challenge, 2616–2620
 Study One: Representation and Sign, 2612–2613
 Study Three: Unity and Endpoint Validation, 2615–2616
 Study Two: Momentary-Valence Estimator Qualification, 2613–2615
 Substitution, Reframing, and Route Reordering, 1386–1388
 Sudden, Diffuse, and Low-Signal Endpoints, 1119–1127
 Sudden and Unobserved Endpoints, 1120–1121
 Summary, Glossary, and Archive Status, 2539–2540
 Support Restrictions and Viability, 1699–1700

Survivor and Immortal-Time Bias, 1490–1491

Survivor Average Causal Effects, 2159–2160

Survivor Conditioning and Pairwise Bias, 1377–1378

Survivorship and Selection, 2048–2050

Synthetic Data Generator, 1192–1194

Synthetic Fixtures and Unit Tests, 2288–2290

T

Technical Synopsis: Claim, Tests, and Verdicts, 219–332

Temporal Additivity as a Component Claim, 367–370

Temporal Narrowing, 2438–2438

Temporal Order and Component Histories, 386–387

Temporal Resolution and Detection Power, 1689–1691

Temporal-Difference Learning, 1972–1974

Temporary Disconnection, 921–923

Terminal and Nonterminal Events, 2158–2159

Terminal Concentration and Equivalence, 294–296

Terminal Dreams and Personal Meaning, 1317–1318

Terminal Physiology, 836–837

Terminal residual and closure, 224–240, 371–380, 390–398, 1051–1059, 2136–2144

Terminal-Window and Intervention Signatures, 1381–1393

Terminal-Window Tests, 1322–1416

Testable Consequences of a Reachability Map, 1539–1541

Testbed Status, 2547–2550

The Book's Evidence Responsibilities, 42–53

The Discriminating Conjunction, 298–300

The Dying Person Owes No Result, 161–161

The Exact Additive Statement, 372–373

The First Decision-Relevant Question, 1147–1157

The First Discriminating Protocol, 1141–1235

The First Empirical Burden, 233–235

The First Five Studies, 35–37

The First Protocol in Miniature, 301–316

The Formal Hypothesis Is Stated, 19–20	The Scientific Claim in One View, 224–240
The Formulation Becomes a Research Target, 21–22	The Strongest Rivals, 2580–2580
The House-Skeptic Function, 17–17	The Truth-Level End of the Stream, 1052–1053
The Integrated OU Ledger, 1908–1917	The Typed Layer Map, 424–425
The Measurement Pipeline, 693–777	Theory Pluralism and Marker Families, 960–971
The Most Testable Near-Term Claims, 2579–2580	Theory-Level Defeat, 326–328
The Next Step Is to Test It, 2646–2647	Theory-Level Defeat and Failure Memory, 2454–2464
The Non-Atomic Obstruction, 521–522	Theory-to-Marker Matrix, 969–971
The Open, Staged Research Program, 2570–2647	Threshold and Error Control, 2181
The Ordinary Middle, 650–652	Threshold Families, 906–908
The Queue Model as an Illustrative Candidate, 1598–1616	Time-Varying and Hierarchical OU, 1903–1904
The Random-Cutpoint Question, 515–517	Time-Varying Loadings and Intercepts, 812–813
The Received Hypothesis, 2575–2577	Timescale Dependence, 1876–1878
The Received Strong Form, 229–232	Topology, Disconnected Supports, and Hidden Barriers, 1537–1539
The Research Program in Stages, 29–41	TOST Logic, 2128–2129
The Reserve-Coupled Route as One Candidate, 556–563	Trade-Off Choices and Behavioral Evidence, 728–729
	Training Data and Simulation, 1030–1031

Transfer, Discharge, and Withdrawal, 1489–1490	Treatment Changes, 1474– 1476
Transition Timing Remains Separate, 2556–2558	Treatment-Conditioned Trajectories, 2001–2003
Translation and Cultural Review, 2323–2324	Trigger for Formal Review, 2512–2515
Transparent Adverse Reporting, 2193–2194	Truncation by Death and Competing Events, 1484– 1495
Transport Across Life Stages, 1434–1436	Truncation Is Not Ordinary Dropout, 2157–2158
Transport and Calibration Recheck, 1229–1230	Truth Endpoint, Protocol Endpoint, and Estimated Endpoint, 409–410
Transport and Stress Tests, 2263–2273	Truth endpoint. See Truth- Level Endpoint Domain
Transport Assumptions, 2079– 2080	Truth-Domain Streams, Ownership, and Maximality, 345–358
Transport Estimands, 2332	Truth-Level and Protocol Endpoints, 1046–1135
Transport Failure, 2271–2273	Truth-Level Endpoint Domain, 1051–1059
Transportability Analysis, 1502–1504	Two-Time Covariance and Martingale Diagnostics, 1369–1380
Transported Predictions, 1733– 1734	Two-Time Covariance as a Route Signature, 1370–1372
Trauma, Hyperarousal, and Dissociation, 1816–1817	U
Trauma Replay and Fragmentation, 1279–1281	Unanticipated Distress, 1210– 1211
Treatment and Care Context, 1175–1177	
Treatment and Care Pathways, 2247–2249	
Treatment and Observation Estimands, 2123–2124	

Uncertain and Revisable
 Horizon, 1331–1332
 Uncertainty Across the Gap,
 927–928
 Uncertainty and sensitivity
 analysis, 841–852, 2176–
 2194, 2433–2453
 Uncertainty in Public
 Language, 851–852
 Undefined Outcomes and No-
 Estimate, 2126–2126
 Underdetermination by
 Terminal Patterns, 107–109
 Unit, Target, Estimand, and
 Estimator, 2117–2126
 Unit and Interval Meaning,
 801–802
 Units, Dual Variables, and
 Local Interpretation, 1743–
 1744
 Units, Rates, and Exposure,
 446–447
 Unity and Endpoint Channels,
 1174–1175
 Unity and Endpoint
 Classification, 2606–2607
 Unity Gating and Qualifying
 Intervals, 352–354
 Unity-Gate Sensitivity, 979–
 981
 Unity-Proxy Accessibility,
 1092–1093
 Unknown Initial Ledger,
 2141–2142
 Unknown Prior History, 1429–
 1431
 Unresolvable Identification
 Failure, 2460–2461
 Unresolved Demand and
 Continuing Influence, 1604–
 1605
 Unusable Endpoint and No
 Adequate Estimate, 1126–
 1127
 Unusable Evidence, 707–708,
 757, 1218, 2189–2190
V
 Valence, Arousal, Control, and
 Meaning, 626–628
 Valence, Arousal, Salience,
 and Urgency, 1780–1781
 Valence measurement and
 lived experience, 586–863
 Variance Shape and Time
 Scaling, 291–294
 Variance-Shape Estimands,
 1184–1185
 Vector and Multidimensional
 States, 457–458
 Vector-State Alternatives, 631–
 633
 Vendor and Firmware Drift,
 1457–1458

Verdicts, Stop Gates, and Open Problems, 317–332
 Verdicts and evidence accumulation, 317–332, 2379–2487
 Version and Dependency Audit, 2521–2522
 Versioned Assumption Registry, 2223–2225
 Versioned Claim, Model, and Evidence Registers, 2488–2499
 Versioned Classification, 1042–1043
 Versioned Data Pipeline, 1178–1180
 Versioned Rival Envelope, 2007–2007
 Versioned Source and Release IDs, 2284–2285
 Versioned Theory Change, 125–126
 Versioning, Drift, and Transport, 1496–1506
 Versioning, Withdrawal, and Successor Routes, 1644–1645
 Versioning and Provenance, 429–431
 Viability, Solvency, and Closure Regions, 1533–1535
 Viability Without Fairness, 1892–1893
 Visuals Orient; They Do Not Prove, 60–62
 Vulnerability, Assent, and Research Proportionality, 185–197
W
 Waking Comparators, 1249–1250
 Wearable Quality, Context, and Drift, 1838–1840
 Wearables, Artificial Intelligence, and Humility, 1837–1849
 Websites and Social Excerpts, 2540–2542
 Weight Uncertainty, 638–640
 Weight Vector w , 637–638
 What Can Be Tested Next, 2642
 What Constructed Controllers Contribute, 1987–1988
 What Defeat Still Teaches, 2109–2110
 What Every Verdict Teaches, 2639–2640
 What Kind of Claim Is the Law of Fairness?, 67–138
 What Neural Findings Contribute, 1796–1797
 What No Result Can Authorize, 240–240

What Support Could Update, 239–240	Why the Program Is Scientifically Interesting, 2577–2577
What Survives Mechanism Defeat, 1645–1647	Wide or Mixed Uncertainty, 2425–2426
What the Study Cannot Establish, 1156–1157	Window and Alignment Sensitivity, 2168–2169
What Would Change the Case, 2580–2582	Withdrawal of Common-Zero Claims, 805–806
When a Kernel Must Be Retired, 1552–1554	Withdrawal of One-Number Claims, 645–647
When Learning and Control Rivals Win, 2018–2026	Within-Person and Between- Person Meaning, 618–619
When Missingness Defeats Inference, 2153–2154	Within-Person Crossover and N-of-1 Logic, 1829–1830
When Predictive Processing Wins, 1955–1956	Within-Person Dynamics, 1866–1867
Why a Net Residual Can Hide Structure, 382–383	Within-Person Validity, 793– 794
Why a Separate Science Volume, 12–17	Within-Person Versus Between-Person Effects, 2044–2045
Why Earliest Divergence Matters, 1683–1685	Within–Between Sign Reversal, 847–848
Why Lived Experience Is the Target, 598–609	Worked Calculation and Parameter-Sweep Design, 1914–1916
Why Model Recovery Comes First, 2199–2211	
Why Not Begin With Exact Terminal Zero, 1150–1152	
Why the Hypothesis Needs a Science, 6–66	

About the Author

Stephen Takowsky has spent his life studying complex systems: how rules shape them, how people cooperate and compete within them, and how hidden constraints can change what becomes possible. His path has crossed finance, competitive strategy, professional esports, and the leadership of global online communities, ultimately leading to the Law of Fairness project, a decades-long effort to investigate whether fairness itself may reflect a deeper structure of conscious life.

Competing as “MrGameTheory,” Takowsky reached number one on the Civilization Revolution leaderboard and in the international Civilization IV and Civilization V leagues while pursuing a career in finance at Morgan Stanley in Beverly Hills. In 2016, aXiomatic, an ownership group led by Peter Guber and Ted Leonsis and backed by investors including Magic Johnson, Steve Case, and Tony Robbins, acquired a controlling interest in Team Liquid. Following the acquisition, Team Liquid selected Takowsky to captain its newly created Civilization team, later recognized by Guinness World Records as the first Civilization esports team. Across thousands of games, Civilization became an unconventional education in strategy: understand the whole system, think far beyond the next move, anticipate intelligent opposition, and keep searching when the obvious paths fail.

Strategy then became community leadership. Takowsky spent seven years at 505 Games, serving as Senior Digital Content & Engagement Manager and leading global communities for Terraria, which has surpassed 70 million copies sold, as well as Ghostrunner, WUCHANG: Fallen Feathers, Eiyuden Chronicle: Hundred Heroes, and other titles. He also founded the United

Servers of Discord Alliance, bringing together leaders from major communities built around Roblox, Pokémon, Star Wars, League of Legends, Grand Theft Auto, Warframe, Animal Crossing, and other properties. Earlier, he served as administrator and producer for TF2Outpost, a major Steam digital-goods marketplace. Across these very different environments, he kept returning to the same insight: better structure can expand what people are capable of building together.

Throughout those years, one question kept following him: could the apparent unfairness of life conceal a deeper structure? That question became the Law of Fairness. Takowsky began developing the idea more than twenty years ago while studying Religious Studies and Philosophy/Law and Society at the University of California, Riverside, and gave it its first public form in his 2009 book, *Of Grandeur*. In the years that followed, he sought out academics and serious thinkers across many disciplines, asking for insights, criticism, and sources that could help separate fact from speculation. What began as a philosophical intuition gradually became a research program built to face mathematics, measurement, competing explanations, and evidence.

The ten-book Law of Fairness series follows that question outward, from consciousness and scientific testing into ordinary life, meaning, and civilization. If the Law is true, then there may be no “free happiness” in the sense of positive experience remaining unresolved by the lifetime balance the hypothesis predicts. That possibility raises a profound practical question: what if humanity has been pursuing the wrong model of utopia?

Rather than organizing life around the endless pursuit of pleasure, the series explores whether greater self-moderation, less needless suffering, and better-designed institutions could help remove some of the forces that keep people and societies trapped in conflict, corruption, and instability.

Takowsky's fifty-year horizon is designed so that building a better future does not require tearing apart the present. It gives institutions and communities time to test reforms, build infrastructure, prepare future leaders, improve technology, and correct mistakes before they spread. Just as importantly, it gives today's generation the chance to be remembered for beginning something larger than itself: laying the foundations for a more transparent, peaceful, and prosperous world it may never live to see.

The project's future is collaborative. Takowsky welcomes researchers, universities, laboratories, funders, technologists, students, critics, writers, artists, community builders, and volunteers willing to bring rigor, imagination, and courage to one of humanity's oldest questions. The next breakthrough may come from a theorem, an instrument, a dataset, a counterexample, or an experiment no one has yet imagined. *The Law of Fairness* began as one person's question. Its next chapter belongs to everyone willing to help discover what is true and build what that knowledge makes possible.
